No. 1. 28"

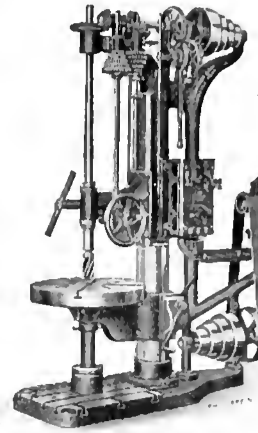
Snyder Celebrated Upright Drills

Are thoroughly well made, rigid and powerful, and are adapted to high grade work. They are furnished with Patented Tapping Attachment, Compound Table, Motor Drive, also Positive Gear Feed, which can be changed from the finest to the coarsest feed instantly, without stopping the machine. Have sufficient power for high speed drills, and are adapted to the most accurate work which can be done on a Drill Press. For twenty years our exclusive specialty has been "High Grade Upright Drilling Machines." By giving our undivided attention to this one line, we are enabled to produce a high grade machine at a reasonable price.

"NONE BETTER THAN THE SNYDER."

J. E. SNYDER & SON, Worcester, Mass.

Sizes 20-in., 23-in., 25-in., 28-in., 30-in. and 36-in.



No. 2 30"

MOTOR DRIVE

The Cheapest Elevator in the World

Because when installed you are done.
Yes sir, done bothering with elevators forever.
Done killing and hurting your men, too.
Done having your work upset by breakdowns.
Done paying repair bills.
Done living under the Elevator Curse.
And done cursing the elevator.

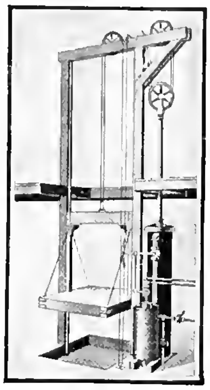
And if you are half as smart a manager as you would like the Powers-That-Be to think you are you will find out about a machine that claims as much as the Steam-Hydraulic elevator.

Of course you know we are putting them in the best plants everywhere. Just equipped the Bureau of Engraving and Printing at Washington with them, and are at work changing over the elevators of the Greatest Concerns in the land to the Steam-Hydraulic system.

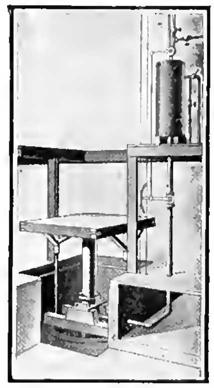
Why not let us refer you to somebody near you where you can go and see for yourself what a perfect hydraulic elevator is really like? If you want what is really the cheapest elevator in the world you will, like a great company of others,

Hook 'er to the Biler

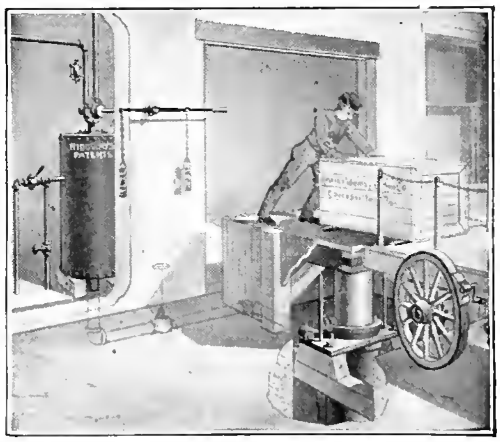
RIDGWAY & SON, Coatesville, Pa.



Double Geared Elevator



Direct Acting Elevator



The World's Greatest Money Maker

The Planer for All your Work

is the "Woodward & Powell," because its capacity ranges from the lightest work to the heaviest, and it is always accurate and very rapid.

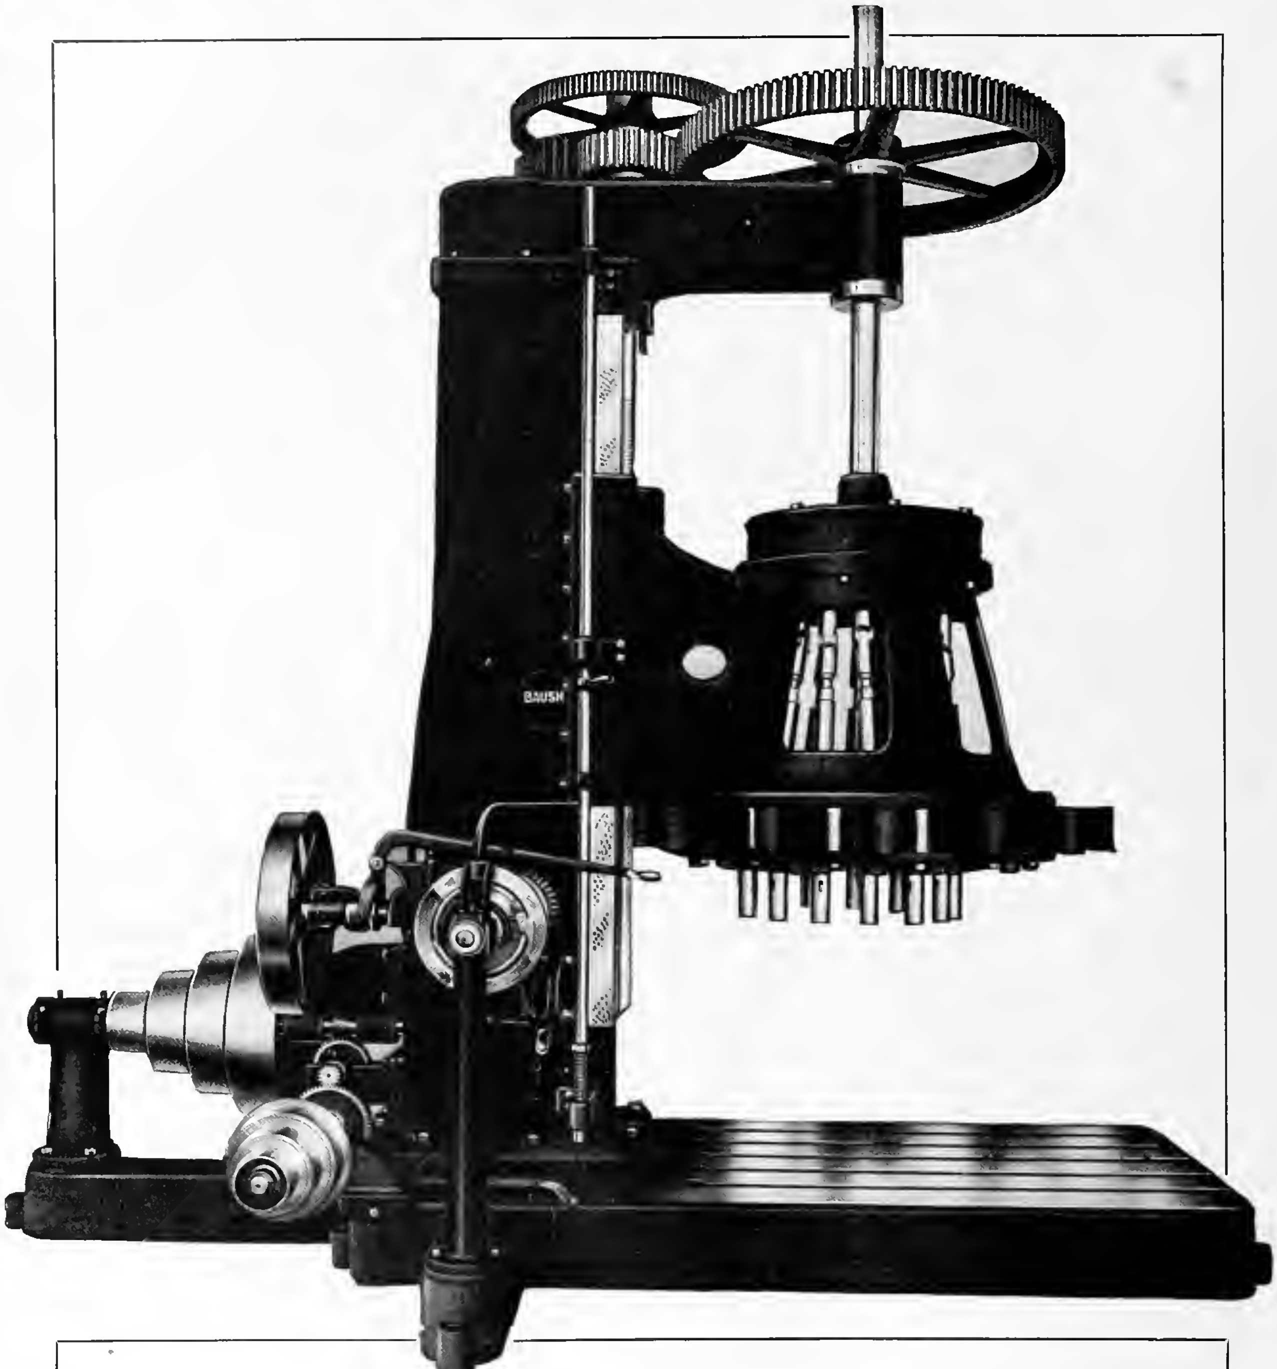
42" x 42" Standard Planer



The Enormous Driving Power

of the No. 30 Screw Type High Speed Multiple Drill Covers the Problems of Heavy Drilling.

Spindles can be adjusted to cover any layout between a minimum drilling circle 10" in diameter and a maximum of 30".

The machine is especially designed for the use of high speed drills and equipped with 12 spindles; capacity up to 1 ½" holes in cast iron. Screw feed has ball bearings; spindles are adjustable vertically to allow for variations in drill length.

Furnished with 12, 14 or 16 spindles as desired.

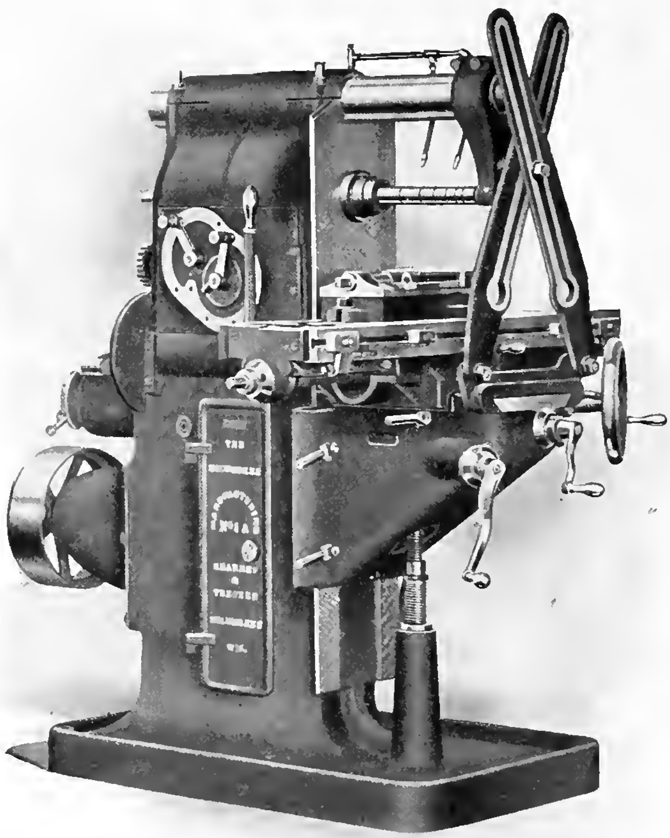
A MANUFACTURING MILLER

So called because it was designed to meet the requirements of quantity in large factories where piece work, High Speed Steel and chucking fixtures are the means employed to carry production to the maximum. There are no unnecessary parts or handles. Everything is boiled down to insure quick handling, and at the same time nothing is omitted, needed to make the machine complete for the purpose intended.



No. 1 A Manufacturing Miller.

There are no overhead belts or countershafts to interfere with the proper grouping of machines to secure the maximum plant on a given floor space. The power is taken direct from the line shaft without friction clutch, T and L pulley or other troublesome devices. Starting and stopping is effected by means of a lever on the machine itself. The machine is self contained and can be set up or shifted to a new position in a minimum of time.

If it ever becomes advisable to use electric drive the pulley bracket can be removed and the motor attached in half an hour.

All shafts and gears have flooded lubrication. Every machine is equipped with pump for oiling cutters, and ample passages are provided to return the cutting lubricant to the reservoir.

They are given the preference by piece workers where there is a choice of Millers in the same factory.

We can refer you to users who have from one to a hundred in operation.

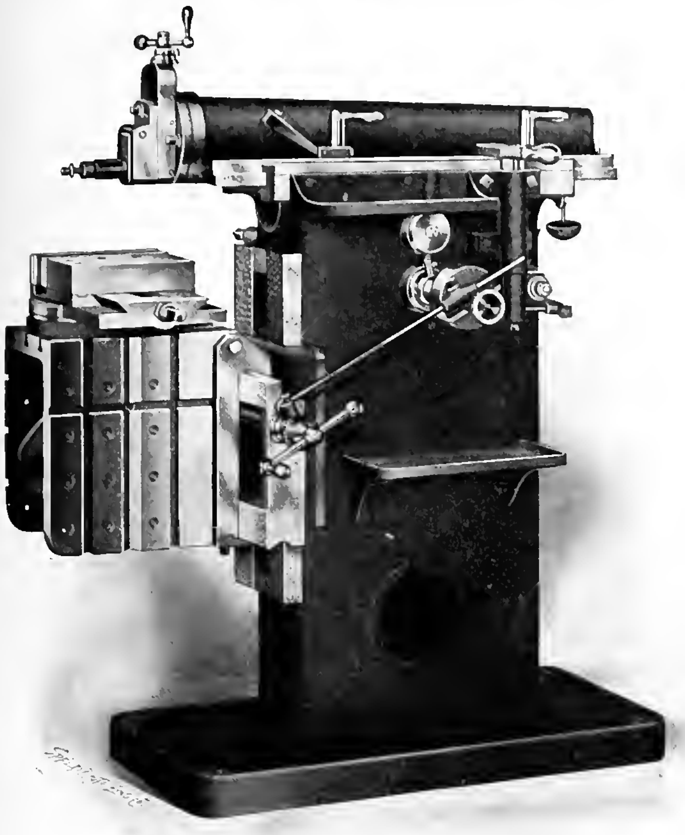
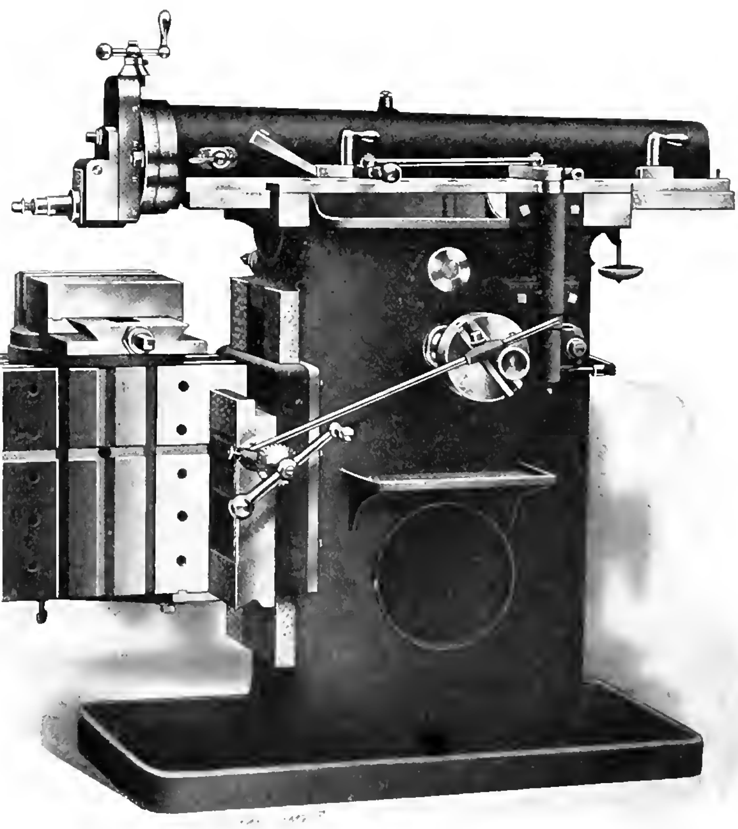
HENDEY Friction Clutch Driven Pillar SHAPERS



Will plane to a line.

Ram is driven by double train of gearing, giving **Constant Speed, Constant Power, Full Length of Stroke.**

Stroke of ram can be quickly changed to any length and position while in motion, simply by moving reversing dogs to necessary position on ram.



Micrometer adjustment on cutting stroke for fine variation in length of forward travel.

Made in 15″, 20″, 24″ and 28″ stroke.

24″ and 28″ shapers have power down feed.

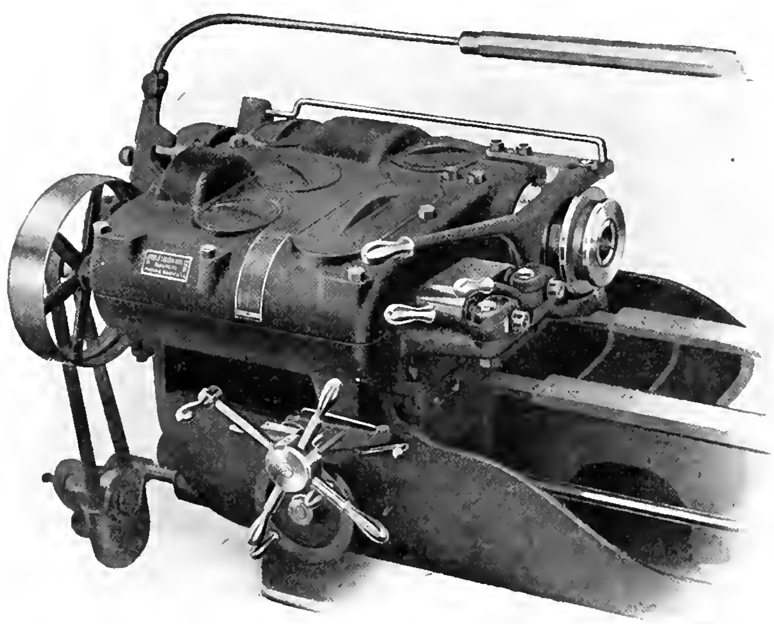
the Flat Turret Lathe will Appeal and Superintendent

6 or 8 pieces only are to be produced. The CROSS SLIDING HEAD is a distinctive point and a point of vantage. This head is securely gibbed to guideways running across the machine, giving the work carrying spindle a cross feed relative to the turret—or in other words, provides a cross feed for every tool, an arrangement which results in incalculable time saving not only for chuck work, but for many other kinds of work. The cross feed has ten stops and the turret twelve stops. Turret turns automatically to position required, skipping other positions. The single drive receives power at a constant speed in one direction and all necessary changes of speed are obtained by an arrangement of gears and clutches.



A WORD ABOUT SIZES:

The Flat Turret Lathe is now made in two sizes, 2 x 24 and 3 x 36, handling respectively bar work up to 24 inches and 36 inches, and chucked work to 12 inches and 14 inches. We shall be glad to estimate the saving possible on your work.

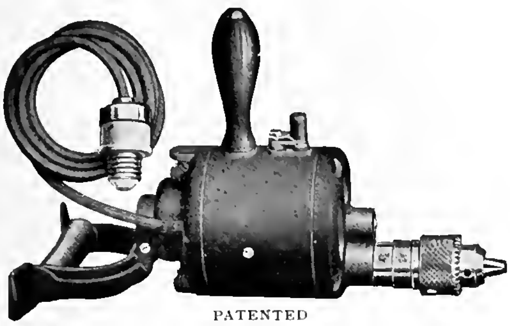
Machine Company, Queen Victoria St., London, E.C.

France and Spain, Ph. Bonvillain and E. Ronceray, 9 and 11 Rue des Envierges, Paris, France. Italy, Adler & Eisenschitz, Milan, Italy.

THE

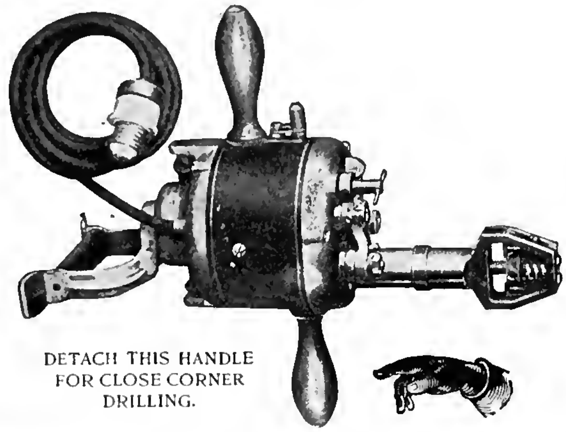
"Hisey" Portable Electrical Drills

Now up to 2" capacity



PATENTED

Made in 3 sizes, $\frac{1}{4}''$, $\frac{3}{8}''$, $\frac{1}{2}''$ capacities. Weights 8, 10, 15 lbs. respectively. Chuck offset for close corner drilling.



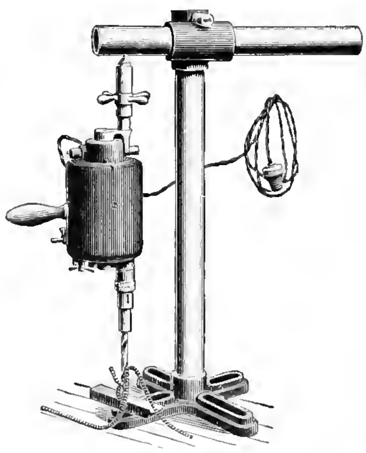
PATENTED.

Type K, 0 to $\frac{1}{2}''$ capacity. Weight 15 lbs. Two speeds. Fitted with screw feed if desired.

Capacities as given are for in steel.

Larger capacities for in softer material.

SENT ON TRIAL.



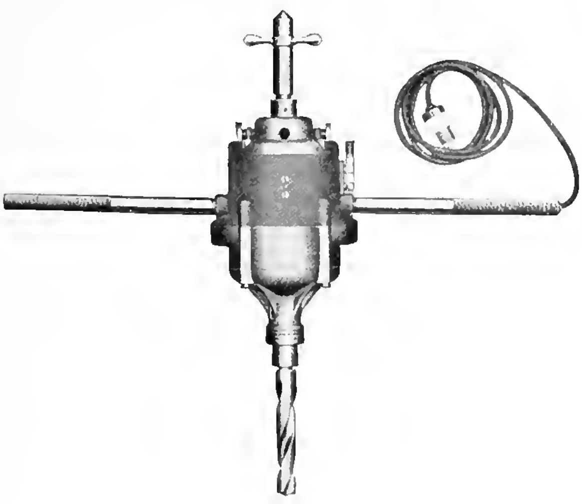
PATENTED.

Type KK, 0 to $\frac{3}{4}''$ capacity. Weight 19 lbs. Two speeds. Fitted with screw feed and taper socket. Breast attachment included. "Old man" furnished as an extra.

ALSO FULL LINE OF

Tool Post Grinders,
Surface Grinders,
Internal Grinders.

Power from any lamp socket. Direct or alternating current.

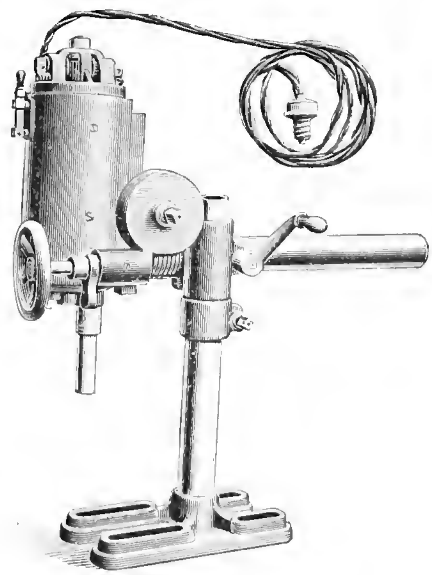


PATENTED.

Center Drive Screw-feed Drill.

Made in 2 sizes, $\frac{7}{8}''$ capacity, weight 27 lbs., and $1\frac{1}{4}''$ capacity, weight 38 lbs. "Old man" furnished if desired. Carry them anywhere.

Our Catalogue No. 5-A illustrates fully.



PATENTED.

Made in 3 sizes, $\frac{7}{8}''$, $1\frac{1}{4}''$ and $2''$ capacities. 12" feed, 24" radius. Two speeds. Motor set at any angle. Will drill in any direction. Hand feed with quick return.

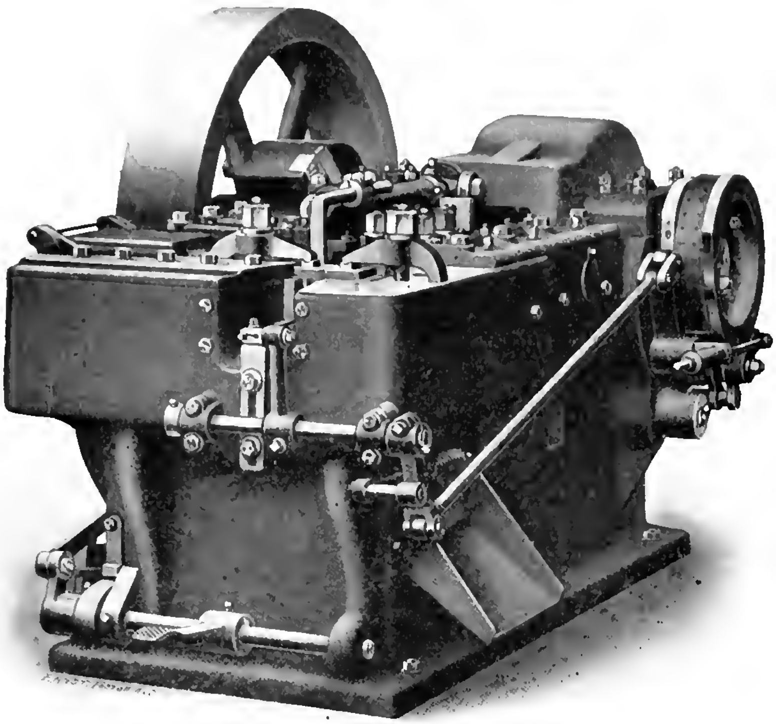
No. 1 STEEL FOUNDRY COLD SAW CUTTING OFF MACHINE

Newton Machine Tool Works, Inc.

Philadelphia, Pa., U. S. A.



The National New Wedge Grip Bolt and Rivet Header

has exceeded even our fondest expectations, and is worthy of the careful investigation of all bolt machine users.

The wedge prevents any "rocking" or springing open of the grip dies, and it is unnecessary to overgrip (hence batter) the dies to secure the required amount of gripping pressure. *As a result the dies will last from three to four times as long as in the regular toggle headers.*

Fins, also are practically eliminated, and this combined with the die saving makes the installation of this machine a plain business proposition.

One customer has ordered twenty-four.

We build complete equipment for Bolt and Nut Plants.

Our aim is to build our machines better, if anything, than need be. Hence we are in position to furnish only the best.

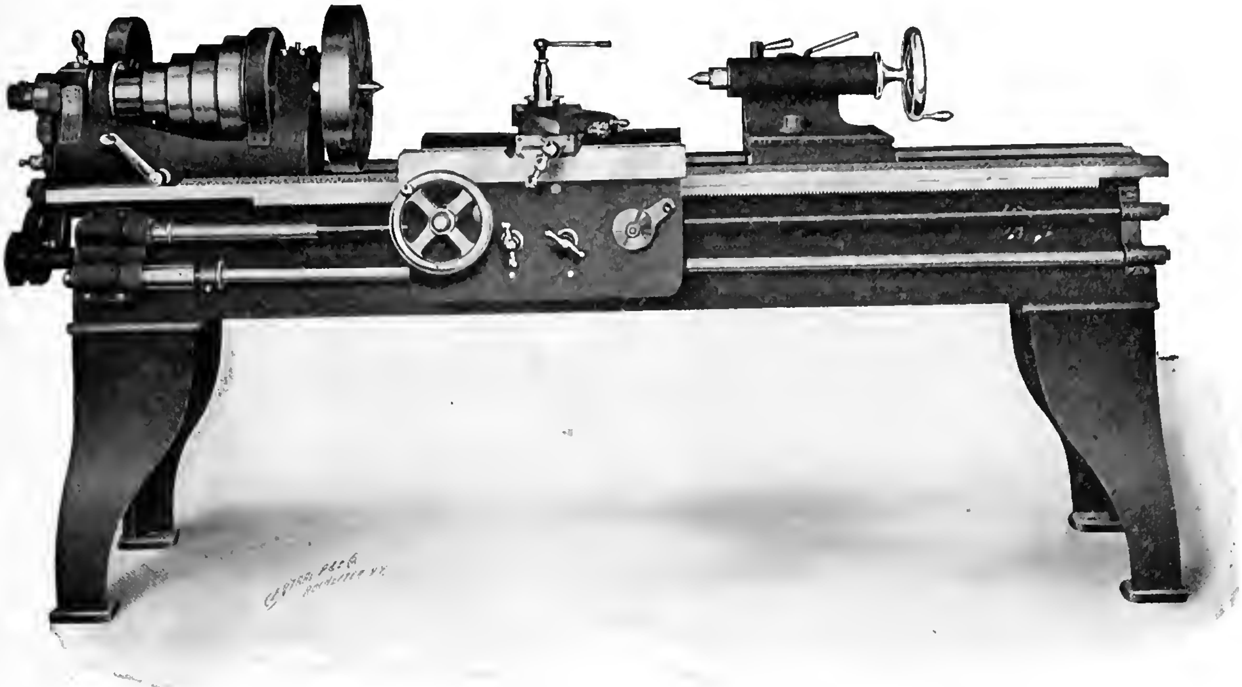
ACCURATE MACHINE TOOLS



DAVIS 14, 16 and 18-inch ENGINE LATHES, with Quick Change Feed also Feed Provided with Automatic Stop.

The above cut represents our latest model of 14, 16 and 18-inch engine lathes. As will be noticed on the cut, ample provision has been made for strength in designing the bed.

The carriage has a long bearing on the Ways, and the tail stock is of improved type, by which the compound rest can be swung around at any angle when work is being finished with the tail stock. There is but one gear to change in cutting any thread, and a change can be made to cut any thread desired in from 20 to 30 seconds.

Our instantaneous feed change is arranged and operated by a lever in the front of the head stock. In bringing out these lathes we have been able to furnish a lathe with all the conveniences required for general use, and actual shop practice, at the same time we have eliminated a large amount of parts found in many of the so called quick change feed lathes.

We believe we are furnishing a tool that will meet all of the requirements of a first-class manufacturing establishment, and at the same time, furnish a tool that will stand up to hard continuous service for many years.

Orders can be sent to us direct or through leading machinery dealers in all large cities of the world.

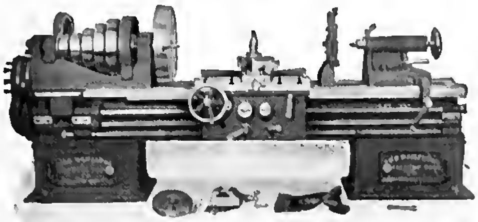
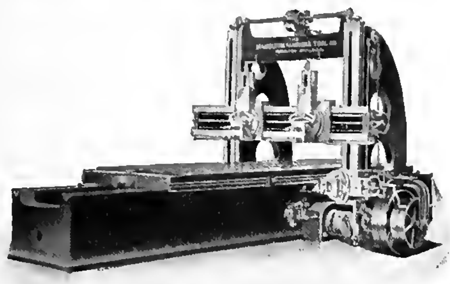
THE W. P. DAVIS MACHINE CO.,

ROCHESTER, N. Y., U. S. A.

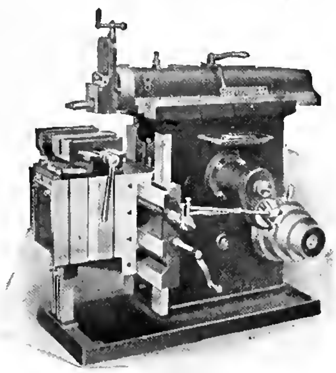
"HAMILTON" TOOLS ARE FAVORITES



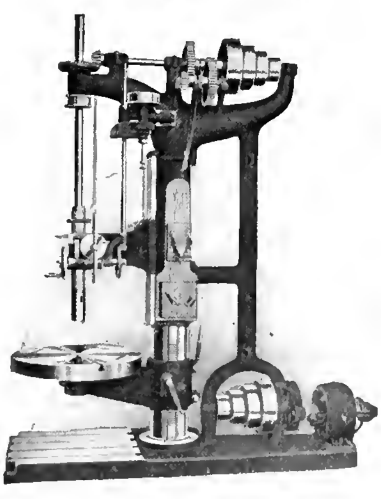
26" x 10' Style "A" Lathe



60" x 48" Planer, Widened Pattern



20" Back Geared Crank Shaper



36" Upright Drill Press, with Motor Drive

Among discriminating buyers, who realize the close relation between efficient equipment and satisfactory production. They are favorites, too, of the men in the shop, who know from daily experience the difference between high grade "HAMILTON" tools and the "just as good" kind.

This is worth remembering when the question of

Lathes, Planers, Shapers, Upright and Radial Drills

is under consideration, also that the selection of "HAMILTON" tools forms the best possible answer.

In both design and construction these machines are unexcelled, and are sure to give a highly satisfactory account of themselves wherever installed. They are furnished in various sizes and styles, either belt or motor driven and with all usual attachments.

Let us send you descriptive matter and further particulars.

The Bullard Vertical Turret Lathe

It's a machine embodying the desirable features of the horizontal turret lathe and the vertical boring and turning mill. It will bore, turn and face any face-plate work that can be done on an engine lathe, horizontal turret lathe or boring and turning mill. It occupies but a third the floor space of a horizontal turret lathe of equal capacity, and requires only about a fifth the tool equipment.

BOOKLET M-602 DESCRIBES THIS MACHINE FULLY.

The Power Behind the Superintendent

THE average shop man can run his lathe, follow his pattern, cut his die, or construct his particular piece of machinery just as well as his "boss"—yet he may plod along for years and never be a superintendent, or even a foreman. Why? Because he has not the ability to meet **difficult extraordinary** situations. He cannot direct, yet he can well do the work when directed. He has learned all he can in the shop, yet realizes he lacks something—but what? **Knowledge—the knowledge which cannot be obtained in the shop.**

¶ Theory must be combined with practice to insure the greatest results. It is this combination which distinguishes the superintendent and the foreman. They have developed their minds by acquainting themselves with the worked-out theories and hints of the leading mechanical experts of the world, and by studying the methods employed by thousands of other progressive concerns—*any man of ordinary ability has the same opportunity.*

CYCLOPEDIA of MODERN SHOP PRACTICE

¶ The greatest mechanical work ever published. Largest—handsomest—most complete. Everything explained in a plain and easy manner. Compiled from the most valuable instruction papers of the American School of Correspondence. **Consists of four massive volumes—each nearly one foot high—2,500 pages—2,000 full page plates. Large type—easy to read—bound in red morocco—marbled tops—gold stamped titles and edges.**

PLANT AND MACHINERY
OF THE
PROVIDENCE STEEL CASTING COMPANY
AT PUBLIC AUCTION

WEDNESDAY, OCTOBER 2, at 12 M., ON THE PREMISES.

Fine Foundry Building, Costing Almost $30,000; some $75,000 worth of Modern Steel Casting Machinery; Fully Equipped Office Building. Valuable Wharf. Rights for use of Tropenus Converter. Lease 95 years to run. The whole representing a recent outlay of approximately $125,000.

The plant is in splendid shape to immediately resume business. It is admirably located on tide water and adjacent to the tracks of the New York, New Haven & Hartford Railroad.

A detailed description of its contents and complete particulars will be furnished upon application to

Fox Universal Trimmers

Everyone now knows that a trimmer is a necessary item of pattern shop equipment. The knowledge of many stops there.

You would not argue that you did not need an automatic screw machine because you happened to have an old engine lathe; but to argue that you don't need the latest improved Fox Trimmer because you happen to have something in the way of a trimmer at present is practically a parallel case.

Our new trimmer catalogue just published, not only describes all the latest machines but gives some points regarding the use of trimmers which are worth having.

Our new core box machine catalog should certainly be in the hands of every pattern shop operator. Get posted.

THE HEATING AND VENTILATION OF MACHINE SHOPS.*

CHAS. L. HUBBARD.†

IN the previous articles, published in the October, November and December, 1905, and the March, 1907, issue, fans and heaters have been treated in some detail without reference to their specific uses in connection with any particular class of buildings. It is now proposed to take up the methods of air distribution, and show the application of hot-blast heating to machine shops and other buildings of similar construction. In order to make the present article complete in itself, some of the data already published will be repeated in condensed form. This is especially for the benefit of those who may not have the articles above mentioned on file.

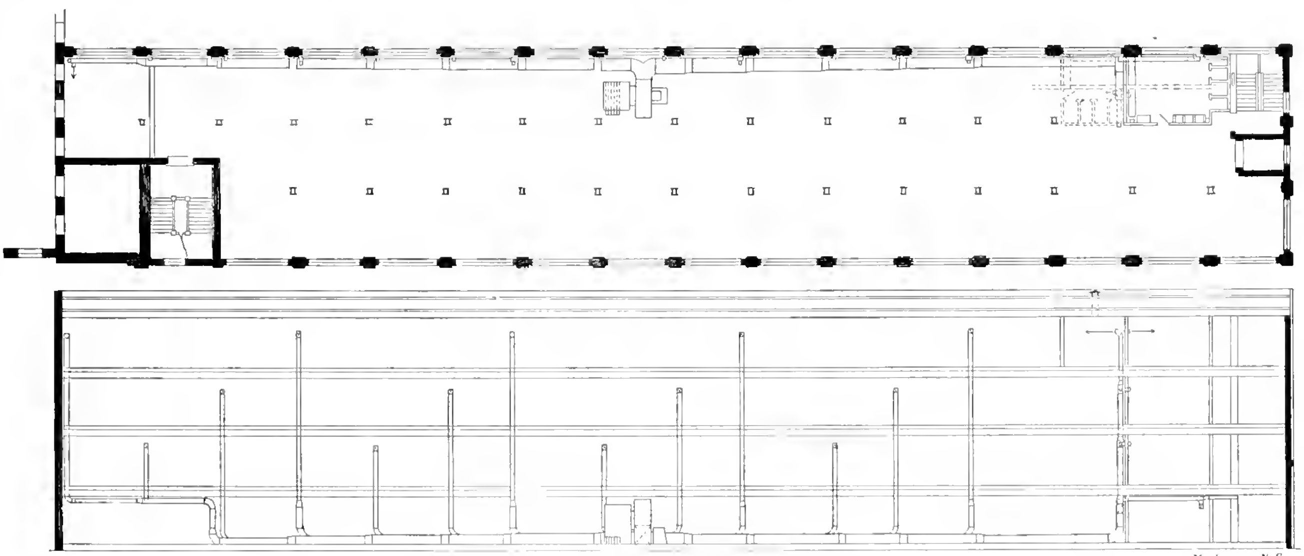
Methods of Heating.

The older method of heating a shop was by means of steam coils, either run along the walls under the windows, or supported overhead as most convenient. This arrangement necessitates a large amount of heating surface together with an extended system of supply and return piping, thus greatly increasing the liability to leaks and freezing. This method provides no fresh air for ventilation, and the distribution of heat is not of the best. When the coils are placed along the walls, under benches, it is uncomfortably warm for those working near them, and if supported overhead, the heat rises directly to the ceiling or roof, thus leaving the lower portion of the room too cold.

The most satisfactory arrangement is where the heating is done by hot air properly distributed through suitable ducts and flues. The heating surface in this case is very compact, only about one-fifth of that required for direct heating being necessary; and as the surface is grouped in a single heater, even in buildings of large size, long runs of piping are avoided. In the largest plants, or where the buildings are more or less detached, it becomes necessary to increase the number of units, but even then the pipe runs are simple compared with those necessary for direct heating. A better distribution of heat is obtained, resulting in a more uniform temperature throughout the rooms. As heating systems of this kind are usually arranged for taking a portion of their air supply from out of doors, it is possible to secure any degree of ventilation required.

General Arrangement.

The location of the fan and heater and the general arrangement of the distributing ducts will depend largely upon the construction and plan of the building. One of the simplest arrangements for a building of small size is that shown in Fig. 2. In this case a single galvanized iron uptake is carried from the mouth of the fan directly upward through the different stories of the building. At each floor the requisite number of outlets are provided at or near the ceiling level, and the air discharged toward the outer walls. In the case of a larger building it would be necessary to extend the distributing ducts horizontally from the main uptake, as shown in Fig. 3.



Machinery, N.Y.

Fig. 1. Heating and Ventilating System of the Ashcroft Manufacturing Company, Bridgeport, Conn.

Another typical arrangement is that shown in Fig. 1, which represents the plan and elevation of the heating and ventilating system installed in the shops of the Ashcroft Manufacturing Company, of Bridgeport, Conn. In this arrangement the fan and heater are centrally located in the basement near one of the side walls. Main distributing ducts are carried in both directions near the floor, and from these, vertical risers are taken off at frequent intervals and carried up to the different stories. The air is discharged into the rooms horizontally at an elevation of about eight feet from the floor. Regulating dampers are provided in each uptake for proportioning the air flow through each outlet.

Fig. 8 shows a plan and elevation of the fan and heater. The fan is of the centrifugal type, with bottom horizontal discharge. The wheel is 6½ feet in diameter, and is driven by a 7-inch by 7-inch vertical direct-connected engine. The heater is made of 1-inch pipe, twenty-two rows deep. The sections are 6½ feet wide by 8 feet high. The building is warmed by air-rotation, no connection being made with the outside air.

Figs. 5 and 6 show plan and sectional elevation of a different arrangement, as installed in the shops of the Houston, Stanwood & Gamble Co., at Covington, Ky. In this case the fan and heater are placed in one corner of the building, and the air carried across one end in an underground concrete

* The following articles on the subject of heating and ventilation have previously appeared in MACHINERY: Boiler Horse-Power for Heating and Power, February, 1903; Notes on Forced Blast Heating Systems, June, 1903; Fans, October, November and December, 1905; Heaters for Hot Blast and Ventilation, March, 1907.

† Address: 551 Boylston St., Boston, Mass.

duct. Two uptakes connect with this, running up beside columns supporting the roof; horizontal branches are then carried the entire length of the building, one on each side, passing through the roof trusses as shown. The air is discharged through short mouthpieces set at an angle to give it a downward direction, and arranged to deliver it both to the central portion and the side aisles or bays. This particular arrangement of the distributing ducts is made necessary on account of the traveling cranes which pass through the entire length of the building in each of the three sections as indicated by tracks at the sides in Fig. 5. This is a typi-

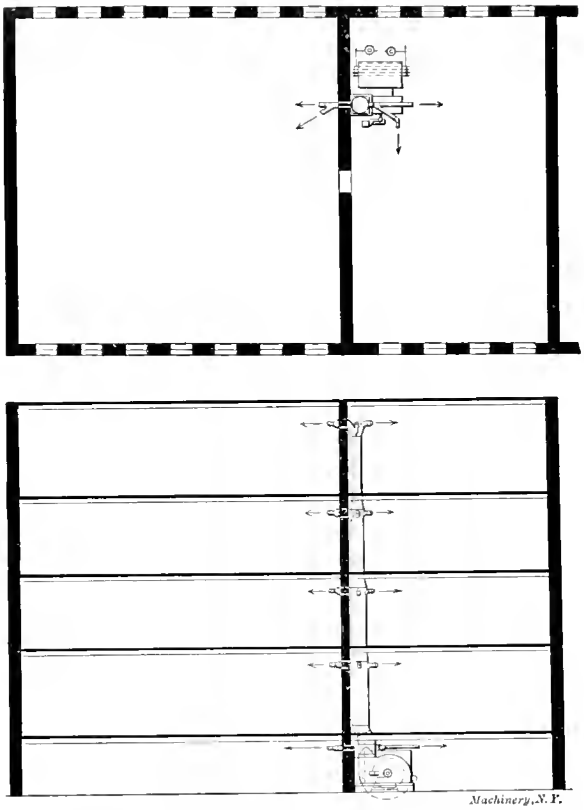


Fig. 2. Simple Arrangement of Heating Installation of a Small Building.

cal illustration of an overhead distribution, the air being discharged at an elevation of about 18 feet above the floor. The apparatus in this case also takes its air supply from the building, leakage being depended upon for ventilation.

Fig. 9 shows a plan and elevation of the fan and heater. The fan is of the three-quarter housed type, with a bottom horizontal discharge connecting with the underground duct. The wheel is 9 feet in diameter. The heater is made up of two groups, with a supply and return header at each side. It is 20 pipes deep, and has an exposed front 8 feet high by 12½ feet wide.

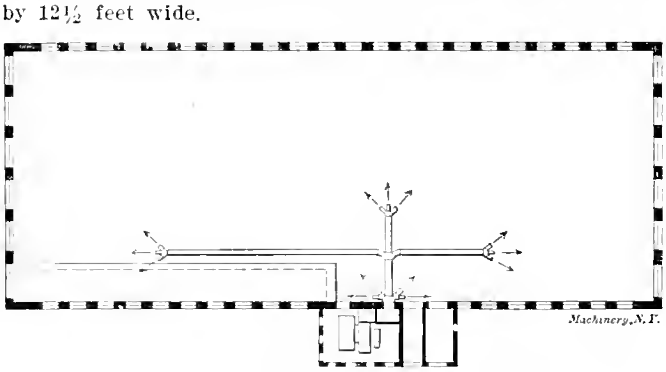

Fig. 3. Heating Installation in a Building of Larger Size than the one shown in Fig. 2.

Fig. 7 illustrates a somewhat similar arrangement, although in this case two overhead units are used, each made up of two fans and a heater, and the air is carried downward to a point about 8 feet from the floor before being discharged. The system is installed in the machine and erecting shops of the Pennsylvania Railroad Company at Trenton, N. J. All parts of the system are symmetrically arranged, which gives practically an equal resistance to the flow of air in each of the four main distributing ducts.

A plan and elevation of the fan and heater of one of the units is shown in Fig. 4. Two double inlet fans are used, with wheels 8½ feet in diameter attached to a common shaft and driven by a belted motor. The heater is made up with a double header, as in the previous layout. It is 20 pipes deep, 13½ feet wide and 10 feet high. The air is taken from

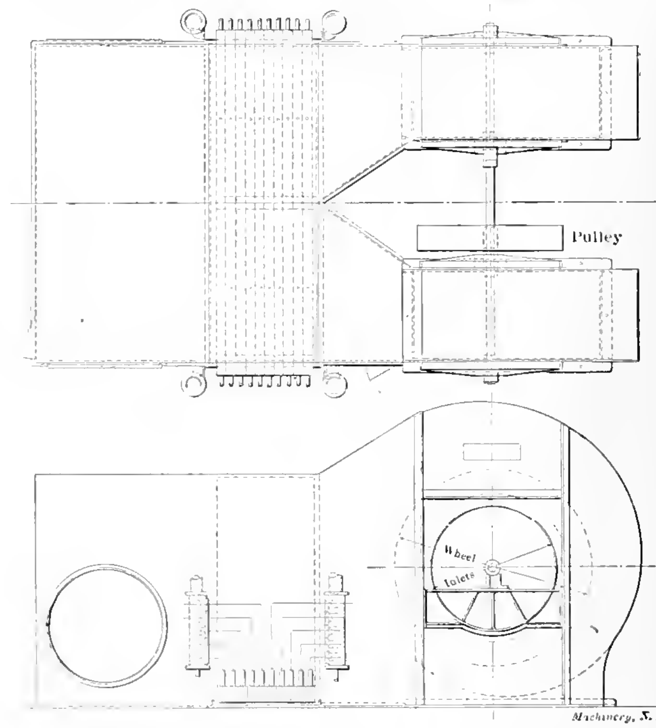

Fig. 4. Fan and Heater of Installation shown in Fig. 7.

the building, but is forced through the heater instead of being drawn through by suction, as in the other arrangements shown.

These five buildings illustrate the more common methods of arranging the distributing systems in the heating of machine shops of modern construction. They were designed and installed by the B. F. Sturtevant Co., of Boston. Having shown examples illustrating the general layout of a system for shop heating, let us now take up some of the details of design.

Material used for Ducts and Flues.

The airways are either constructed of brick or galvanized iron. In brick buildings where the heating system is planned

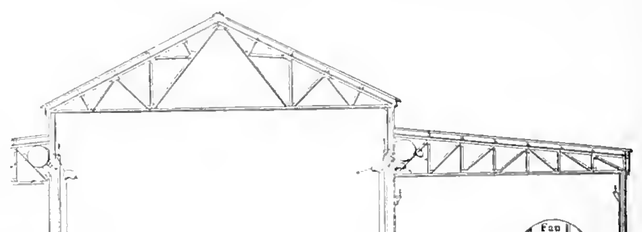

Fig. 5. End Elevation of Installation shown in Fig. 6.

before the building is constructed the flues may be most readily and economically built in the walls as the building is erected. When this is done, care should be taken to give them as smooth an interior as possible by removing all projecting mortar from between the bricks.

Underground ducts are built either of brick or concrete for the larger sizes, and generally of glazed tile for the branches. In buildings of wooden construction, and also those of brick when erected before the heating system is laid out, it is customary to use galvanized iron. This is easily worked into the required form, is light in weight, and takes up a minimum of space for a given area.

Construction of Ducts and Flues.

Great care should be taken in the design and construction of a system of ducts and flues. When a change in the di-

rection of flow is necessary, a gracious curve should be provided. For 90-degree turns, the elbow should be made with at least five pieces, and the radius of the inner side of the elbow should not be less than the diameter of the pipe. This relation between the radius of curvature and the size of pipe should hold in the case of rectangular ducts as well.

When a branch is taken off from a straight run of pipe, it should be given an angle of 45 degrees at the point of connection, and the remaining change in direction made by an easy turn. The main run of pipe is commonly reduced at each branch or take-off by an easy taper, about 28 inches in length, which can be made from a sheet of iron of standard width, which is 30 inches. Whenever the duct or pipe branches, the construction should be such as to divide the air volume into the required proportions, giving to each branch an easy change in direction, when possible. While due regard should be given to the proper proportioning of the pipe areas, it is not possible to get a sufficiently accurate distribution of air without the use of dampers and deflectors. In the case of a large number of small outlets from a main duct, the best results are usually obtained by the use of adjustable dampers in each outlet. Where there are several branches of considerable size leading from the main, it is well to place adjustable deflectors at the junction of the ducts, so that the air volume can be deflected into the branches in such quantities as may be desired. In the case of brick or concrete underground ducts, the same points relating to curves, dampers, etc., should be observed as described above for galvanized iron.

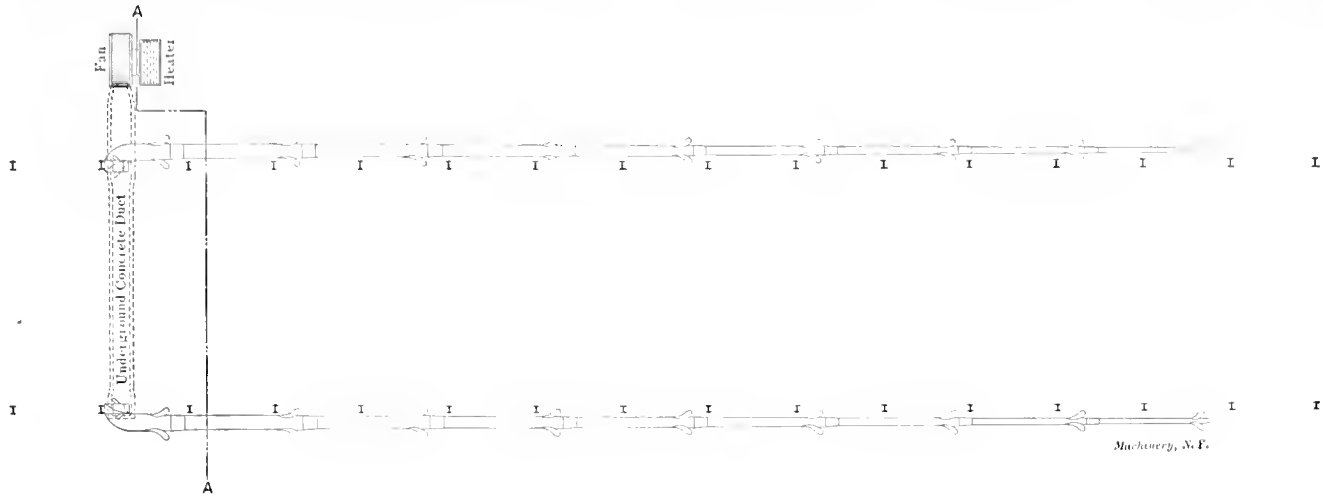

Fig. 6. Plan of Heating and Ventilating System of the Houston, Stanwood & Gamble Co., Covington, Kentucky.

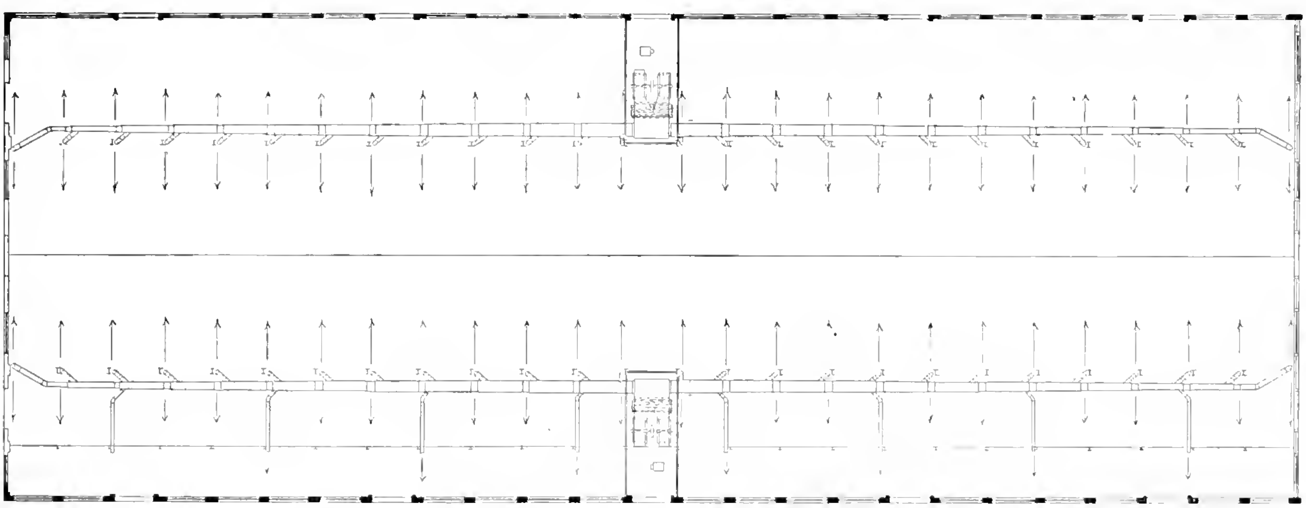
Size of Ducts and Flues.

The sectional area of the ducts and flues is based upon the velocity of the air flow through them. It is a well-known fact that the frictional resistance to the flow of air through pipes increases as the square of the velocity, hence if the power required for driving the fan was an important factor, very low velocities would be required. As a matter of fact, this is generally neglected in practice, and velocities are based upon the most desirable speed of fan for this class of work, which is about 5,000 linear feet per minute tip velocity. This results in a velocity through the fan outlet of about 3,500 feet per minute. The size of the main duct is made such that the velocity commonly runs from 2,000 to 3,000 feet per minute, although some engineers make a practice of starting with a duct the same size as the fan outlet, but making a small increase in the size of the branches, so that their aggregate area shall be from 30 to 40 per cent greater than the area of fan outlet, thus bringing the velocity down to from 2,500 to 2,800 feet per minute.



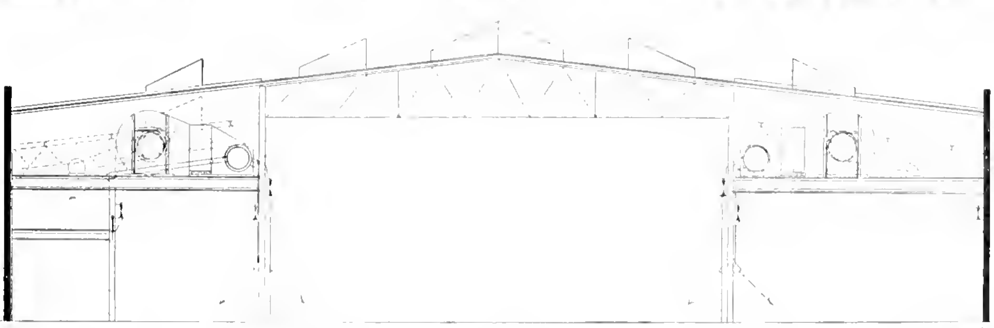


Fig. 7. Heating System of Pennsylvania Railroad Company's Machine Shop at Trenton, N. J.

It is frequently possible in shop practice to secure satisfactory circulation of the air with a limited extent of ducts by discharging it at a high velocity, as noted above, thus compelling it to continue its direction of movement for a consider-

able distance without the use of conducting pipes. It is not uncommon in such cases to force the air 100 feet or more from the outlets at a velocity of 2,000 to 3,000 feet per minute.

Weight of Iron Used.

Table I gives the gage of iron commonly used for pipes of different diameter. All sizes above 60 inches are made of No. 16 gage. If the pipe is made much lighter, particularly in the larger sizes, it will not keep its shape when supported horizontally, which results in loosening the joints and also decreasing the area of the pipe. The common practice is to make rectangular pipes of the same gage as round pipes having the same sectional area, but under certain conditions, as in the case of a thin, flat pipe, bracing is necessary to prevent sagging, even with heavy gages. When braces are used, lighter iron may be used than given in the table.

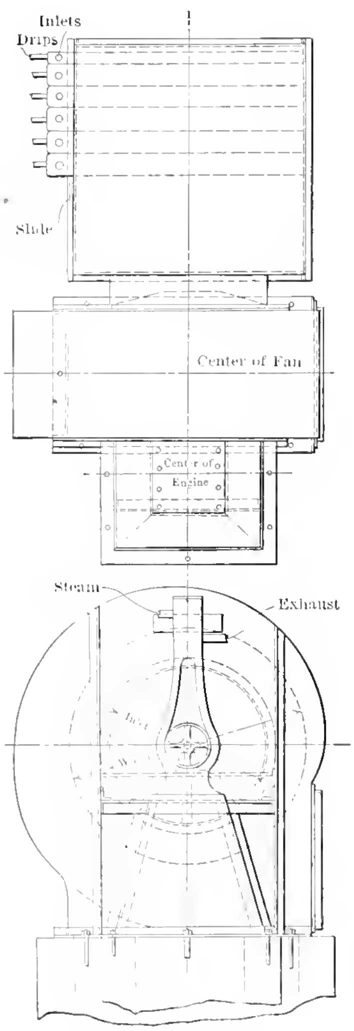

Fig. 8. Fan and Heater of Installation shown in Fig. 1.

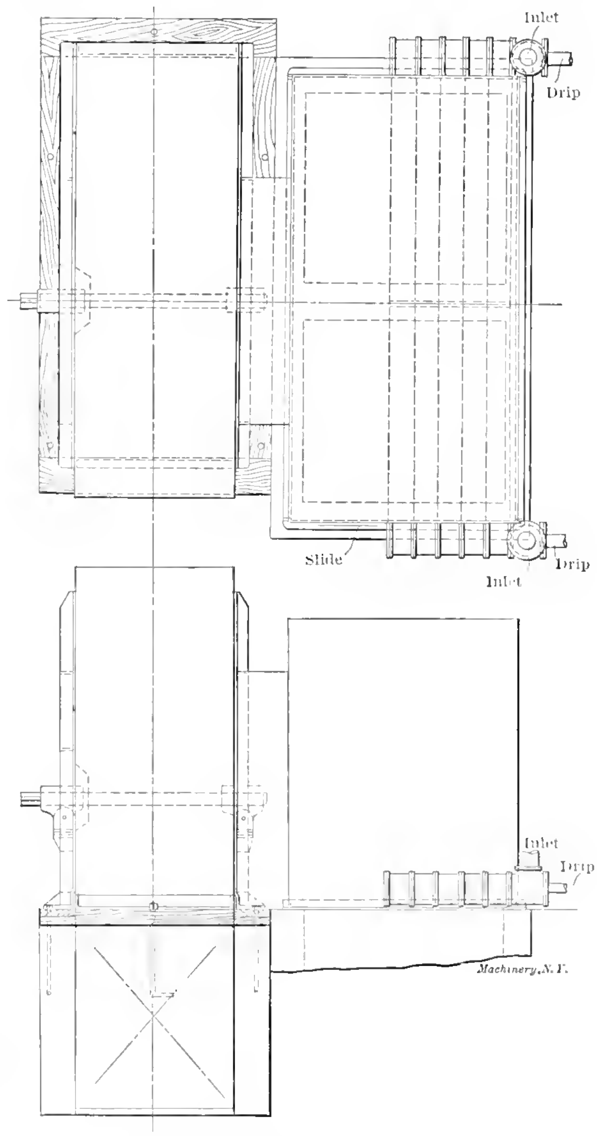

Fig. 9. Fan and Heater of Installation shown in Figs. 5 and 6.

Heaters.

The subject of heaters for shop heating was quite thoroughly discussed in MACHINERY for March, 1907. A few of the results noted there will be given in the present article together with some special reference to heating by air rotation. In shop practice, the amount of heating surface is generally expressed in linear feet of one-inch pipe for a given space to be heated. This, for average conditions, may be taken as follows. With all of the air taken from out of doors, there is generally allowed 100 cubic feet of space for one foot of pipe when exhaust or low-pressure steam is used, and 150 cubic feet with steam at 80 pounds pressure. When the building is heated by air rotation, the above figures may be raised to about 140 and 200 for low-pressure and high-pressure steam, respectively. The heater is generally made about twenty pipes deep under ordinary conditions. Heaters of this type have an efficiency of about 1,300 heat units per square foot of surface for steam at 5 pounds pressure, and an efficiency of 1,600 for 60 pounds pressure.

TABLE I.

Diameter of Pipe.	Gage of Iron
Less than 9 inch	28
9 inch to 14 inch	26
15 inch to 20 inch	25
21 inch to 26 inch	24
27 inch to 35 inch	22
36 inch to 46 inch	20
47 inch to 60 inch	18
61 inch and above	16

Volume of Air Required.

When the air is taken from out of doors for the purpose of ventilation, it may be based upon the number of occupants or upon a given number of air changes per hour. Usually the cubic contents is large per occupant and may vary considerably in different shops, so that under ordinary conditions it is best to use the former method. The air supply per occupant may be taken as about 25 or 30 cubic feet per minute, unless the building is very openly constructed, in which case the air volume may be reduced and leakage depended upon to a considerable extent. In many shops the heating is done entirely by air rotation, and leakage is depended upon entirely for ventilation. This is made possible because of the large enclosed space in proportion to the number of occupants and to the thorough mixture of the inleaking air with that which is in rotation. When this method of heating is used, the air simply becomes the medium for transferring the heat to the different parts of the building, and the volume required will depend upon the amount of heat to be transferred and the temperature to which the air is raised.

Suppose the air is returned to the heater at a temperature of 60 degrees and delivered at a temperature of 140 degrees, the total rise being 80 degrees. In cooling one degree, one cubic foot of air gives out 1/55 of a heat unit, or in cooling 80 degrees will give out $1/55 \times 80 = 80/55$, or 1.4 heat unit. Therefore, if we divide the total amount of heat to be supplied in a given time, expressed in heat units, by 1.4, it will give the volume of air to be rotated in that time, assuming, of course, that it is cooled through 80 degrees during its passage through the room.

The heat loss from the building may be computed by any of the common methods in use, or the size of the heater may first be computed by the method already given, and the heat given off taken as the equivalent of the heat lost. Referring to Table II in MACHINERY for March, 1907, we find that a heater twenty pipes deep with steam at 5 pounds pressure will raise the temperature of air from 0 to 140 degrees, and has an efficiency of 1,300 heat units. Steam at 5 pounds pressure has a temperature of 227 degrees. The average temperature of the air passing through the heater is $\frac{0 + 140}{2} =$ 70 degrees, hence the difference in temperature between the steam and air is $227 - 70 = 157$ degrees. In case the air is rotated, its average temperature is $\frac{60 + 140}{2} = 100$ degrees,

and the difference between the steam and air is 227 — 100 = 127 degrees. The efficiency of a heater varies directly as the difference between the temperature of the steam and air; hence, in the second case, with the air rotated, the efficiency would be 157 : 127 = 1,300 : x, and x, the efficiency in this case, would be approximately 1,100 heat units. Then the square feet of surface in the heater multiplied by 1,100 will be the heat given off per hour, and this divided by 1.1 will give the cubic feet of air to be moved per hour by the fan.

Size of Fan.

The required size of fan for moving any given volume of air may be taken from Table II, which also gives the approximate speed and the horse-power required for driving the fan.

TABLE II.

Nominal Size of Fan, Height of Housing in Inches.	Diameter of Fan Wheel in Inches.	Width of Housing in Inches.	Ordinary Speed Giving ½ Ounce Pressure.	Cubic Feet of Air Delivered per Minute.	Horse-power of Engine to Drive the Fan.
30	18	9	870	1000	½
40	24	12	580	1600	1
50	30	15	465	2600	1
60	36	18	390	4500	2
70	42	21	333	6000	2½
80	48	24	293	8000	2½
90	54	28	260	11000	4
100	60	32	233	12500	4
120	72	43	195	21500	7
140	84	48	167	28600	9
160	96	48	147	31800	10
	108	54	130	40400	13
	120	60	117	51000	16

The speeds given in the table are for ½ ounce pressure; should it be desired to deliver the air under a higher pressure, in order to force it a long distance from the outlets, it would be necessary to increase the speed of the fan somewhat, depending upon local conditions.

NOVEL HIGH COMPRESSION OIL ENGINE.*

ALFRED GRADENWITZ.†

In oil engines of the injection type, the liquid fuel, as is well known, is injected in an atomized condition immediately into the combustion chamber, where an immediate ignition and combustion takes place owing to the heat from the previous compression of the air. Now the main difficulty met with in the construction of these motors has been to conveniently atomize the fuel, and to produce the highly compressed injection air which is indispensable for the process. This air must be raised to a pressure superior to the terminal compression in the clearance space, in order to pick up the oil and spray it in a finely subdivided state into the combustion chamber.

In the Trinkler motor, recently brought out by Messrs. Körting, Ltd., this is neatly and efficiently effected by the aid of a small auxiliary "injection" piston, which, towards the end of the compression, separates a certain amount of compressed air from the clearance space, driving it with the necessary injection pressure through the injection nozzle, along with the oil contained in the latter, into the combustion chamber. The construction of this motor will be understood by reference to Figs. 1 and 2, and the accompanying description.

The Trinkler engine is a single-action four-cycle motor, with a working stroke on every alternate rotation, the working process being as follows: The piston A, on the out stroke, draws in through the inlet valve pure air, which it compresses on the return stroke to a pressure of from 28 to 30 atmospheres. At the same time the compartment D, situated in front of the injection piston C, will be filled with compressed air from the cylinder through a compensating channel E, which connects this compartment with the clearance space. Through channel G, at the same time, the compressed air flows into injection nozzle F, which permanently communicates with the compression chamber through a relatively small injection aperture. A charge of liquid fuel is stored in the chamber of the injection nozzle F, being supplied to it through a valve I from a fuel pump, connected with the valve through the conduit K.

Toward the end of the compression stroke, the injection piston C (owing to the difference in pressure on the front surface turned toward the compression compartment and the annular surface formed by the piston rod of the injection piston) will be rapidly moved outward, sliding across the channel E, and separating the air in compartment D from that in the cylinder. With the further motion to the left of piston C, this amount of air is forced from the chamber D through conduit G and injection nozzle F back into the combustion chamber again. As the mouth H of the nozzle is relatively narrow, while the motion of the piston C is extremely rapid, the injection air will be highly compressed, and will traverse the injection nozzle F of the fuel-storing compartment with a

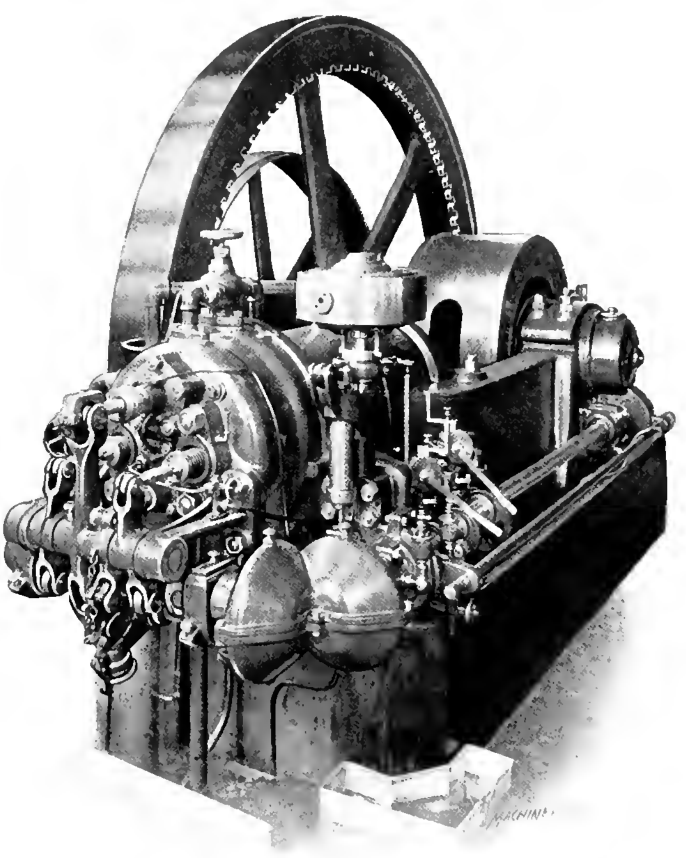

Fig. 1. The Trinkler Oil Engine.

high speed, so as to carry along the fuel and to throw it in a state of finely atomized spray into the combustion chamber, in which, owing to the high temperature of the compression, the fuel will be ignited, whereupon piston A will be thrown forward, transferring the impulse to the crank. Shortly before the end of the working stroke, the outlet valve will be opened by the valve gear, and the products of combustion will be exhausted on the return stroke of the piston. During the subsequent advance of the piston, the suction and further working processes will be repeated as above described.

The motor is started by means of compressed air, supplied to the engine through a mechanically controlled valve N. The compressed air reservoir used for this is charged from the compression space of the engine itself through a charging valve (not shown) cooled by the jacket water.

The high thermal efficiency of oil injection engines is generally known. As regards the other features of these motors, the absence of any igniting or heating apparatus should be noted, as well as the perfect elimination of soot and smell, due to the perfect combustion of the fuel. As regards their ease of operation, and the safety and elasticity of the service, these engines may be said to equal those using gas fuel, while

* For further information on internal combustion engines, see the following articles previously published in Machinery: The Oil Engine, September 1898; The Commercial Advantage of the Oil Engine, June, 1899; An Interesting Engine, May, 1899 Internal Combustion Engines and the Diesel Principle, September, 1901 Patents in their Relation to the Gas Engine and the Automobile, January, March, and May, 1906; Oil Engines, August, 1907; The Johnston Crude Oil Engine, August, 1907.

† Address: 25 Kornerstrasse, Berlin, Germany.

far excelling from the former point of view the steam engine. One of the main special advantages of the Trinkler motor is the simplicity of the injection apparatus, which is free from any valves and special pressure reservoirs. The motor, thus, is free from any part requiring to be packed permanently against high pressure. As the fuel pump has not to work against high pressure, the ease of regulation of this motor is especially remarkable.

The most valuable feature of this novel engine is its extremely low fuel consumption, both with full and partial loads. According to tests made by Prof. E. Meyer, of the Charlottenburg Technical Institute, a 12-horse-power motor of this type showed in permanent operation a consumption of 0.4863 pound Russian crude naphtha per hour and effective (metric) horse-power. The minimum heating value of the crude oil in question was found to be 9,863 thermal units per kilogramme. The engine thus used up 2,180 thermal units per effective horse-power hour, corresponding to a thermal fuel efficiency of 29.2 per cent. This is the more remarkable, as the consumption of fuel with half load was found to be only 7½ per cent higher than with full load, that is to say, 0.524 pound per hour.

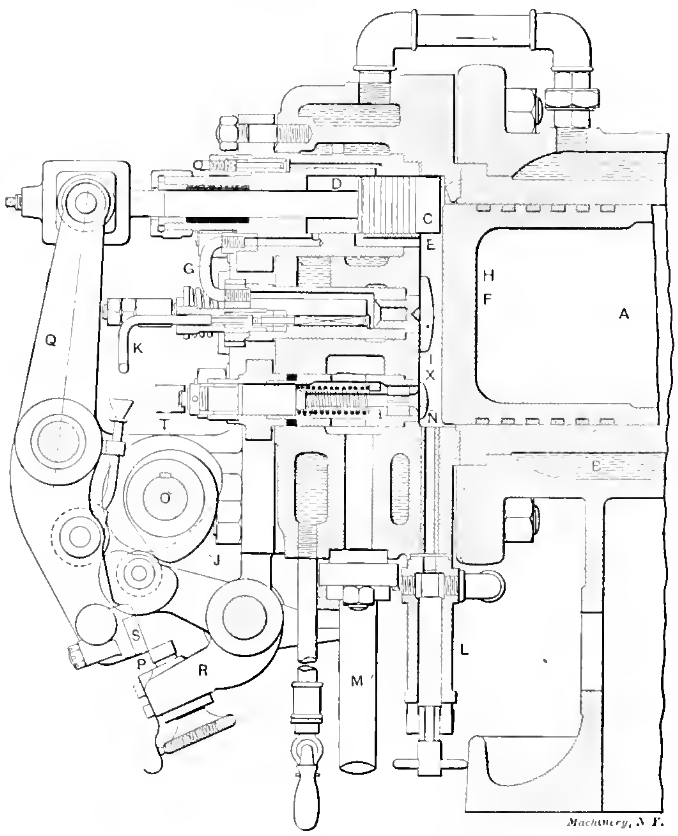

Fig. 2. Cross Section through Oil Injection Mechanism.

[Two or three other points of interest besides those mentioned by Dr. Gradenwitz, may be noted from a survey of the cuts. The auxiliary piston *C* is evidently moved to the right positively, by arm *Q* and cam *T*. It is then held in this position by the engagement of latch *P* against the hardened block *S* at the lower end of lever *Q*. As piston *A* approaches the end of the compression stroke, at the proper moment cam *J* presses down lever *R* and latch *P*, releasing lever *Q*, and allowing piston *C* to move to the left as described, under the influence of the pressure in the compression space *X*. On the release of lever *Q*, the spraying of the fuel and its consequent ignition take place almost immediately. Owing to this, the time of ignition can be regulated by changing the time of release of the lever *Q*. This is done by making latch *P* adjustable by the knurled thumb screw shown. The speed of the engine is regulated by the action of the governor on the fuel pump, which is thus made to furnish a greater or less charge to the nozzle, as may be required.—Editor.]

A brass much used in marine vessel construction, because of its excellent resistance to the corrosive action of sea water, is 1 part tin, 39 parts zinc, and 60 parts copper.

EDUCATION FOR INDUSTRIAL WORKERS.*

A PLEA FOR A MACHINE TRADE SCHOOL.

ARTHUR D. DEAN.†

There are several movements now on foot for the establishment of trade schools. One is that initiated by the schoolmaster. He states that boys do not remain in school long enough, and that some scheme of education must be devised whereby they will remain after the legal limit imposed by the compulsory attendance laws. He claims that they leave school at 14 and waste two years drifting along lines of work which do not give them an economic hold on the industrial life. I regret that the schoolmaster advocates for these boys only manual training when I believe that he should propose trade training for them. I regret that he impresses upon the public that the public school does not and will not teach a trade. He states that the shop work in the schools is to teach only the mechanical principles underlying the trades, and these merely for their educational value. Only 6 per cent of 2,500 graduates of our manual training high schools have become mechanics.

Need of a New Type of Trade School.

This result may justify the existence of the manual training high school, and at the same time it strongly points to the need of another type of school which will teach the youth of our land to become *first-class mechanics.* I believe it is the proper function of the school official to advocate a type of school which in its purpose frankly and openly states that it can and will fit a boy for a good workman at a chosen trade. Our head workers must come from the ranks if we are to get the best work out of these workers. To eliminate the chances for promotion which give a worthy purpose for ambition and foresight by taking into our industrial system foremen and superintendents outside of the ranks is to crush the workers, and eventually kill the industrial system. The phrase "room at the top" must not lose its significance through closing the entering door by taking into the industrial system too many men trained outside the industrial ranks.

Among the objections to trade schools is that they cannot teach a trade, and that the only place to learn a trade is in the shop. I believe that this statement is unfair, as the few trade schools which exist have demonstrated that a trade can be taught as a part of an educational system, and the graduates have gone into the shops and made good. I do not claim that they can learn all that concerns a trade in any school. Neither do they learn all there is to a trade in a shop. It is a self-evident truth that no man learns all that there is to a trade or profession, no matter where he receives his training nor how long he practices it. It seems to me that definite organized instruction in the use of various tools and machines in a trade school will turn out workers superior to those who, like Topsy, simply "grew up" in such manufacturing establishments, which take no pains to give systematic instruction to their young workers.

Why an Ideal Trade School can Develop Better Mechanics than the Shop.

Let us consider some of the reasons why a trade school can render better service than the average shop in developing skilled mechanics.

1. The school can help make a profitable workman in a shorter time by giving him, under instruction, legitimate shop practice in the work of the trade. Definite practice in the work of the trade from the very beginning in a school is a far different proposition from sweeping, piling castings or running errands for several weeks or months in the shop.

2. The school can give a series of graded lessons, general and fundamental, upon which other work may be based, and future efficiency more certainly developed. The lack of sequence in the ordinary shop work becomes for the average boy merely routine work, and he flounders around.

* The subject of industrial education and kindred subjects has been treated previously in the following articles in Machinery: Technical Education, January, 1901; Technical Education, December, 1903; Contemporary Technical Education, January, 1905; Factory Education, December, 1905; An Experiment in Industrial Education, January, 1906; An Experiment in Industrial Training, September, 1906; A Step Toward Increased Facilities for Industrial Education, December, 1906; Vital Needs of Evening Schools for Industrial Workers, January, 1907; Apprenticeship Education, February, 1907; Unique Experiment in Technical Education, March, 1907; Promoting Industrial Education, May, 1907.

† Address: 167 Tremont St., Boston, Mass.

3. The school can give the opportunity to do a task over and over again until it is done right, the opportunity to study each problem closely and deliberately. In a shop there is little chance to try again. The work must be thrown away. A "call down" in a shop can never take the place of *definite instruction* in a school.

4. The school can give a broader, more intelligent idea of the relation of the parts to the whole. The beginner learns the dependence of one part on another. The tendency to keep a cheap grade of labor doing one thing may make a first-class operator, but if we expect our bright boys to respond to an unusual problem, they must have a chance to practice all the usual operations of production.

5. In the school the instruction is direct and personal, given by one who is selected not only because of his superior qualities as a workman, but because of his ability to teach. The instruction in the average shop is haphazard and accidental, given by a foreman who is already harrassed by a multiplicity of details.

6. The school comes nearer to taking the place of the shop as it approaches the commercial standards of the shop. The incentive of the commercial demands of the shop will emphasize the value of time. A clear conception of how a piece of work should be done is necessary at the outset to avoid a waste of time.

Municipal Authorities Slow to Respond.

To hope that municipal authorities will take the initiative with reference to trade schools is expecting too much, for unfortunately some politicians only see the popular mind of the people through the eye of the labor leader, and labor leaders are opposed to trade schools. There will also be difficulty in disposing of the finished products of these schools if they are under municipal auspices. In order that the work may be of a thorough, practical sort, it must illustrate actual trade conditions. The parts must be assembled into a complete machine in order to illustrate all the commercial processes. When these machines are complete, they must be disposed of in the market. If we bear in mind the past experience of some state reform schools which have attempted to dispose of their products and have been prevented from so doing, and finally have given up their industrial and trade work, one can readily see that the disposition of the finished product becomes a real and serious problem.

Private Trade Schools Needed for Purpose of Illustration.

We need a few trade schools to serve as practical illustrations of what they are capable of doing. We need schools which can practically answer the statements that a trade can be learned in a school, and that trade schools are a benefit to the working man. We must show what a trade school is like. I believe that these schools must pass through the same experience which was undergone when cooking, manual training, and kindergarten schools were established. They were introduced at first under private auspices, and demonstrated their value before they were accepted by the mass of the people. I am a believer in the theory that *private initiative creates public enterprise*, and that no better service can be done than to educate through private trade schools the public conscience to the point where it will see some practical examples of their value. In the preliminary development the trade school movement will go forward only when it is a private enterprise. These schools must have the interest of the manufacturer. They must have his suggestions. He has been the largest factor in industrial development. He recognizes that the trade school can substitute definite systematic instruction for the haphazard, uneconomic training in those shops where no special effort is made to train industrial workers. Practical men know that special education for a trade, accompanied by training in mechanics, mathematics, science, and precepts of clean living, will serve as a basis for stable equilibrium for the industrial world, now so often upset through industrial strife.

The two points to keep in mind in all this discussion of trade schools are first, the American boy who is desirous of an opportunity to learn a trade, and second, the establishment of a school which will give him such training.

Naturally you want to know what sort of a definite proposition I can present, and so, as an illustration, I offer the following suggested outline for a trade school preparing students for the machine trades.

Should have no Other Name but Trade School.

In regard to its nomenclature it must be called a trade school. It must not be called an industrial school or a preparatory school for the trades. Its name should not cover up the character of the work which it intends to do. It should in its very name define the nature of its proposed work. There should be no hesitation in calling it just what it is.

Schools not to Create Class Distinction.

Naturally the question arises, what class of students will be taken into the school. The students should be recruited from any class wherein an individual feels that a knowledge of a trade will be of value to him. In all probability the great majority of recruits would come from the rank and file of workers, and the whole atmosphere of the school should be such as to make them feel that its work was for their benefit. It must be a school which will instil in the minds of the boys the idea that they are going to become workmen, and good workmen at that, and that if they are good workmen they may become superintendents and foremen. It must avoid starting them out with the idea that they are to be superintendents and foremen immediately upon graduation. It should awaken in them a desire to be *good workmen*.

School Schedule Same as Shop Schedule.

The school should run eleven months in the year, fifty hours a week, or in other words should imitate the hours and holidays of the factory. The hours and working days being practically the same as those in the shop would teach the students habits of regularity which they must learn in actual employment. I would suggest that the month of August be taken as a shut-down period. This does not imply a vacation, but rather an opportunity for making necessary repairs for next year's work. Boys in the school who need money should be hired to do this repair work.

Should be Open both Day and Evening.

The school should be open both day and evening, although whether such a school could be run successfully for two kinds of work depends entirely upon its organization. To run it successfully both day and evening would require practically a double force of instructors. This, however, is a detail in organization. The day class should be composed of boys who have been secured with a great deal of care as regards mental and physical fitness for the future work which they are to do. They should be taken into the school for a trial period of three months. They should be set at work the very first thing on a job which will test their ability to do mechanical work. Sweeping floors may demonstrate a boy's ability to sweep, but it will not point out to the school managers his ability to make a good mechanic.

The school should be open evenings for young men who wish to advance themselves in their trade. Few, however, will care to spend their evenings in the same class of work in which they are engaged during the day. This departure will reach fellows of a different caliber, whose qualities of mind and mechanical ability cannot be judged by written entrance examinations. Their fitness to enter the school can be determined by a practical examination in one or two pieces of shop work and a five minute interview in order to size up their characteristics.

Kernel of Instruction should be Shop Practice.

The kernel of instruction should be shop practice and book learning which fits in with the machine trades. This means that the major subject will be machine shop practice. It also means that there must be some mechanical drawing, pattern making and molding. The course of instruction will not be complete unless there is academic work in English, business forms, mechanics, arithmetic and physical science. The instruction in all this work must be carried on expressly to meet the needs of the machine trades. It must not be taken from elaborate text-books in general arithmetic, general English, etc., but rather from courses which have been carefully worked out by practical men who know what topics are of vital importance to a boy who is to be engaged in a machine trade. Incidentally, there should be inculcated in the minds of the students a power to reason on social and economic

problems along lines which will give them tnat proper point of view so necessary in these days of the relation of their individual responsibility and life's responsibility. To so teach boys that they may earn good wages at a trade, and at the same time neglect to give them that training wnich will enable them to live wisely while earning that money, is a false position for any school to take. However, I should not have social and economic work incorporated as a set course. It is rather a point to be considered as entering into all the instruction.

Tuition Fee should be Charged.

There should be a tuition fee both for the day and evening work. It is the experience of most of us, not only in school work, but in all concerns of life, that what we pay for, we value, and that what we get free is not always appreciated. Provision should be made for those applicants who cannot pay the necessary fee by some scheme of scholarship fund, provided for by those patrons of the school who are enough interested in boys to take care of them financially while in school. When the boy goes to work the loan can be returned to the scholarship fund or to the one who lends the money.

Work Must be Done in a Commercial Manner to Command Respect.

In order that the trade school shall command respect, it must do work in a commercial manner, which is another way of saying that it must do commercial work, and if it does this, it will be possible to pay wages to the boys. The boys should be paid wages after the trial period, and these wages should be increased regularly according to the ability which each boy shows. It may seem strange to propose a tuition fee and at the same time return it in the form of wages. The tuition fee is a guarantee of business earnestness of the boy, his parent, guardian, or patron. Paying boys a small wage on a rising scale is done simply because we must recognize the moral value which accrues to a young man when he finds that his advancement in his trade is appreciated. It puts a practical aspect on the school's methods, and affords immense satisfaction to the young man when he receives definite compensation for his labor through an advancing scale of wages due to increased efficiency.

There is no one who ought to be more qualified to teach these young mechanics than a competent, practical man. That there would be some difficulty in obtaining such a teacher I will acknowledge, and in itself it forms an argument for the need of trade schools when we are obliged to acknowledge that not even a few men can be founa who are competent to be teachers in a trade school. A successful instructor for a school of this character must be a man of exceptional ability. He not only would be required to know his trade fully, but would have to combine with that knowledge ability as a teacher, tact and diplomacy, which perhaps would fit him for positions paying far higher salaries than would be given to the instructor of a trade school. At all events the instructors will determine the success or failure of these schools.

As the school is to be a trade school and is to teach machine trades, it must for the very sake of this aim make the work of practical character, or, in other words, must make work of a commercial character, of the sort which will take a boy into real commercial life. This involves the turning out of products which will satisfy in points of accuracy and skill the demands of the industry. It means the doing of things according to commercial processes. It means that time and material consumed must be considered. In fact the school must imitate schemes of "works management" in order that the graduate may immediately fit into the economics of shop life. Throughout all the work the students must be taught the economy of material, tool-room methods, shop kinks and cost accounts. Frequent excursions should be made to the neighboring manufacturing establishments.

Lines of Work that a Trade School Can Do.

In order that the school may best illustrate commercial methods it should make things to sell. It is understood that these things are not made merely to sell for the sake of financial return, but to illustrate completely the commercial requirements of a trade. The school can do the following lines of work.

1. The making of some regular line of machinery like a bench grinder, speed lathe, bench lathe, arbor press, etc., which will illustrate to the boys how jigs and fixtures can be used in modern manufacture when a number of machines are turned out at one time. This procedure should serve to keep the shops going at all times regardless of the other lines of order work which might be on hand.

2. The school should also take repair work for small concerns. It can buy up second-hand machinery and repair it. This sort of work gives a splendid opportunity to turn out all-round workmen. It will serve to illustrate re-babbitting, re-surfacing, making of patterns from broken parts, making of castings directly from the iron form, etc.

3. Doing order work in the making of jigs and fixtures for various manufacturing concerns. This special order work can be done by older and brighter boys who understand the reading of drawings and the laying out of the work. It will give them an opportunity to use their ingenuity in discriminating between that work on the jig which must be done very accurately and that which can be slighted without damage to the commercial efficiency of the jig. It will teach the boys how to figure on the cost of jobs, etc.

4. The making of patterns and castings for special orders of outside firms.

There is not a city of any size having machine trade industries which cannot have such a school, providing there are enough resident manufacturers who have an interest in the American boy as well as an interest in the future of American industry, and providing these manufacturers and public spirited men will put their hands down into their pockets and give the money necessary to start the school.

Can such a School be Made Self-supporting?

I suppose the school can never be completely self-supporting, although some men who think they know what they are talking about (and two of them have tried it) say that it can be made self-supporting. Personally, I think it would be well to allow considerable financial leeway. It is not necessary to wait until these interested men can gather up money enough for a fine building. All that is necessary is to lease for a term of years a building suited to the purpose. There are manufacturers of iron working machinery in the country who will be glad to contribute liberally to the equipment. It is not necessary to have a power plant in the building, and thus the cost of an expensive portion of ordinary school equipment can be saved. Purchased electric power will suffice for the first few years. I have estimated that a yearly expense of $20,000 will give instruction to 200 boys in the day school and 275 boys in the night school. This sum includes administrative and teaching force, rent, heat and light, and materials.

Certain features of this school probably prohibit it being, at its inception, a part of the public school system, but some such plan as I have presented can open the way for larger public enterprise.

* * *

A CURIOUS RESULT OF HIGH TARIFF.

A curions aud amusing illustration of the effects of protection, says the *Mechanical Engineer* (London), was afforded a few days ago by a deputation of American watch dealers which waited upon the president of the Board of Trade. It appears, from their statements, that the four great watch manufacturing companies of America are banded together with a view to keep up prices. This, of course, is possible in the United States, with its tariff wall, but in the British market, where the trust has to meet Continental competition, the goods are supplied at much lower prices than those which rule in the United States. As a consequence of this, American retailers have been in the habit of purchasing their supplies of American watches in the British market at an increase of 5 per cent on the invoiced price, and then reshipping them to the United States, where, being of American manufacture, they are not liable to duty. In this way the trust finds itself undercut in its own market by its own goods; and it would appear from the statements of the deputation that the trust is making desperate efforts to prevent this undercutting. British traders are informed that they can only be supplied on condition that they undertake to forfeit £5 if they allow a watch to get into the hands of an American dealer. But it is difficult to see how such efforts can prove effective, or why American dealers should seek assistance in this country (England)!

MAKING SWISS FILES IN AMERICA.—1.*

The plant of the American Swiss File and Tool Co. of Elizabethport, N. J., was described in MACHINERY, April, 1905. In that article the processes used at the time were quite fully described and illustrated. Since then the business has grown rapidly, manufacturing methods have been improved, and a new and enlarged factory has been built. These changes have offered so much new material of interest and value that it has seemed decidedly worth while to describe the plant again, touching lightly on the points fully treated in the previous article, and going more into details on other points.

Most of the tools a machinist or tool-maker uses have nothing of great difficulty or mystery connected with their making. Any good tool-maker, if necessity demands, would feel competent to make for himself a twist drill or a micrometer caliper, even though these tools are seldom made for personal use, but are almost invariably purchased. There is a different feeling in the case of files, however. A good file is treasured by the man who owns it. He looks upon it with friendliness, and respect as well, for while he can buy files by the thousand (good, bad and indifferent) from people who make a business of making them, he would not be able to make one himself. The matter of cutting those fine teeth, so well formed and regular, and yet so delicate as to be in the finer sizes almost invisible, and afterwards the hardening of the tool to the proper degree without injuring the sharpness of these multitudes of little teeth, he feels to be beyond the range of his ability. File makers, in general, have rather catered to this idea of mystery. Their shops are surrounded by high fences and the visitor gets no further than the office. Their catalogues are full of little hints and suggestions of the complicated special machinery used, and the secret and mysterious formulas and processes followed in the annealing and hardening departments.

* The following articles dealing with file manufacture and machinery have previously appeared in MACHINERY: File Cutting Machine, October, 1903, engineering edition; The Making of Fine Toolmakers' Files by American Methods, April, 1905.

In the face of all this mystery, Mr. E. P. Reichhelm determined to embark in the manufacture of files, and not merely in the making of ordinary hand machinists' tools of the coarser grades, but those of finest and most delicate shapes, in which the Swiss makers had hitherto held undisputed preeminence. We have had occasion before now to refer to cases where men have resolutely embarked in work of this mysterious nature with not much more than determination and common sense, and nothing in the way of tradition and prejudice, to guide them. This is still another case in point. While it is not to be supposed that Mr. Reichhelm developed his methods of manufacture full-fledged from the start, and that there is no further improvement possible in his methods, yet he has already succeeded in building up a business which is limited in extent only by his ability to get good workmen, and he is to-day turning out a product which at least equals the best that is produced abroad.

As stated in the previous article, Mr. Reichhelm was led to undertake this business from his previous experience in the hardening and annealing of steel. He is the moving spirit of the American Gas Furnace Co. which has made a specialty of that work for many years, so his experience is a most valuable one. The one point of superiority of European hand-cut files over American machine-cut ones, is in the matter of uniformity in size and sharpness of the teeth; the advantage of the hand-cut file is not due, as many have supposed, to a quite different condition—the irregularity of the spacing. The reason why it is possible, usually, to obtain more regular shaped teeth from hand cutting done by skilled workmen is that, until now, the best methods of annealing with the best and most uniform tool steels produced uneven results. In the machine, whenever the chisel comes to a hard spot, a shallower cut is made; when it comes to a softer spot the cut is deeper, and the tooth sharper. In cutting a file by hand, however, the workman can follow the effect of his chisel, striking it harder in the hard spots, and lighter where the metal is soft. With these conditions understood, it is evident that uniform annealing is the prime requirement for

Fig. 1. Plant of the American Swiss File and Tool Co., Elizabethport, New Jersey.

producing a first-class file of the high grade required by tool-makers and watch-makers. On his skill and experience along this line Mr. Reichhelm based his confidence. The present extent of the business, and the rate at which it is growing, tend to show that his confidence was not misplaced.

The Buildings.

The plant is located on an irregular tract in Elizabethport, N. J., bounded by streets on three sides. The place was specially selected on this account with the idea of having it always open to light and air. As shown in Fig. 1, the main building is two stories in height. Back of this is a one-story building, with a power plant at the eastern end. The lay-out of the departments is shown in Fig. 2. The rough stock is received at the shipping door at the front of the main building, whence it is carried through into the stock and cutting-off rooms in the one-story extension. From here the cut stock is taken to the blacksmith shop, thence to the annealing room, the grinding department, the stripping department and the blank storage, all as indicated in the cut. The teeth are formed by either of the two processes of cutting or etching, as will be described later. The cutting is done downstairs at the north end of the building, while the blanks which are to be etched are taken to the room directly above the cutting department on the second floor. After cutting, they go to the hardening room near the center of the main building, and from there are taken to the packing room directly above. It will be seen from this that there is a complete circuit with no loops or backward movements, from the receiving of the raw material to the delivery of the finished goods. All the rooms are of ample size for an equipment of three times the present capacity, so this increase can be made without disturbing the arrangement shown. Having the general plan of the works thus before us we can follow the process from step to step.

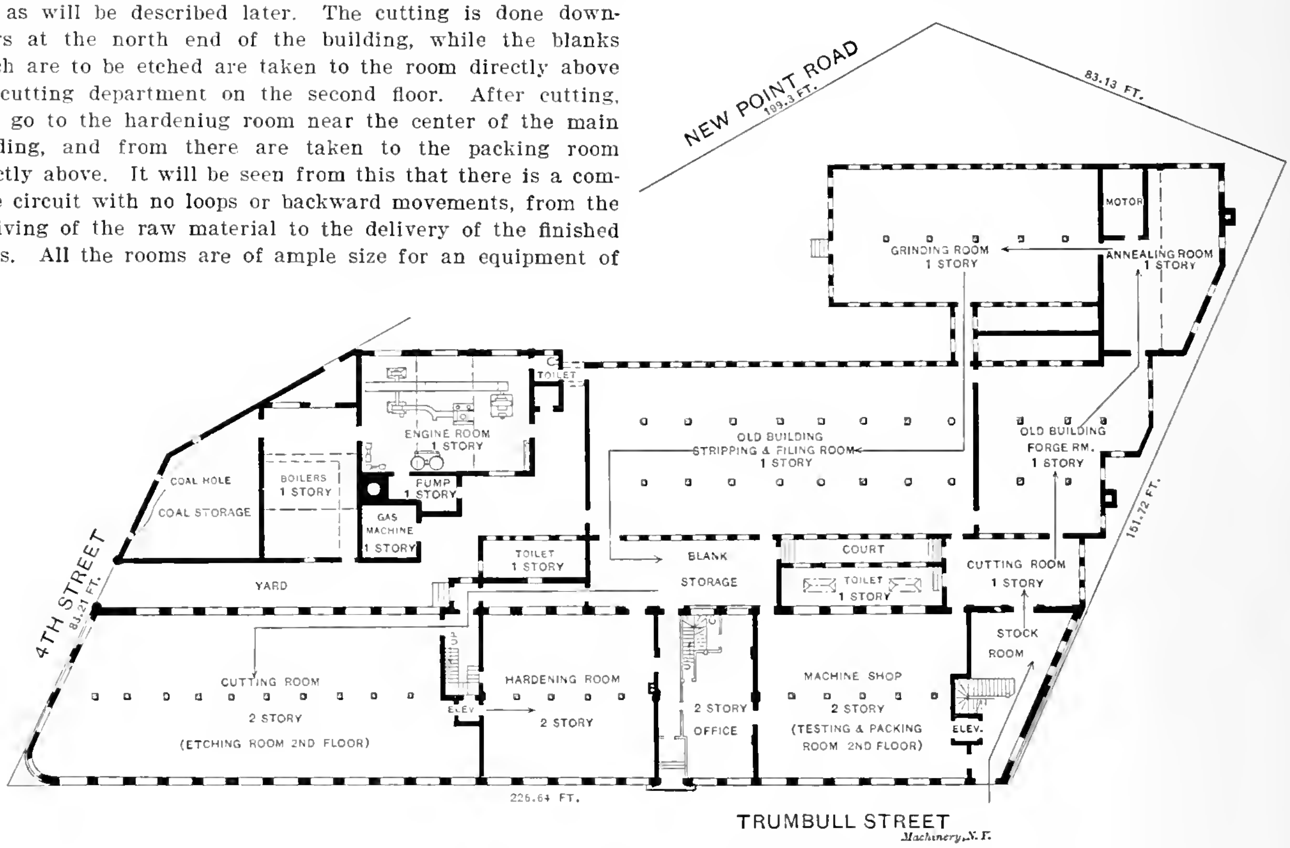

Fig. 2. Plan of the Shops of the American Swiss File and Tool Co., showing Route of the Work.

Blanking and Forging.

The raw material received comes in various forms, generally of the exact shape of the "amid-ships" section of the file. In a few cases sheet stock is used for thin flat files of various forms and uniform thickness. These are punched in blanking dies under a punch press. For half-round, round, square, barrette and other styles, stock of appropriate shape is cut in the shears to the proper length. From here it is taken to the forging department. In this room, aside from the noise which is unescapable where power hammers are used, the thing which first strikes the visitor is the clearness and comparative coolness of the air. There is none of the dust and smoke usually associated with the operation of forges. This, of course, is due to the use of gas furnaces with their smokeless, dustless fuel in the place of the coal forges ordinarily found. A furnace stands at the side of each smith, and a very small and inconspicuous affair it is. A fire-brick lining in an iron casing with four legs to stand on, with piping and burners for gas and air, is all there appears to be to the apparatus. The furnaces are quite small, being only just wide enough for the length of the files being heated. The uniformity of the temperature throughout the whole area of the furnace is remarkable, there being no difference visible to the eye in color anywhere within the heated area. The first operation is the forming of the tang. Then the blanks are reheated, and worked to the proper shape under dies. The face of each die is made in three sections. That on one side of the die is used for breaking down the stock, that on the other side for bringing the edge of the stock to approximately the right dimension, while the central section is used in forming the sides or faces of the blank. The workmen handle these with great rapidity and dexterity, changing the work quickly from one side to the other, and back again to the middle, turning and re-turning the blank until it is formed to the shape determined by the dies. It is impossible to form some shapes correctly under the power hammer. The barrette, and the point of the half round, for instance, have to be finished by drop forging. The former shape of file is struck up from a round blank. The amount of scale found around the hammers and drop presses is very small—an indication of the non-oxidizing quality of the flame in the gas furnace. Each workman has a private supply of cool air from the pressure service which he can direct on himself in whatever way best suits his convenience and comfort.

Annealing.

As stated in the beginning, Mr. Reichhelm considers that the secret of fine file making lies primarily in the matter of annealing. This is the next operation after the forging. One might expect from the importance of this part of the work to find elaborate precautions taken. One would suppose that the blanks would be packed with charcoal in cases having covers luted with fire-clay; such precautions are generally considered necessary to get even heat and freedom from oxidation. Nothing of this kind is seen in Fig. 3, which shows a general view of the annealing room. There are here, as shown, a number of gas furnaces of various sizes. The big ones are for big files, and the little ones, for little files. The blanks are packed in the furnaces, unprotected, exposed to the direct action of the flame. The precaution of packing them with the tangs outward and the points inward is taken, but otherwise the metal is not shielded in any way. The flame is lighted and kept going at a temperature of 1,500

degrees Fahrenheit, for about four hours, ordinarily; then (the doors being carefully closed) the work is allowed to remain over two nights and one day, until it is perfectly cool. There is a very slight, thin scale resulting from this heat treatment, but no pitting or corrosion. What little scale there is comes from air which leaks in during the cooling process, the flame itself being absolutely non-oxidizing. It would be difficult to find a better commercial test of the excellence of the fuel gas process used, than this.

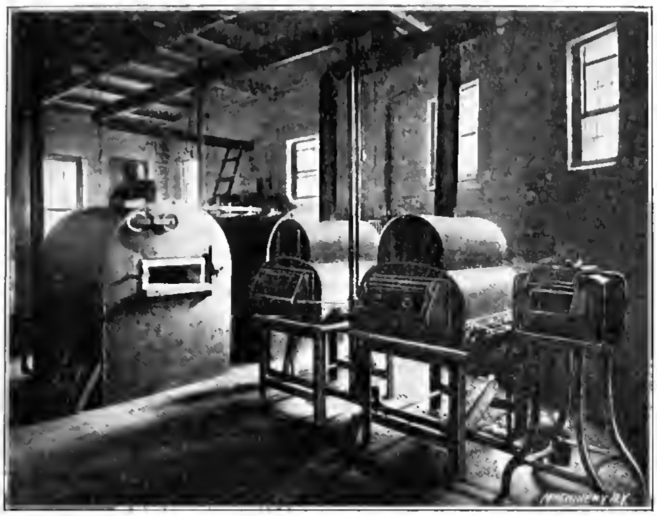

Fig. 3. A View of the Annealing Room.

The uniformity of annealing obtained is the result of the fulfillment of several simple conditions. There must be a constant quality pressure and amount of gas, and a constant pressure and volume of the air mixed with it. With these mixtures determined, the nature of the flame and the temperature will be constant. Too much cannot be said about the composition of the flame. The vaporized naphtha used is free from injurious elements, such as sulphur, and is provided with a slight under supply of oxygen, so that there is no danger of any of that element combining with the metal. The furnace must be so built that the heat is evenly distributed throughout the whole of the interior. The file on the bottom of the pile must be heated under the same conditions as the one at the top. The ends and sides of the furnace must each be subject to exactly the same degree of heat. With these points carefully looked out for, and with the matter of time of exposure to the heat attended to, it only remains to provide the proper steel to be able to get the same results day in and day out, in the annealing of file blanks. For the finest work, Mr. Reichhelm has been unable, sad to say, to find an American steel which will give good results. The best that can be obtained varies in composition and resulting hardness from one bar to another, and from point to point in the same bar. The necessity for uniform hardness in the annealed blank involves in this case the necessity of patronizing a foreign firm instead of a home industry.

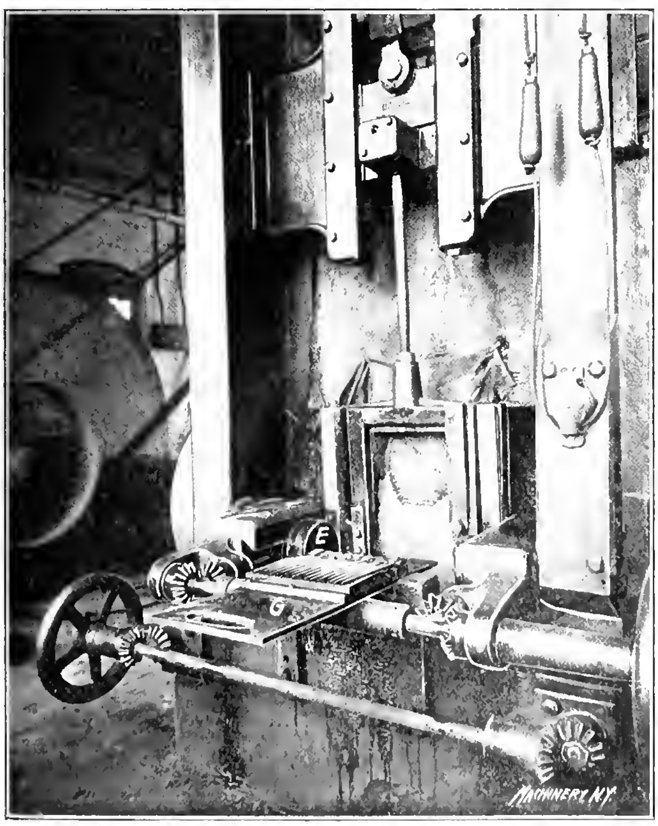

Fig. 4 Machine for Grinding Flat Files.

Grinding and Stripping.

In order to form sharp teeth of uniform height, it is necessary to provide a smooth, even surface to start with. To produce this surface the blanks are first ground and then draw filed or "stripped." The files with flat cutting surfaces have them ground on automatic machines. A near view of one of these machines is shown in Fig. 4. At *B* is a grindstone of large diameter, revolved at suitable speed and traversed slowly back and forth by a cam, to equalize the work across its face. The files, shown at *A*, are ranged in a row, with suitable backing and supports, on the flat plate or holder *G*. This frame or holder is dropped in a vertical position in slide *D*, and pressed up against the face of the revolving grindstone *B* by the rollers *E* and the adjusting screws operating them. The mechanism which reciprocates slide *D* up and down, so that the blanks are ground from one end to the other, is then started. In the machine shown this motion is operated by an adjustable crank at the top of the machine, connected to crosshead *C*. The matter of grinding a frame full of blanks is one of a few strokes and a few seconds only. The wheels used are five or six feet in diameter, and means are provided in the machine for keeping them constantly trued.

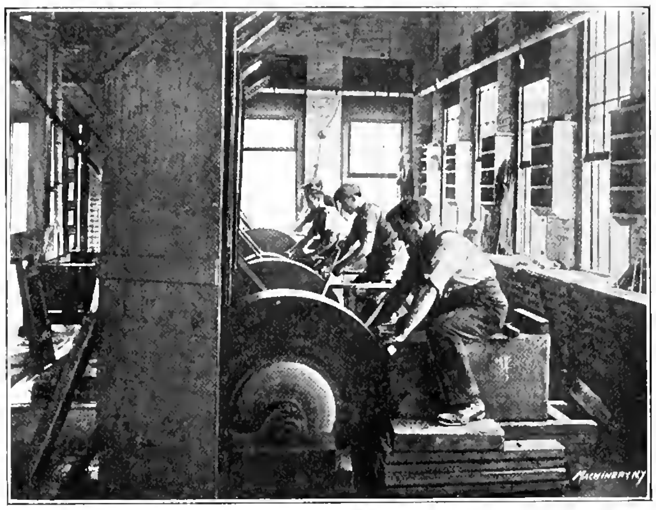

Fig. 5. Grinding Round File Surfaces by Hand.

This machine grinding is done on flat surfaces only. On round surfaces the grinding is done by hand. In Fig. 5 may be seen workmen engaged in this operation. Most of them are working on half-round files. As may be seen, they are sitting on wooden blocks in front of large grindstones, all except the man in the foreground, being astride of a board with a steel hook or holder on the end of it, which holds the work down to the wheel. The weight of the workman thus furnishes the pressure needed for grinding. The smallest and finest files, whether flat or round, are ground by hand on carefully trued wet emery wheels.

The surface produced by this grinding is not quite good enough for the purpose desired, so the finishing touches are given by draw filing or "stripping." Both flat and round surfaces are finished in this way, and all burrs are removed from edges and corners. The men work at benches, with the blanks supported by their ends in wooden blocks. For stripping flat surfaces, a new machine has recently been introduced. One of these is shown in Fig. 6. The blanks, *B*, are held in suitable holders. These holders are pressed upward

by levers and weights against the cutting files E in slide D. This slide is moved in and out for the stroke, being carried by saddle G, which slides along ways on the under side of overhanging arms $H H$. It is also traversed back and forth to distribute the action over the full length of the cutting files by a drunken screw at F. The work is relieved from contact with the files on the back stroke. It might be expected that it would be a matter of some difficulty to avoid "pinning" in a case of this sort. This is not often met with, however. In the first place the files are made specially for the purpose, with plenty of clearance. Besides this, the pressure on the work is unvariable, being determined by the weights and levers mentioned. A workman, even though expert, might momentarily use more pressure than he ought to on his file, so as to cause it to tear the steel and get the broken particles wedged or "pinned" in the teeth. With a machine, having once found the conditions necessary to avoid this trouble, these conditions may be preserved indefinitely, and the trouble practically avoided. When it does occur, perhaps once a day, the blank thus injured has to be reground and refiled.

Flat files are ground and stripped on all of their cutting surfaces before going to the cutting department. On files having sharp edges, however, such as half-round, barrette, and other shapes, this course is not followed. On a half-round file,

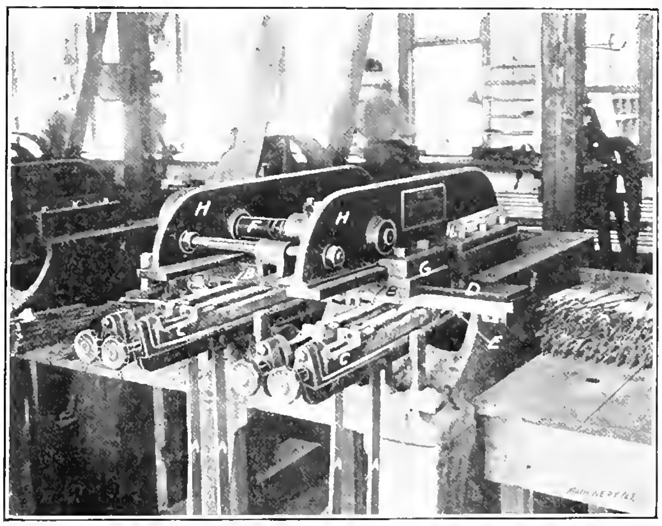

Fig. 6. Stripping Machine for Draw Filing the Blanks.

for instance, the flat surface is stripped; then the first cut is taken over it, and it is returned to the stripping room to have the round surface finished, which then, in turn, is treated with the first cutting; after this the second cut is given to the flat side, and then to the round side. This working first on one side and then on the other, on a blank having sharp edges, is necessary to keep the teeth perfect in shape clear out to the edge. If one side were finished completely before the other was touched, the edges would be turned over, away from the surface last finished, making a sharp burr on the side which was cut first.

After the blanks have been stripped, they are taken to the blank storage, awaiting their turn at the cutting machines. The cutting of the teeth and the hardening of the file will be described in a succeeding installment of this article.

* * *

USING A CANNON FOR DISSOCIATING A SHRINK FIT.

A contributor to the *National Engineer* of May, 1907, describes a device which is well known and much used in railroad shops. Machinists in other lines, however, are probably not so familiar with it. This device is a cannon which is used as a sort of desperate remedy, when everything else has failed, for knocking out crank-pins, axles, and other shrunk and rusted joints. It is somewhat dangerous to use, so should not be ordinarily employed.

The writer referred to says in substance: "On a recent visit to the plant of the Kittaning Iron & Steel Co., I witnessed a novel method for removing broken crank-pins from crank disks. A crank-pin 8 inches in diameter had broken off close to the crank disk, and several men had spent considerable time in a futile effort to drive out the remaining part of the broken pin. Finally the chief engineer ordered one of the men to bring in the cannon. It was made, as shown in Fig. 1, of a piece of steel with a 2-inch hole bored in it longitudinally. A ¼-inch hole for the fuse and a 2-inch hole for the escape of the gases of combustion after they had completed their work, were drilled in from the sides as shown, to meet the center hole of the device.

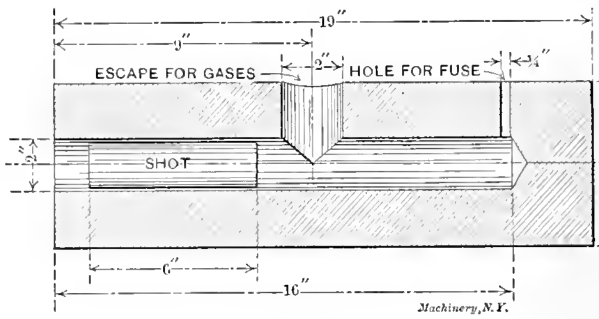

Fig. 1. Cannon for Machine Shop Use.

"The cannon was loaded with about ½ pound of giant powder. A piece of 2-inch case-hardened steel called the 'shot' was inserted in the opening, and all was firmly chained to the disk, as shown in Fig. 2, with the opening of the cannon directly over the crank-pin. A fuse was inserted in the small opening, and ignited. All hands then sought places of safety. A heavy explosion soon followed, after which an examination showed that the pin was still intact in the disk, notwithstanding that the shot had embedded itself in the pin ¼ inch. The cannon was again loaded, fastened in position, and fired, which loosened the pin so that a few blows from a heavy hammer drove it out of the disk.

"When the cannon was fired, the smoke and flame caused by the explosion followed the shot until the latter passed the 2-inch opening on top, through which they escaped to the atmosphere.

"The engineer informed the writer that the cannon had been in use over a year, and that during that time it had been used over sixty times for removing keys, pins, etc., without an accident, except on one occasion. On this occasion the fuse hole was by mistake turned toward a window, and the resulting concussion destroyed the glass and sash of the latter.

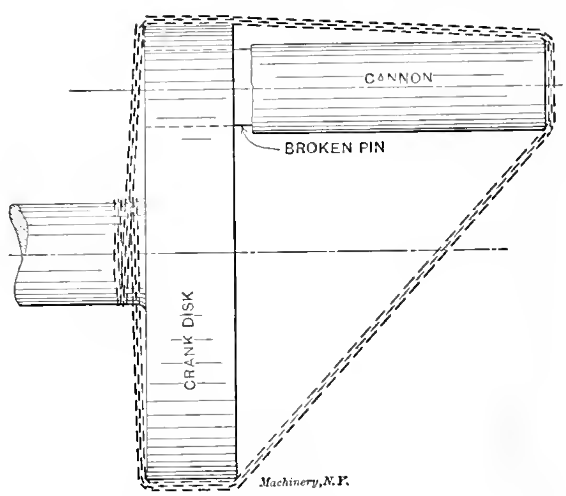

Fig. 2. Cannon Charged and Aimed, ready for Firing.

When the shot was first made, it was only hardened for about two inches of its length. The result was that the impact of its striking the object to be removed, enlarged its diameter so that it stuck in the bore of the cannon and had to be bored out."

* * *

One of the causes of a serious less in the transmission of compressed air is pumping the air of the engine room rather than air drawn from a cooler place. This loss amounts to from 2 to 10 per cent.

METHODS OF DELICATE TURNING.

There are some kinds of work that do not come up in the ordinary run of business, but which are met with occasionally, and are liable to give considerable concern when they do appear. It is not often, for instance, that one has to turn a 3/16 inch steel rod 26 inches long down to a diameter of 1/16 of an inch. This delicate operation may be performed easily when called for, if it is gone about in the right way. *Engineering*, of London, in the June 7, 1907 issue, contains a description of the way in which an Englishman, Mr. Henry Lea, of Birmingham, performed this operation. The stock, which is of mild steel 3/16 inch diameter as stated, was placed in a $5\frac{1}{2}$-inch (11-inch swing) lathe, one end being caught in a chuck on the spindle, and the other supported by the tail-center. It is necessary of course to use a follow-rest to do turning of any kind with such slender work. The follow-rest used is shown in Fig. 1. It is composed of a bracket *A* fastened to the rear of the carriage. This bracket carries a vertical slider *B*, which again carries a horizontal slider or steady plate *C*, which is hardened and has notches in the four corners, of sizes to suit rods of different diameters. The bolt *D* locks plates *B* and *C* to the bracket. *E* is an arm pivoted at *F*, and provided with a coiled spring *G*, the effect of which is to press the nose *H* against the under side of the revolving rod in a slightly inclined direction, as shown by the arrow, thus keeping the revolving rod in contact with the two sides of the notch in plate *C*.

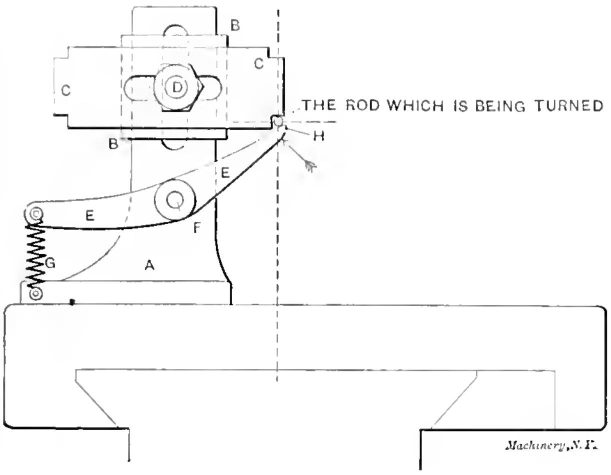

Fig. 1. Follow-rest for Delicate Turning.

A portion of the rod next the chuck was turned true, and the steady was adjusted to it. The turning tool (Fig. 2) is a very keen side-tool, facing away from the chuck, and its cutting edge was normal to the axis of the rod, so that the tool had no tendency either to force the rod inwards or to draw it outwards. The point of the tool was set about 0.02 inch in advance of the steady plate. The speed and feed were about 250 revolutions per minute and 180 turns per inch of travel. Oil was kept dropping on the point of the tool. The first few cuts were about 0.002 inch deep; the final cuts were 0.0005 inch each.

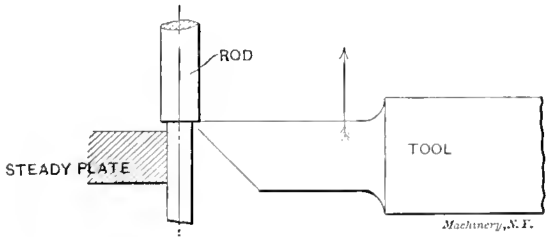

Fig. 2. Setting of Tool and Steady Plate.

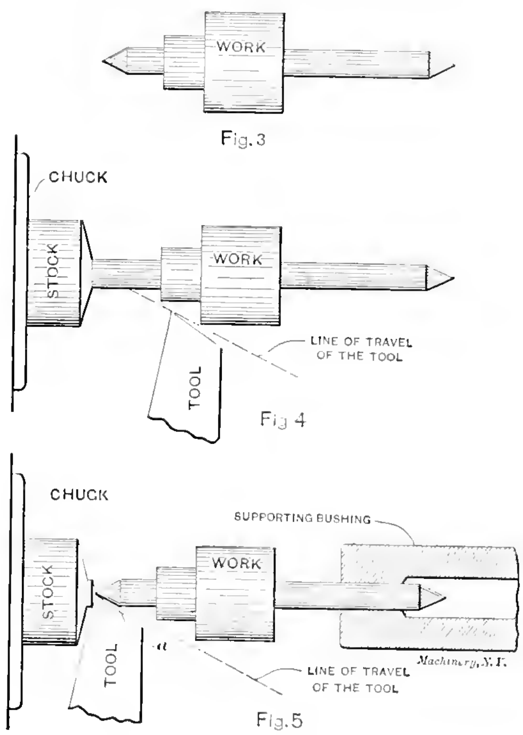
It is most important in work of this kind that the cut should be taken in a direction away from the chuck, and that the pressure of the tail-center be so light as not to bend the rod by end compression. As the work proceeds, the rod becomes so slender that the steadying effect of the tail-center is practically nil, and two loose wooden supports standing on the lathe-bed were used instead, having V-notches for the rod to revolve in. As the saddle receded from the chuck, one, and then both, of the supports were transferred to the left-hand side of the saddle, so as to support the portion already turned. The time required for each cut was $12\frac{1}{2}$ minutes. The first one or two cuts removing the skin left the rod rather crooked, but it became more and more straight after each succeeding cut, and the last cut left it practically straight.

There is another delicate lathe operation of a different kind which is well known to clock and watch tool-makers, though perhaps not to machinists engaged in heavier work. Supposing it were required to finish complete from the bar in one chucking a small pinion blank, such as shown in Fig. 3. It is apparent, after looking the piece over, that the only difficulty in making it thus, lies in getting a sharp point where the bearings are, on each end of the piece. It will at once be seen that the end next to the solid bar from which the piece is formed will break off, under the pressure of the cut used in forming and separating this end, a considerable time before the tool point has reached the center, thus leaving a blunt, ragged pivot where a sharp, smoothly finished one is desired.

The way in which this operation is performed is shown in Figs. 4 and 5. The work is cut off, and the point shaped in such a way that the entire pressure of the cut comes on the bar of stock held in the chuck, and none of it on the work. The outer end of the work is held in a supporting bushing in the lathe or screw machine in which the work is being done. A tool of the shape shown is used for severing the work from the bar. This tool, it will be noticed, is not fed straight in, but is moved in on an angle that will form the pivot to the right shape. Face *a* is beveled so that it clears the work entirely. The point is quite sharp. The cutting action is thus entirely on the face of the stock, and the work is not subject to any pressure whatsoever. Being supported by the bushing in the rear, even the weight of the piece has no tendency to sever it before it is cut away by the tool, and when it is finally separated it is still supported in the same position as before the separation took place. This method of doing the work saves the separate operation which would otherwise be necessary for pointing the pivot at the end where it was severed from the bar.



Figs. 3, 4 and 5. Finishing a Pivot at the End where it is Cut from the Bar.

* * *

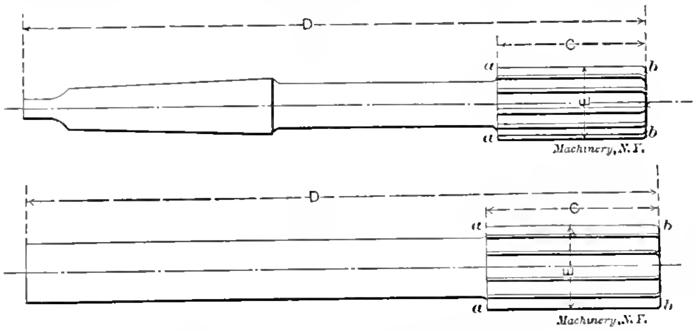
The *Brass World* calls attention to the fact that too much phosphorus in a phosphor-bronze bearing causes the tin to liquidate in the form of "tin-spots," which are nearly as hard as steel. Such "tin-spots" cut the axle and cause the bearing to heat.

REAMERS.—2.

ERIK OBERG.

Fluted Chucking Reamers.

Fluted chucking reamers are used in machines for enlarging holes as well as for finishing them smooth and true to size. These reamers are usually provided with either straight or standard taper shanks, as shown in Figs. 6 and 7. They are not intended for removing a large amount of stock, 0.005 to 0.010 inch being all that should be required. The cutting edges are along the lines *a b*. At the front end of the reamer there is a slight round as shown at *b*. It is a well known occurrence that reamers held rigidly at the end of the shank are liable to cut holes somewhat larger in diameter than their own size. In cases where a very accurate hole is desired, reamers used for chucking purposes should therefore be somewhat smaller than the final size of the hole to be reamed, be



Figs. 6 and 7. Fluted Chucking Reamers.

held in a floating reamer holder, and after having reamed the hole by a chucking reamer, it should be finished by a hand reamer.

Number of Flutes.

The number of flutes with which fluted chucking reamers should be provided is given in Table IV. It will be noticed that the pitch of the cutting edges, or the distance from cutting edge to cutting edge, is in some cases a trifle smaller than in the case of hand reamers. The same fluting cutters as are used for hand reamers are used for fluted chucking reamers also. The radii of the small rounded corners at the end of the flutes at *b*, Figs. 6 and 7, should be 1/32 inch for sizes up to and including ¾ inch diameter, and 1/16 inch for larger sizes.

TABLE IV. NUMBER OF FLUTES IN FLUTED CHUCKING REAMERS.

Size of Reamer.	Number of Flutes.	Size of Reamer.	Number of Flutes.	Size of Reamer.	Number of Flutes.
1/8	6	7/8	8	1 3/4	12
1/4	6	1	8	2	12
3/8	6	1 1/8	10	2 1/4	14
1/2	6	1 1/4	10	2 1/2	14
5/8	8	1 3/8	10	2 3/4	16
3/4	8	1 1/2	10	3	16

TABLE V. NUMBER OF MORSE TAPER SHANKS FOR FLUTED CHUCKING REAMERS.

No of Morse Taper Shank.	Sizes of Reamers, inches.	No. of Morse Taper Shank.	Sizes of Reamers, inches.
1	1/8 — 1/2	4	1 9/32 — 1 3/4
2	17/32 — 7/8	5	1 25/32 — 3
3	29/32 — 1 1/4	..	....

Dimensions of Fluted Chucking Reamers.

The principal dimensions of consequence are the over-all length and the length of the cutting portion of the reamer, denoted *C* and *D*, respectively, in Figs. 6 and 7. The over-all length of the straight shank and the tapered shank chucking reamer are usually made the same. The Morse standard taper shank is nearly always used on this class of reamer. The sizes of reamers and the corresponding Morse taper shanks with which they are provided are given in Table V.

The length of the cutting edges *C* and the total length *D* may be determined from the formulas

$$C = E + \tfrac{3}{4} \text{ inch, and}$$
$$D = 4E + 4 \text{ inches,}$$

in which formulas *E* denotes the diameter of the reamer. Dimensions figured from these formulas are given in Table VI.

The diameter of the neck between the fluted part of the reamer and the taper shank, Fig. 7, should be about 1/32 inch smaller than either the diameter of the reamer, or the diameter at the large end of the shank, depending upon which of these two diameters is the smaller, so that the grinding wheel will clear the necked portion both when the reamer part and the shank part are ground.

The diameter of the straight shank should be from 1/16 to ¼ inch below the size of the reamer for sizes up to 1½ inch diameter. For larger sizes the shank may be proportionally smaller, so that the shank for a 2-inch reamer is 1½ inch, and for a 3-inch reamer, 1¾ inch.

Rose Chucking Reamers.

The rose chucking reamer is not intended for finishing holes smoothly or true to size, but is merely used for enlarging cored holes, and is so constructed as to enable the removal of a considerable amount of stock. As shown in Fig. 8, the cutting edges are beveled to a 45-degree angle at the end of the reamer. The teeth are cut on the end only, so as to give a cutting edge to this 45-degree bevel. At every other cutting tooth there is a groove cut the full length of the reamer body. This groove serves the purpose of providing a way for the chips to escape, and forms a channel for lubricants to reach the cutting edges. The groove, however, does not provide for any cutting edge on the cylindrical part of the reamer.

Formerly rose reamers were often made without these

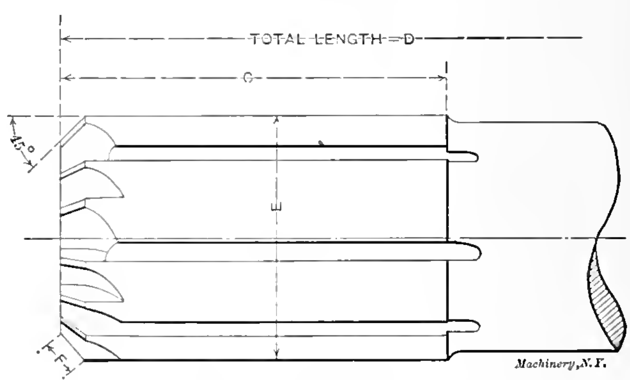


Fig. 8. Rose Chucking Reamer.

grooves; the body of the reamer was solid with the exception of the cuts made to form the teeth at the end, but this construction caused a great deal of trouble on account of the reamer binding in the hole to be reamed. The binding effect is overcome by cutting the grooves for every other tooth, as mentioned. In fact, there is no reason why this groove should not be cut for every tooth, excepting that it would increase the cost of making the tool, and not being imperative, this cost is, of course, properly avoided.

Rose chucking reamers are slightly back tapered on the cylindrical body, that is, the diameter at the point with the beveled cutting edges is slightly larger than the body where it joins the shank. This provision also aids to prevent the tool from binding, in the hole being reamed. The back taper ought properly not to exceed 0.0005 inch per one inch, although it is usual in the manufacture of these reamers to make this taper as much as 0.001 inch per inch.

The length of the beveled edge *F*, Fig. 8, should increase with the diameter of the reamer. The length of this bevel for different sizes of reamers is given in Table VII.

The rose chucking reamer will produce holes slightly larger in diameter than the actual size of the reamer, and for this reason this tool should always be made from 0.005 to 0.010 inch smaller in diameter than the finished size, and should be followed, when in use, by a fluted reamer for finishing. For enlarging cored holes, however, these reamers are of great advantage, firstly, because they are able to take a heavy cut, and secondly because they will cut a hole that is more nearly parallel or straight than will a fluted reamer, particularly if there are blow-holes or hard spots in the walls of the surface being worked upon.

Fluting Rose Reamers.

The grooves with which rose reamers are provided along their cylindrical surface, not being intended to produce cutting edges, are not of the same shape as those cut in fluted reamers. A convex cutter, having a width equal to from one-fifth to one-fourth the diameter of the rose reamer itself, should be used for cutting the groove. The depth of the groove should be from one-eighth to one-sixth the diameter of the reamer. The cylindrical part of the reamer between the grooves should not be relieved, but should be left circular.

TABLE VI. DIMENSIONS OF FLUTED CHUCKING REAMERS.

Diameter of Reamer.	Length of Flute.	Total Length.	Diameter of Reamer.	Length of Flute.	Total Length.

$1\frac{1}{4}$	2	10	..	..	..

Rose reamers smaller than ¼ inch in diameter may be made without grooves, but in such a case they should have only three teeth on the end, and fairly deep cuts between the teeth to take care of the chips. The best practice is, however, to provide rose reamers of all sizes with grooves on the cylindrical part.

The number of cutting edges on the 45-degree beveled end of the reamer are made according to the figures given in Table VIII. The number of grooves is evidently equal to half tne number of cutting edges, there being one groove on the cylindrical part for every second cut at the end. The cuts at the end are milled with a 75-degree angular cutter. The width of the land at the cutting edge should be about one-fifth the distance from tooth to tooth. If an angular cutter is preferred, rather than a convex, for cutting the grooves on the cylindrical surface, because of the higher cutting speed permissible when milling the grooves, an 80-degree angular cutter, with a slight round at the point, may be used.

$\frac{5}{8}$	8	$1\frac{3}{8}$	10	$2\frac{3}{4}$	16
$\frac{3}{4}$	8	$1\frac{1}{2}$	10	3	16

Dimensions.

Rose chucking reamers are, like fluted chucking reamers, made with both straight and taper shanks. The same dimensions for the total length as were given for the fluted reamers apply to the rose reamers also, but the length of the grooved portion of the reamer, or the body, is longer. If E is the diameter of the reamer, and C the length of the grooved part (see Fig. 8), then

$$C = \frac{3E}{2} + 1\frac{1}{8} \text{ inch.}$$

In Table IX are given the dimensions for rose chucking reamers in accordance with this formula. What was said in regard to the straight and taper shank of these reamers, and the diameter of the neck in the latter class, in connection with fluted chucking reamers, applies to rose reamers also.

Principles of Grinding Reamers.

When grinding reamers, whether they be given an eccentric or flat relief, it is necessary to rest the face of the tooth being ground against a guide finger which can be adjusted to give any desired amount of clearance.

TABLE IX. DIMENSIONS OF ROSE CHUCKING REAMERS.

Diameter of Reamer.	Length of Body.	Diameter of Reamer.	Length of Body.	Diameter of Reamer.	Length of Body.
E	C	E	C	E	C
$\frac{1}{4}$	$1\frac{1}{2}$	$\frac{7}{8}$	$2\frac{7}{16}$	2	$4\frac{1}{8}$
$\frac{5}{16}$	$1\frac{5}{8}$	1	$2\frac{5}{8}$	$2\frac{1}{8}$	$4\frac{5}{16}$
$\frac{3}{8}$	$1\frac{11}{16}$	$1\frac{1}{8}$	$2\frac{13}{16}$	$2\frac{1}{4}$	$4\frac{1}{2}$
$\frac{7}{16}$	$1\frac{3}{4}$	$1\frac{1}{4}$	3	$2\frac{3}{8}$	$4\frac{11}{16}$
$\frac{1}{2}$	$1\frac{7}{8}$	$1\frac{3}{8}$	$3\frac{3}{16}$	$2\frac{1}{2}$	$4\frac{7}{8}$
$\frac{9}{16}$	2	$1\frac{1}{2}$	$3\frac{3}{8}$	$2\frac{5}{8}$	$5\frac{1}{16}$
$\frac{5}{8}$	$2\frac{1}{16}$	$1\frac{5}{8}$	$3\frac{9}{16}$	$2\frac{3}{4}$	$5\frac{1}{4}$
$\frac{11}{16}$	$2\frac{1}{8}$	$1\frac{3}{4}$	$3\frac{3}{4}$	$2\frac{7}{8}$	$5\frac{7}{16}$
$\frac{3}{4}$	$2\frac{1}{4}$	$1\frac{7}{8}$	$3\frac{15}{16}$	3	$5\frac{5}{8}$

Fig. 9 shows an end view of a reamer being ground. A represents the emery wheel, which should run in the direction of the arrow, so that the tooth of the reamer may be pressed down on the finger B. If the wheel were running in the opposite direction, it would have a tendency to pull the tooth of the reamer away from the guide finger; the cutting edge of the tooth would then be ground away, and the reamer would be spoiled. It is claimed that when using a dry grinder, that is, one where water is not used on the emery wheel, the danger of heating the tooth and drawing the temper is greater when the wheel is run in the direction shown in Fig. 9; but if the face of the wheel is kept free from glaze, and ordinary care is exercised, there is little danger of drawing the temper, provided a cutting wheel that is not too fine is used. In order to give the tooth the proper clearance, the guide finger is adjusted to bring the cutting edge below the center line. It should not be attempted to remove too great an amount of stock at one cut; it is better to take a number of successive cuts, going around the reamer several times.

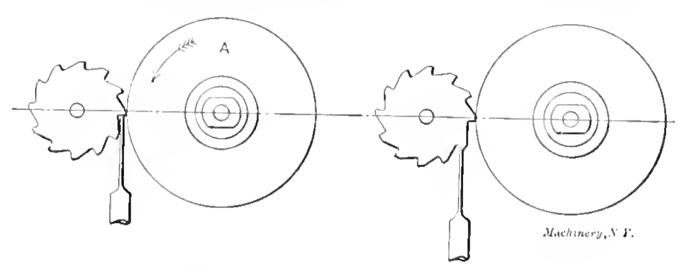

Fig. 9. Fig. 10.

When grinding reamers it is absolutely necessary to rest the face of the tooth being ground on the guide finger, otherwise the teeth, particularly when irregularly spaced, would not be ground with an equal amount of clearance, nor would all the cutting edges be at an equal distance from the center line of the reamer, and some of the teeth, consequently, would not cut when such reamers were used. Figs. 9 and 10 show, respectively, the correct and incorrect way of applying the guide finger, it being, in Fig. 10 applied to the tooth nearest below the cutting edge being ground.

Care should be taken not to give the cutting edge of a reamer any more clearance than is necessary to permit it to cut freely. Too much clearance produces a weak edge which is liable to chatter, and the reamer soon loses its size.

CREAM SEPARATOR BOWL BALANCING.*

YANKEE.

The balancing of cream separator bowls is the art of poising the rotating part or bowl so that it will run to full speed or beyond without producing any perceptible vibration in any part of the machine at any period of acceleration or falling off of speed. It is usually done by means of weights soldered in place on the bowl, or on the skimming device, and suitably distributed. A perfectly balanced bowl is one that answers the above definition, but practically slight vibrations are expected, and whatever the balancer is unable to overcome, is taken care of by using a spring bearing directly underneath the bowl. One design of this bearing is shown at the right, upper part of Fig. 1. In this design the springs are three in number and are placed in holes drilled in G. The proper pressure is applied by screws H.

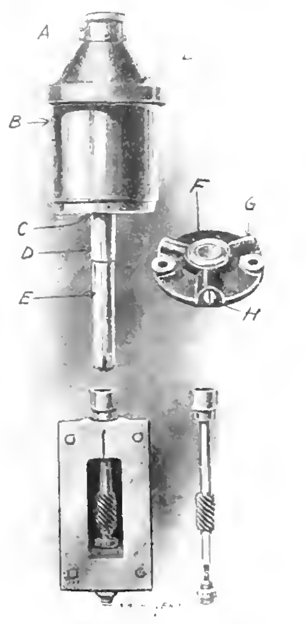

Fig. 1. Cream Separator Bowl and Stem or Spindle.

The balancing is done as follows. After mounting the bowl in a suitable frame, it is brought up to full speed, preferably by a rope drive, thereby avoiding the vibrations that result from the use of leather belting or gears. A soft blue pencil is held in a horizontal position and the bowl is marked at point B, Fig. 1. The spindle is marked at D, both over and under the spring bearing; it is also marked again at E.

The blue lines will show on the bowl on the lighter side and on the spindle at points D and E on the heavy side. The lines on the spindle at D and E should be directly in line with each other. When otherwise, it is a sure indication that the machinist did a poor job on this part. Imperfect spindles must be corrected before proceeding further.

Fig. 2 represents the top view of the spindle and bowl shell. We will now suppose that a line extends from 1 to 13 on the bowl shell at point B, and from 3 to 7 on the spindle at the points D and E. Draw a vertical line on the bowl shell directly above the center of the lines on the spindle. This is done merely to make it easier for the balancer to locate the proper place for the weight. After locating the point at about 16, melt in the bowl head on the same side, at about the point L, an amount of solder that is thought sufficient to bring the bowl shell up. This amount is arrived at by the cut-and-try method, and can only be guessed at by the balancer who judges the amount required by the noise of the bowl when running and the length of the line obtained. The size of the balancing weights required may range from a pinhead to that of a marble.

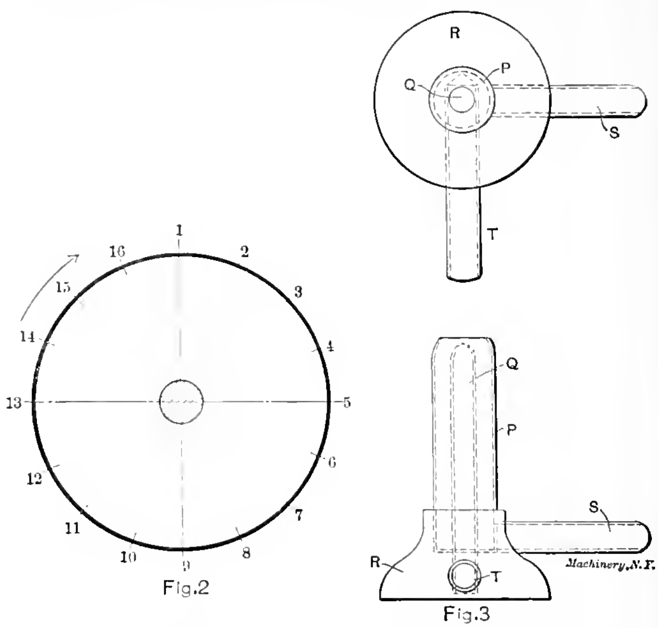
On the spindle we locate a point opposite, about 1 or 2 inches in advance or to the left of the line marked on the bowl above the center of the line on the spindle, which in this case would come at about 16. The bowl revolves, of course, in the direction of the arrow. The necessary amount of solder for this case is melted inside the bowl where it makes a joint with the bottom. All this work should be done neatly so that it is not readily noticeable by the purchaser, and also to facilitate cleaning.

Another case of a defective balance met with is as follows: Sometimes the blue-pencil lines on the bowl are directly above the lines on the spindle. In this case we put the weight in the top only and above the center of the lines. If the spindle should run very "rough" we work as described in the first case. A bowl very nearly balanced will finish up nicely and easily when showing such marks.

Still another case may be the condition in which we find the spindle when the top is not out very much, or the right end of the lines on the spindle falls under the left end of the bowl lines. All that is required in a case of this kind, usually, is to throw the weight in the bottom of the bowl slightly to the right, being governed by the amount the bowl is out of balance.

The reason that a bowl shows marks on the light side is that the axis of gyration lies between the axis of the bowl and the heavy side. This, then, makes the light side eccentric and causes it to describe a circle of a longer radius than the heavy side, hence it touches the pencil point first. The bowl being above the spindle is in a measure free to move as the forces direct, but being confined in the bearings the condition is exactly opposite. To insure perfect alignment between the bowl and spindle, revolve the bowl slightly and mark a line on same at point B. If this line does not extend entirely around the bowl, or should the bowl, as is many times the case, be more or less oval in shape, and the broken lines are not directly opposite, place a calking chisel in the fillet between the bowl and spindle and directly under the center of the lines on the bowl. Give the chisel a blow with the hammer according to the degree that the bowl is out. The chisel should be ground the same as the radius of the fillet, so as not to mar the spindle more than necessary. Repeat the operation, if required, until the alignment is perfect, as this condition is very important. Unless the alignment is perfect the bowl will shake badly when running up to speed.

A Bunsen burner for melting in the solder can be made as follows: Referring to Fig. 3, R represents a base, about 2 inches diameter. The air inlet T is about 3/8 inch diameter, and the gas inlet S is of the same diameter. The tubes Q, about 1/4 inch diameter, and P, about 5/8 inch inside diameter, are connected as follows: Q is connected with T, and P with S. Tube P is drawn in slightly at the top so as to throw the gas toward the center. Tube Q is drawn in at the top until the outlet is about the size of a common pin. The top of this tube must not extend above the top of P.



Figs. 2 and 3. Plan View of Bowl, and Bunsen Burner.

A soldering fluid which is stainless and which enables the bowl balancer to make the soldered weights flow nicely should be used. In case it is desired to place the weights in the bowl without soldering, melt about 4 ounces of resin and pour in about three teaspoonfuls of red oil. After cooling, this composition will never harden. It is superior to putty.

The above-mentioned cases are not all of the conditions that a separator bowl balancer has to meet, but they are sufficient for a beginner to contend with, and it is practically certain that if he learns to handle these cases well, he can become a first-class balancer.

LAYING OUT A PROPELLER.*

J. S. WATTS.†

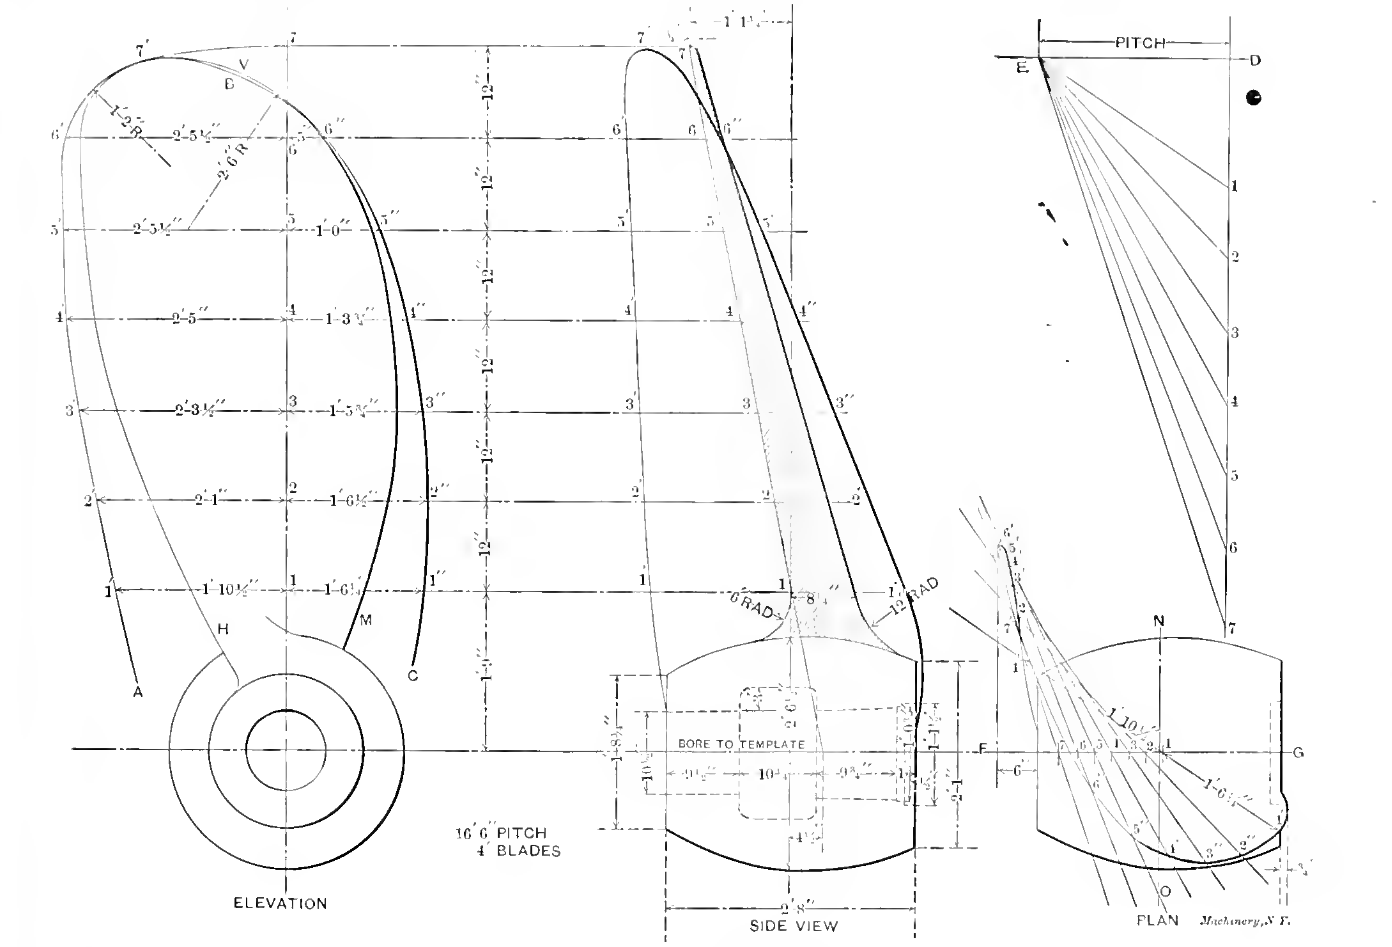
The making of a working drawing of a propeller is a problem that seems to be neglected by all technical works which the writer has had access to, and there are very few draftsmen who can successfully cope with it. The following method, while only one of the many ways in which it can be solved, may therefore be useful and interesting to many.

Formulas for finding the diameter, pitch, and surfaces required for any given horse-power and model of ship can be found in most books on marine engineering, and we will assume these dimensions of the propeller to have been fixed. The propeller shown in the cut is 15 feet 6 inches diameter, 16 feet 6 inches pitch, and 86 square feet developed surface of blades. The pitch is, of course, the amount the blade would advance in one revolution if it were made continuous around the shaft, similar to the thread of a screw. The surface is the total surface of the four blades flattened out or developed as shown in the elevation by the line *A B C*.

We will start by drawing in the boss in the elevation. The proportions can be found in any marine engineering book. Then draw an arc of a circle equal to the diameter of the propeller. Now we can sketch in by free hand the blade laid out flat on the sheet, or, in other words, a development of the blade to about what we think will give us the right area, that is, in a four-bladed propeller one-fourth of the total surface required. Then, by trial with a planimeter, and adding to or cutting off as required, we finally arrive at the correct area and shape of blade, keeping in mind that this is not a true view of the blade as seen in elevation, but is a development of the blade. The shape of the blade is largely a matter of experience and varies for different models of boats. Every designer, in fact, has his own peculiar shape, and the variety of the forms of blades on equally efficient propellers would seem to show that, within certain limits, it is not a matter of vital importance, so long as the pitch, diameter and area are correct.

We will assume that the development of the blade, as shown by the line *A B C* in the elevation, fills all the requirements, and we are to proceed to lay out the true elevation, side view, and plan view of the blade. First, on the development of the blade fill in dimensions at every 12 inches by scaling the drawing. Then draw out the blade in section, showing the droop which it is desired to have. This dimension is, like the shape of blade, a matter of controversy, varying from about 1½ inch per foot of diameter aft to about the same amount forward. The plan view of the blade can now be drawn; lay off the boss, and mark, on the center line of the boss, the positions of the center line of the blade at each 12-inch line as at 7, 6, 5, etc., taking the distance from center line of boss from the side view.

Now we must find the angles at which the blade must stand to the vertical center line to give the required pitch. To arrive at this we lay off a vertical line *D*-7 equal in length to the circumference of the circle on which point 7 is located



Layout of a Large Propeller.

in the elevation, and a horizontal line equal to the pitch, making this figure to any convenient scale as shown. From point *D* measure off points 1, 2, 3, etc., equal to the circumferences of the circles which these numbers represent on the elevation, that is, in this case, the circumference of a 42-inch diameter circle to be the distance from *D* to 1, of a 66-inch circle to point 2, and so on. Now join these points to the other end of the line representing the pitch, and we have the angles of the blade at each of the seven points. This will be evident, if one remembers that the figure just made is a development of the thread of which the blade is a part, or, in other words, that while the propeller makes one revolution, that is, travels through one circumference (which at point 1 equals the distance from *D* to 1; at point 2, equals distance from *D* to 2, etc.), the points 1, 2, 3, etc., on the blade advance an amount equal to the pitch. This figure is generally drawn on the plan view to save trouble in transposing the angles from one view to another, but it shows the idea clearer to have the views separated in this way.

Now draw a line parallel to *E*-7 through point 7 in plan

* The following articles dealing with the design and making of propellers have previously appeared in MACHINERY: A Screw Propeller Planing Machine, October, 1903; Bauer Propeller Blade Shaping Machine, November, 1903.

† Superintendent of I. Matheson & Co., Ltd., New Glasgow, Nova Scotia.

view, one parallel to E-6 through point 6, and so on for all the points. On these lines mark off the distances shown in the elevation for the respective points, as on line 1 lay off 1 to 1′ equals 1 foot 10½ inches, and 1 to 1″ equals 1 foot 6¼ inches; then draw a curve through all these points, which curve is a plan view of the edge of the blade. We can now find the projection of the blade in elevation by measuring the perpendicular of each point 1′, 2′, 3′, etc., and 1″, 2″, 3″, etc., from the center line $F G$, and transferring them to the elevation. Then, by drawing a curve through these points, we get the blade as shown by line $H L M$. And, similarly, by taking the horizontal distances of each point above or below the center line $N O$, and laying them off on their respective lines on the side view, we can draw in the projection of the blade by drawing curves through the points obtained. This view should have the propeller aperture of the ship drawn round it to scale in order to be certain of the clearances, which ought not to be less than 3 inches at any point.

* * *

A writer describes in a recent issue of the *American Blacksmith* how he fits brass gear teeth in a broken gear. A dovetail is first cut out at the base of the broken tooth to a depth of about ⅛ to ¼ inch, depending on the size of the tooth and the thickness of the rim. Then two or more holes are drilled in the bottom of the cut, and threaded. Short studs are screwed in and cut off slightly shorter than the height of the tooth. Then a form is made of thin iron plates of the height and width of the tooth and shaped to the proper curves. This form is set with care and two plates are clamped on the ends, and the whole is luted with clay on the sides and ends so as to hold the plates firmly in place to prevent the escape of the molten metal used to make the tooth. The form is filled with melted brass poured from a plumbago crucible. After cooling, the form plates are removed and the tooth dressed down with a file. It is claimed that this method of repairing is successful in mill work and other machinery employing cast teeth.

THE UNIVERSAL MILLING MACHINE PATENT.

The Brown & Sharpe Mfg. Co., Providence, R. I., has sent us photographs of patent No. 46,521, this being the patent granted to Joseph R. Brown, February 21, 1865, for the universal milling machine. The accompanying half-tone reproduction of three pages of the patent is of considerable interest in view of the fact that the universal milling machine has come to be one of the most useful of machine shop tools. The patent is on parchment, and the pages are about 14 x 18 inches.

When the universal milling machine was exhibited by J. R. Brown & Sharpe in 1867 at the Paris Exposition it attracted much attention from foreign engineers and manufacturers, this being the first public exhibition of the machine, which was destined to make the name of its manufacturers known all over the world, and which undoubtedly has had a great influence on the development of the mechanical arts. A comparison between it and the latest type with constant speed drive gives a good idea of the growth of the milling machine in size and power during the past forty years.

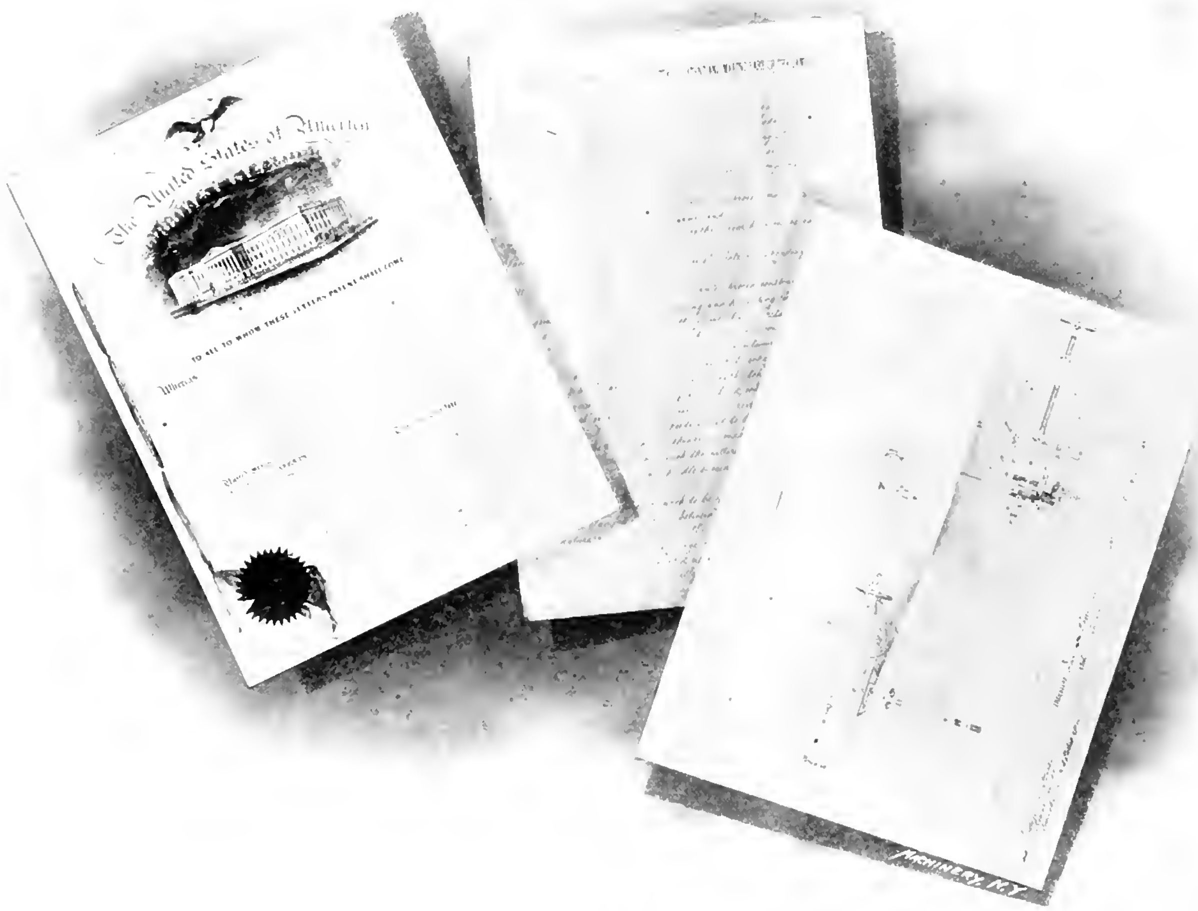


Fig. 1. Three Pages of the Universal Milling Machine Patent granted to Joseph R. Brown.

In this connection we also show in Fig. 3 a view of the old shop in which the original milling machine was designed and built. As most of our readers no doubt know, the business is one of the oldest in New England, having been founded in 1833 by David Brown, and his son Joseph R. Brown. In 1853 Lucian Sharpe became the partner of Joseph R. Brown, David Brown having retired in 1841. The firm was then known as J. R. Brown & Sharpe. The early growth of the business was very slow. In 1853, twenty years after inception, the total floor space was only 1,800 square feet, and in 1857 the total force comprised only 20 men, but in 1872 more than 300 men were employed. In this year the Brown & Sharpe Mfg. Co., which had been incorporated under this name in 1868, removed from the old shop to the present site near the center of the city. The present floor area of the five manufacturing buildings is 436,200 square feet and of the foundry, 160,740 square feet.

TOOTHED GEAR MEMORIES.

INTERNAL.

In ancient days in England, when water wheels were common, there was a large amount of heavy mill gearing work to be carried out. There are no great water powers in Great Britain, but quite numerous mill sites with a fair volume of water and a low fall. In order to get a fair amount of power, the water wheels were made very wide and of the low breast variety. To prevent racking stresses there were large spur

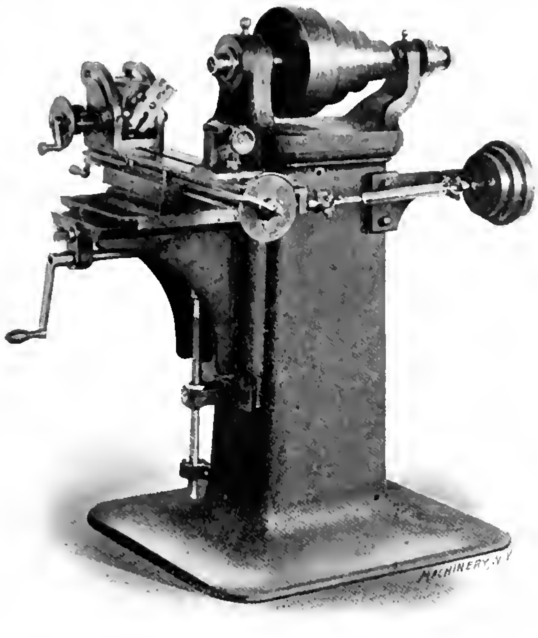

Fig. 2. The First Universal Milling Machine, built in 1862.

toothed gears at the ends of the wheel, and these drove two pinions on one second motion shaft. The large spur wheels were built up of segments bedded on the timber framing of the water wheel. The timber bedding brackets were turned off to a true radius by fixing up a tool rest and letting the wheel run, and turning down the bracket to the true radius to fit the segments. It was customary to lay out the segments on the ground, which had been packed level, and to set them to the radius by means of a trammel, or long board pivoted

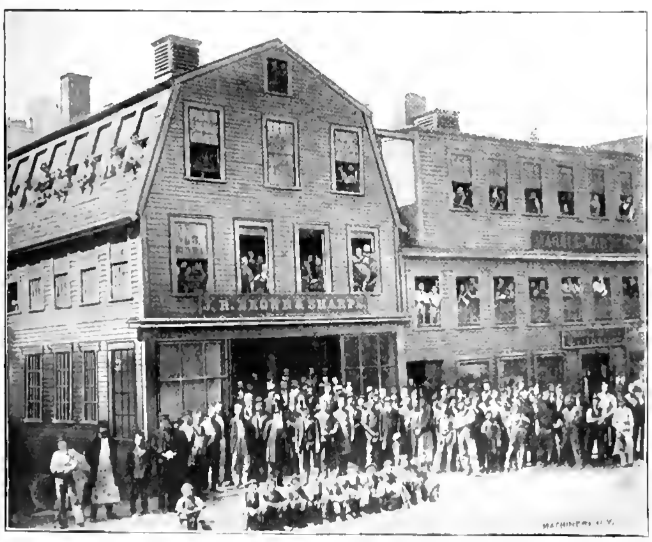

Fig. 3. The "Old Shop" in which the business of the Brown & Sharpe Co. was conducted until 1872.

upon a center post and carrying a scriber. The segments were moved in and out until, when properly butted at the ends, the scriber just touched each segment end when the trammel was revolved round the circle. Then this scriber was measured to the center of rotation and gave the radius on the brackets.

Sometimes, in spite of care, too much was turned off the brackets, and the segments would not bed when butted end for end. This was a very trivial matter. What was one tooth in 375? So one tooth would be cut off one segment and the bedding-down carried out with the smaller wheel of 374 teeth. On one occasion when this had been done the men forgot to do the same by the opposite end wheel, and so there was one wheel of, say, 375 teeth at one end of the water wheel, and there was a 374 tooth wheel at the other end, and both drove equal pinions on the second motion shaft. Such a combination forms a most powerful differential gear, capable of working up an enormous stress. The water wheel was started under these curious conditions, which, it is needless to say, made themselves known by the amount of wreckage produced as regards wheel teeth, all of which were stripped. There was a great wreck.

Another curious oversight occurred in connection with an engine. It was usual, when the engine had not a spur fly-wheel, that is to say, one with teeth directly on the rim face, for a toothed wheel to be built in segments upon projecting brackets cast on the arms of the fly-wheel. The spur wheel was thus slightly less in size than the fly-rim. With the above method of construction the second motion pinion was close alongside the fly-wheel and it overhung its bearing, for there could be no support on the fly-wheel side of the pinion. But on one occasion when a new engine was being put into a mill the fact was overlooked that the engine was at the middle of the building, and that the second motion shaft ran each way from the engine. This was discovered only when it came to putting things together, when of course the fact that the second motion shaft passed through the arm space of the fly-wheel produced some disconcerting moments. The net result was that new fly-wheel arms and a new rim of smaller diameter and heavy section had to be made, in order that the rim might not extend to the second motion shaft. Such were some of the incidents that added color to life in the old shops.

Another very funny incident occurred at Bellhouses' foundry in Manchester, where a large wheel rim was wanted, cast in one piece, and there was not room enough to do this anywhere between the wall and the post of the old-time center post jib crane. Some genius, however, offered a solution of the problem which was at once accepted heedlessly and with acclamation. Let us cast it round here, said he, indicating the ample space of which the crane post formed the center. And cast it round the crane post they forthwith proceeded to do. The error was found out when the time came to move the casting. Only then was it found how much a fourth dimension in space is really required. I am told that if there was a fourth dimension of space one could turn an India rubber ball inside out without having any hole in it through which to do the turning. Presumably, in a fourth dimensional heaven even a cast rim could be gotten off a crane post, fast at both ends to floor and ceiling. But being only—for a time—in a three dimensional "other place," they had to break the rim to set it free.

To-day, when a man has an engine to put up, he waits until the overhead traveler is ready and proceeds to lift all the heavy pieces into place by its aid, just as easily as if they only weighed a few ounces. In the old days, engines were erected with no aid but the hand crab and block tackle. With these, the heavy cylinders, the boss of the fly-wheel, and the great beam, all had to be gotten into place, and it was often necessary to carry such pieces through long distances, and even over other buildings to get them to their final resting place. This work required a considerable degree of judgment and careful handling, for the hand crab was a paltry affair, and I have since marveled at the way we had to risk life and limb in order to get along at all. Once when lifting a four-ton spur pinion with a ¾-inch chain, the chain snapped, and the wheel fell about eight inches with the leading erector standing on its face; it was being lifted in vertical or running position. This man (who never hurt himself or anyone else, but was most risky in his hazards) used the same chain again, lifted the wheel about eight feet, and through a window right above the four men who were working the crab. As they were nervous, he stood with them at the crab handles so that if the wheel fell it would have fallen on him worst of all. He traversed that wheel from "hang" to "hang" across

the engine room and to its place; he threaded the second motion shaft through the eye of the wheel; and had got everything lowered within an inch of its bearing, when the chain again snapped and the wheel fell, but only an inch or less, for the shaft was nearly down on its lower brasses. The salient facts are that the same chain broke at each end of the journey. It might just as well have broken when the great spur pinion hung three feet above the five men when working at the crab handles. They do say that Satan cares for his own; he certainly does seem to have done so effectually that time, and many others, for the man died properly in the end, and not by accident.

Cheap makers of wheels would only make one pattern for a pair of bevel wheels. A pair of true bevels of equal size maintained an equal speed of both shafts, but good makers laid greater value on a hunting tooth, and a pair of equal bevels were always made 1 tooth different. One wheel would have 45 teeth; the other 44 or 46 teeth. Many have heard the story of the hysterical locomotive—a tale founded on this practice, which records how one Sammy built a locomotive valve gear which involved the use of a pair of bevel wheels, and how the engine sawed itself back and forth on the shed tracks like a steering gear engine—always overtaking the phase of its valve gear and finally getting it so far over that the engine ran back, and got as far into the opposite phase—and so on, all because the bevel gears had the hunting tooth.

The old water wheels had their large spur driving wheels built up of many segments, and some of the patterns were very rough and warped with usage, so that the cast teeth were often more or less twisted and out of pitch. They would work noisily at first, but it was usual when the noise was too pronounced to correct it by grinding the teeth—a very simple operation performed with very simple apparatus—water and sifted sand. The wheels being set to work were supplied with sand and water until they ran reasonably quietly. They could not help grinding truly to pitch for there was always some hunting of the teeth even if the wheel and pinion were not prime to one tooth. The heavy bearing teeth got the most grinding and soon the pitch became even.

It was many years ago that we made the first departure from the traditional length of tooth of $\frac{3}{4}$ pitch, which had once been regarded as short. We made a pair of wheels for a corn mill in the County of Durham, and gave them a length of two-thirds the pitch, and they looked well. It was about that time that the Hawkins translation of Camus on Wheel Teeth fell into my possession; the genial Hawkins fell terribly foul of the men who had stood by chord pitch measurement. He advocated short teeth of only half pitch length, and though this is too long, it was a length I used myself for several years; not that I would not have used much shorter teeth, but that one had to make certain concessions to public taste, and a very short tooth frightened men accustomed to the older lengths. My own advocacy of short teeth dated from the above book, and the idea spread until at last one found teeth with a length on the true teeth faces of only about one-eighth the pitch; but some men also conceded to public opinion in a way they ought not to have done, for they made the teeth with true short faces, and then joined them into apparently long teeth by means of semi-circular arcs below the flanks, and similar arcs above, so that the teeth looked just like a series of corrugations of circular arcs. The arcs were absolutely meaningless, and were hideous and clumsy additions merely to conceal the actual fact of very short teeth. They were, in fact, a sort of mechanical lie or fake construction, offensive to good taste and to mechanical rectitude. If public opinion had to be bowed to at all, why go beyond a certain shortness of tooth? A tooth of one-third pitch should be all tooth if it can be pressed on the purchaser, but to give him a tooth of $\frac{1}{8}$ pitch, and build it up to approximately $\frac{5}{8}$ pitch by meaningless additions and subtractions of metal of no use, is bad taste and bad concessions into the bargain.

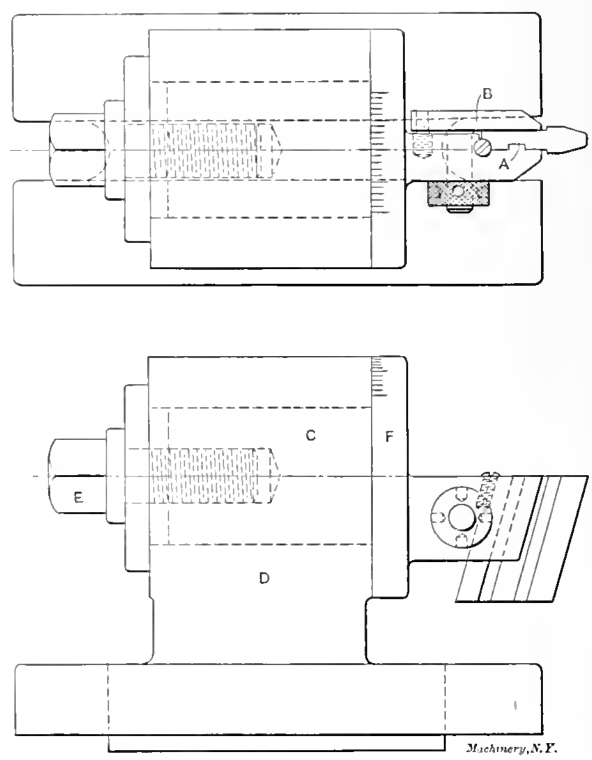
It is known that teeth drive easier when in contact past the line of centers than when approaching. In a full wheel pattern, either of two wheels may be the driver, and it is therefore not practicable to make one wheel with all the teeth projecting above the pitch line, while the teeth of the driven wheel are nearly all below pitch line; for the contact, when the latter became the driver, would be all before the line of centers. Where, however, wheels are molded from a simple gap pattern of two teeth, every pair of wheels may well be thus made, the driver having only points, and the driven wheel flanks only, so that little or no contact takes place before the teeth have passed the line of centers. Such teeth will run quietly.

At one time a very quiet running tooth was made under the patent of one Gee. He argued that wheels run one way only, so he only made one side of a tooth to the proper tooth form. The backs he sloped off so as to get a tooth very strong at the root, and a very little increase in depth of mesh reduced the play or back lash to nothing. By this means he could practically reduce back-lash to a minimum, and his teeth certainly ran very quietly.

* * *

THE INFLUENCE OF THE THREAD MILLER ON TAP MAKING.

With the advent of the thread milling machine the extreme accuracy of thread forms hitherto scrupulously adhered to was sacrificed for the greater commercial advantages in rapid thread cutting. The thread milling cutter, while, as a rule, itself ground to the correct form of the thread, is, when in use, swiveled around a horizontal axis at right angles to the axis through the center of the hole of the cutter in order to



Swiveling Tool Post for Thread Cutting.

conform to the angle of helix of the thread to be cut. By swiveling the cutter in this way the exact form of thread is not duplicated in the screw to be cut, inasmuch as the correct angle of the thread will not be measured in a horizontal plane through the axis of the screw as it ought to be, but in a plane at right angles to the direction of the helix of the thread. It is obvious that the inaccuracy is increased in proportion to the angle of helix; for fine pitches the inaccuracy is so small as to be insignificant for practical consideration, but as the pitches grow coarser, the same diameter being retained, the differences between the correct thread form and the one produced become enough pronounced to demand attention.

It is particularly when cutting Acme threads that this difference is great enough to cause difficulties, because of the fact that the pitches on Acme screws are usually twice as coarse as those on U. S. or V-standard screws. The head of the thread milling machine carrying the cutter has to be tilted over so much in cutting the screw that the dimensions of the thread produced differ by measurable amounts from the standard thread, and if a screw with such a thread is placed in a nut cut with a tap having a correct thread, a very poor fit

will result. The variations are, of course, even greater in the case of multiple threaded screws, and the use of the thread milling machine for cutting such screws may be prohibitive in extreme cases, unless the taps for the nuts are produced in a manner similar to the one used for the screws.

One way would be to mill the taps on screw milling machines. This is also done to a certain extent by manufacturers of these taps. But if it is desired to cut the taps in a lathe, and there are not enough taps to be made to warrant the making of thread tools to suit all the different angles of helix which may occur, a correct thread tool or single point cutter may be used and placed in a tool post or holder capable of swiveling adjustment, so that the tool can be tilted over to the same angle as the milling cutter would be set to in cutting the screw. Such a tool-holder is shown in the accompanying cut. An incidental advantage and saving of expense is gained by the use of such a holder, because of the tool or single point cutter, being set over to conform to the angle of the thread, does not need to be provided with side clearance, but can be made as if intended for cutting a circular groove or a thread of very fine pitch.

The tool-holder shown is provided with a tongue *A* and a clamp *B* to hold single point cutters of the kind manufactured by the Pratt & Whitney Co. The stem *C* of the holder is fitted to a cast iron bracket *D*, which is clamped to the cross slide of the lathe. The screw *E* clamps the holder in position. The shoulder *F* of the holder is graduated in degrees in order to indicate the angle to which the tool is tilted. The holder, as shown, is of the very simplest construction in order to merely convey the idea of the tool. With a little more elaboration in the design a still more efficient tool may result, but for temporary use the one shown will prove efficient.

* * *

A RECORD WITH AN AUTOMOBILE.

A remarkable record was made June 28 and 29 by Mr. S. F. Edge on the Brooklands racing track at Weybridge, near London, England. In twenty-four hours he traveled 1,581 miles with a Napier six-cylinder car. This is at the average rate of nearly 66 miles per hour, and is said to be the greatest distance ever traveled by man in the same length of time. It is noteworthy that notwithstanding the locomotive has done so much to promote the world's progress in increasing the speed and ease of transportation, a car built to run on the ground instead of on steel rails has made a far higher record than any locomotive has ever accomplished. Of course the comparison is not really so very bad for the locomotive, for the automobile record was made on a racing track and under conditions that permitted instant repairs to be made from time to time as they were required. No doubt under similar conditions a locomotive could be made to run as far or further in twenty-four hours. A very important difference is that the locomotive is a practical machine for conveying freight and passengers and earning its way, whereas the motor car is as yet largely the plaything of a sporting class.

In the August issue of MACHINERY we published a letter from one of our readers concerning industrial life insurance. In this letter the enormous waste in connection with the industrial life insurance companies was pointed out. A remedy of the evil of the present condition in this respect has been proposed and acted upon in Massachusetts, and in that state the conduct of industrial insurance is about to be undertaken by savings banks. Investigations having shown that of the total amount of assessments paid by those insured in regular industrial companies nearly 40 per cent is used for conducting the business, it is gratifying to find that in the Massachusetts savings banks the expenses of management are only 1.47 per cent of the amount of deposits. As industrial insurance is a necessity to the majority of industrial workers, this departure is a very important one. Hereafter it will be possible for the residents of Massachusetts to obtain industrial insurance at actual cost, and, for the same amount expended, about double the previous amount of insurance can be carried, the payments being made easy by applying the installment plan in the same way as do the industrial life insurance companies.

FORGING A LATHE BORING TOOL.

J. F. SALLOWS.*

J. F. Sallows.†

Cold shuts, the starting point of the water cracks so often found in lathe tools, may be caused by heating the steel too quickly or too slowly. In heating too quickly, the center of the bar does not reach the same degree of heat as the outside of the bar, and consequently the outside part of the bar draws out under the hammer more freely than the center, thus causing a parting of the metal. This is the starting point for a water crack when hardening the tool. Heating a tool too slowly, and exposing it to the air either at the top or bottom, decarbonizes the steel, and a poor lathe tool may be the result.

When heating tool steel a heavy fire should be used, a good solid foundation of coke being laid in the bottom of the fire, and the steel should be well covered with coke. The smith must watch the steel carefully and not allow it to remain in the fire and "soak," as is sometimes the case, especially if he has struck a position that is restful, or has started an earnest conversation with his working mate.

When forging a boring tool, a bevel set should be used of the form shown in Fig. 1, having a round corner at *A*. After

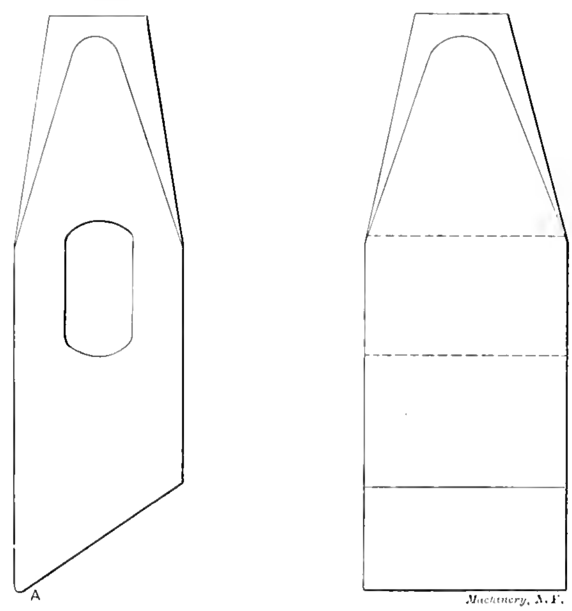

Fig. 1. Bevel Set.

heating the steel, drive the set down making a "V," as shown at *A*, Fig. 2. The rounded corner forms the fillet at the bottom. Some smiths use a large top fuller for making the "V," but the result is a clumsy round corner as shown by the dotted line *B*. If after drawing out the stem of the tool we turn over the lip on the end on an anvil having sharp corners, we shall get another sharp angle that may be the starting point for a water crack. See *A*, Fig. 3. The same also applies to angle *B*, lower view Fig. 3. The anvil used by the tool-dresser

* Address: 1437 Washington Ave., S., Lansing, Mich.

† J. F. Sallows was born at Guelph, Canada, 1865. He served a five-year apprenticeship at general blacksmithing, horseshoeing, plow, carriage and wagon work. Owing to an accident received while shoeing a horse he was unable to follow horseshoeing for a living, and then became a tool-smith for the Canadian Pacific R. R. at Portage La Prairie, Manitoba, where he first gained his experience with machine shop methods and requirements. Since then he has been in the employ of the Snyder-Hughes Co., Cleveland, Ohio; Baldwin, Tuthill & Bolton, Grand Rapids, Mich.; Olds Motor Works, Lansing, Mich. Mr. Sallows is now with the Reo Motor Car Co., of Lansing, Mich., acting in the capacity of foreman of the forging, tempering, case-hardening, brazing and riveting departments. Mr. Sallows has written a book entitled "The Blacksmith's Guide," which will soon be published by the Technical Press, Brattleboro, Vermont.

should have round corners for about four inches from the square end on both sides. Then, when forging a tool that should have fillets in place of the sharp corners, as shown at *A* and *B*, Fig. 4, the means are at hand for forming them. Never use a chisel on a lathe tool if it can be avoided.

When about to lengthen out the stem on a boring tool, it is a common practice to heat the tool to a lemon heat, and with a chisel chop out a piece at *A*, Fig. 5, thus leaving the tool

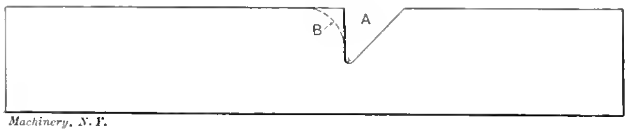

Fig. 2. Characteristic V made by Set.

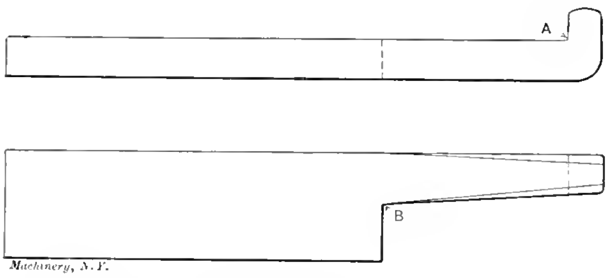

Fig. 3. Tool Blank with Objectionable Sharp Anglee.

marred by chisel marks that cannot be removed by hammering. Now, when the tool is used up to that part, it cracks every time it is put in the water. The proper way to lengthen a boring tool is as shown in Fig. 6. Drive the bevel set down as at *A*, then cut off the corner *B*, and draw out the stem to the proper length and size. If a boring tool has a fairly good lip and has to be lengthened in the stem, give the stem a half twist after lengthening, and the job is completed.

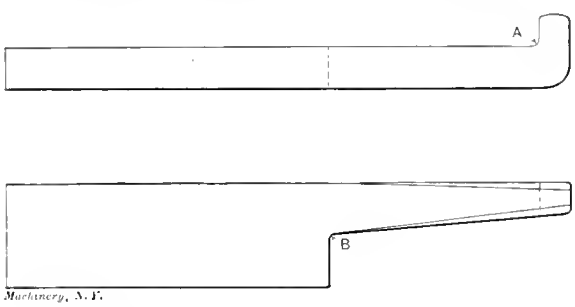

Fig. 4 Tool Blank with Form of Fillets to be Provided.

A common mistake a great many smiths make when tempering or hardening a boring tool is to heat the tool a little too hot, and dip the end into fresh water to a point just above the lip, and hold it still until it is cold. This is bad practice. In the first place the tool-dresser should use salt water for hardening all kinds of tools, for the tools will harden at a much lower heat, and this will do away with cracking. In the

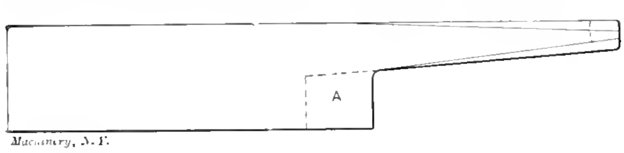

Fig 5. Bad Practice in Lengthening a Boring Tool Stem.

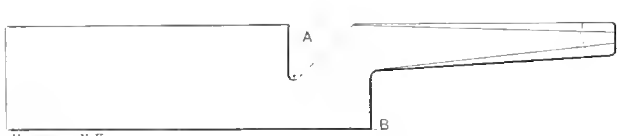

Fig. 6. Recommended Practice for Lengthening a Boring Tool Stem.

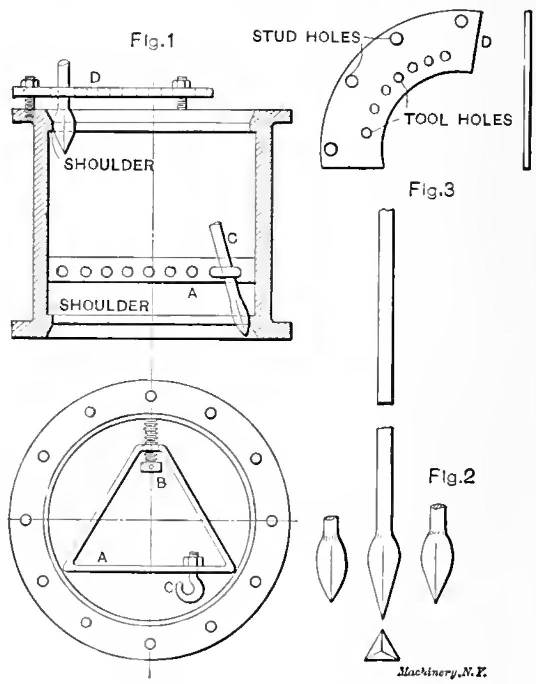
second place the tool should be moved around in the water constantly until ready to be removed.

An inside threading tool should be forged in the same way as the boring tool, except that, when trimming off the cutting part, it is shaped differently, being brought to a sharp point with clearance below. It should be tempered the same, however, as the boring tool, but will not stand to be quite so hard.

ITEMS OF MECHANICAL INTEREST.

SCRAPING OUT THE CYLINDER OF A MARINE ENGINE.

A few months ago a contributor to the *Mechanical World* described how he accomplished the job of scraping out the cylinder of a marine engine. After opening up the cylinder, it was found that the counterbore at each end had not been carried in far enough, and that a sharp shoulder had been formed by the piston at the end of the stroke. This shoulder had to be removed. It was almost impossible to chip it out or to use a file to any advantage. Finally the device shown in the cut was rigged up. The tools used, Fig. 2, were made from $\frac{7}{8}$-inch octagonal steel, 4 to 5 feet long, with one end drawn out to a triangular point. In the plan view, Fig. 1, is shown the tool stay *A* for working at the bottom of the cylinder. A piece of bar iron was bent into a triangular shape and welded, the corners being slightly rounded, and one side being longer than the others. At the corner opposite the long side a hole was tapped for a pointed screw *B*. This, when screwed out, together with the two opposite corners



Tools used for Scraping Out a Cylinder.

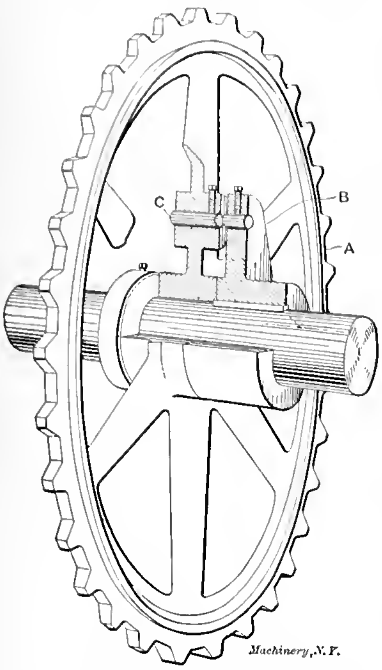
of the triangle, pressed against the wall of the cylinder, and formed a rigid frame. Holes were drilled around the triangle to take a hook *C* against which the tool pressed when cutting. Fig. 3 shows the tool stay *D* used when scraping the top of the cylinder. A piece of plate was cut to about one-quarter circle, and holes were drilled to the same circle and pitch as the studs in the cylinder; inside these another row of holes was provided, large enough to allow the cutting tool to pass through. After a little practice, says the contributor, it is surprising what an amount of metal can be removed, as the long lever gives a considerable amount of power.

THE BREAKABLE PART AS A PREVENTION FOR OVERLOAD.

In a contemporary we find reference made to a design of hub for a chain wheel used in connection with some kind of hoisting apparatus. The design is shown in the accompanying cut. In order to prevent the overload and consequent breaking of other parts of the machinery, a safety device is applied in the form of a pin connecting the driving hub *B* with the hub of the gear *A* itself. As seen from the cut, the gear, instead of being keyed to the shaft, is loosely mounted, and the hub *B* is keyed to the shaft instead. This hub is connected to the chain wheel by pin *C*, which is necked, the extent of the reduction of the neck of the pin determining the amount of power which may be safely transmitted. If the apparatus is subjected to an unusual strain, the pin will break, leaving the wheel free, and thus preventing the breakage of parts which would cause serious accident.

This scheme of applying a breakable part in machinery

to prevent overload and the breakage of more important portions has been resorted to in several classes of work. It is, however, one that can hardly be recommended as an extremely happy one. In the case of a pin for transmitting the power, the temptation of the operator will always be, in case the pin should break, to replace it with one of stronger material so as to prevent the annoyance due to frequent replacement. In the case in hand there is, of course, an obvious temptation, if the pin should break, to replace it immediately with another pin without taking time to neck it down, in which case the new pin may have a power of resistance about double that of the one broken, and the original object of this safety device would be lost. The ideal safety device is one which does not break in the case of overload, but which is simply thrown out of action when the load becomes too heavy, and which can be moved back in position again by simply turning it like a lever. In such a case there is no temptation for the operator to prevent the proper action of the safety device, and there is less risk that the device will be inoperative at the very time when its action is most required. In electrical work this principle has been realized and acted upon, and the old-fashioned fuses which were inserted in circuits in order to prevent overload are being replaced by circuit-breakers. The fuses, in fact, correspond directly to the breakable pin, and circuit-breakers have their direct counterpart in some kind of a lever arrangement in mechanical design which would automatically be thrown out of engagement in case of too heavy load.



Example of a Design having a Breakable Pin as Safety Device.

REPAIRS TO A DYNAMO ENGINE ON A REVENUE CUTTER.

A writer in the May issue of *International Marine Engineering* describes a rather discouraging repair job which was successfully undertaken by the engineers of the United States revenue cutter *McCulloch* in Alaska. The dynamo engine of that craft was wrecked by the breaking of a crank-pin bolt. The damage consisted of a broken piston and ring, bent, and upset piston rod, bent connecting-rod, and smaller injuries.

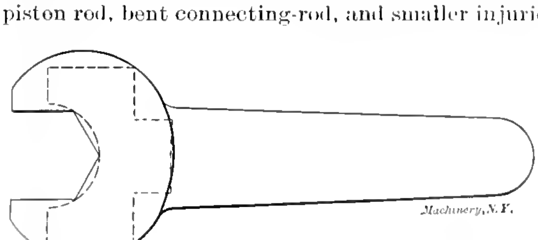


Fig. 1. Wrench from which the Stub End of the Connecting-rod was Made.

For repairs, the material available was sufficient for all purposes except to make a new piston, and the ship had a lathe and drill press. For a piston, a piece of cast iron was secured from the scrap heap at a mine, and drilled out and turned into shape. A spare piston rod on board was found to answer, after a bushing and a new gland had been made for the stuffing box.

When the repairs were practically finished, the connecting-rod disappeared, having supposedly been thrown overboard by a drunken fireman. There was nothing on board from which a connecting-rod could be forged, and a search at the next two points touched at failed to produce suitable material. It was therefore decided to build a skeleton rod of material that was available. The stub end was made from a disused open ended wrench of sufficient dimensions to be cut into shape. The handle of the wrench was cut off, and the jaws were sawed, filed, and machined to the proper size, as shown in the sketch, and holes drilled for the crank-pin bolts.

For side pieces a grate bearer-bar, 7-16 by $2\frac{1}{2}$ inches, was used. These pieces were shaped and temporarily bolted to the stub end with five $\frac{1}{2}$-inch bolts. A block of hard wood, the length of the cross-head pin, was placed between the upper ends to hold the side pieces rigid while the holes for the pin were being drilled. When a new cross-head pin had been turned, the bolts in the stub end were removed, and the pin

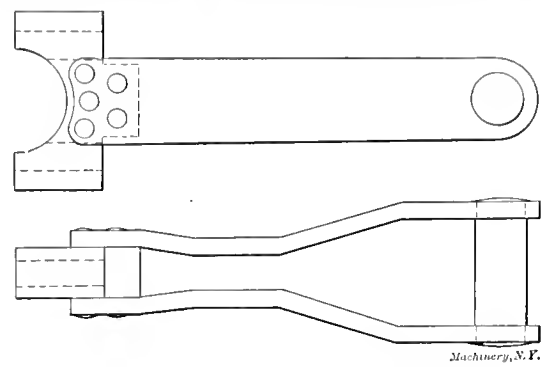

Fig. 2. Two Views of the Completed Connecting-rod.

was shrunk in and peened. The lower ends of the side pieces were then secured to the stub with five $\frac{1}{2}$-inch rivets of soft steel turned to a driving fit, annealed, and riveted cold.

The shape given to the side pieces as shown in the cut was necessary to clear the counterweights on the crank. The completed connecting-rod was found to be sufficiently rigid without the use of distant pieces, and proved to be satisfactory in every way.

THE RESISTANCE OF SOFT MATERIALS.

The note in the May issue of MACHINERY with the above title served as a text for a discourse by the editor of *Wood Craft*, in which he brings together a number of other illustrations along the same lines as those we gave.

He speaks, for instance, of cases in which hardened tool steel bearings have been replaced by soft cast iron shells with great success, especially where the journals had been hardened and ground. This combination of hardened journal and hardened bearing is a rather risky one, as every machine operator who has ever met with it knows. The difference between bronze and babbitt also presents some puzzling peculiarities. Many a hard metal bearing has been replaced by an emergency job of babbitting that, at the time, had nothing but its immediate applicability to warrant its use, but which was found, in service, to make good in every sense of the word. The use of *lignum vitæ* and other wood bearings under water lubrication, and not infrequently in places where they get very little care, is also well known and need not be enlarged upon, beyond referring to the really remarkable showing the bearings often made under these conditions. There is also the common practice of using wooden teeth in water-wheel gearing, where the shock and strain usually form a severe combination.

But a more curious case of metal being quickly worn away by a very much softer substance, plus an abrasive, was quoted from *Stone*. This journal says that yarn with powdered stone can cut a steel bar. The facts to bear out this claim are thus presented. Major McClaughry, warden of the Federal prison at Fort Leavenworth, found a prisoner working away at one of the bars to an outside window. A grating of the same description was placed in his cell, and a guard stationed over him to watch the cutting process. With the limestone dust and silicate from the stone pile, the yarn from his sock and a little water, he cut through the Bessemer steel bar in eighteen working hours. With some fine emery, a chalk line and two wooden handholds to save his fingers, he made a clean cut of the other Bessemer bar in five hours. *Stone* does not say what thickness the bars were nor are we told what reward was earned by the prisoner's persistence.

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

49-55 LAFAYETTE STREET, CORNER OF LEONARD,
NEW YORK CITY.

The receipt of a subscription is acknowledged by sending the current issue. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

SEPTEMBER, 1907.

PAID CIRCULATION FOR AUGUST, 1907, 23,474 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages. The Engineering Edition—$2.00 a year—contains all the matter in the Shop Edition and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

PHOTOGRAPHS FOR ILLUSTRATION.

One of the editor's difficulties is getting good photographs for half-tone illustrations. Many subjects are offered, but the majority of photographs submitted lack sharpness and the clear cut quality necessary for "snappy" engravings. More negatives are spoiled by under-exposure than by over-exposure, and the former fault is very marked in most machinery and shop interior photographs.

Machinery and machine shop interiors generally lack sharp contrasts, and all dark surfaces need plenty of time to impress themselves on the plate. There is little danger of over-exposure in the ordinary run of shop interiors. Our experience with an f-8 rectilinear lens in a 5 x 7 camera indicates that with a 16-stop, exposures of from 40 to 50 seconds generally result in fair negatives. This, of course, is only a rough and approximate rule, but we find that it applies very well in most cases.

Another fault of present-day photographs is the very general use of gas-light papers instead of sun-printing papers. The latter are far superior to the former for illustrative purposes, but on account of convenience the tendency is to use gas-light papers almost exclusively. The best photographs that we get come from abroad. Few of our professional photographers are able to produce as good prints as those that are made every day in Great Britain and other European countries.

The gist of the above is that contributors who would please the editor, and who would see the best half-tone illustrations in their favorite trade journal should insist on first-class negatives and "silver" prints for all contributions and descriptions that they may submit.

* * *

THE DROP FACE FLANGED LOOSE PULLEY.

The drop face flanged loose pulley is a feature of shop installation more frequently used in wood-working establishments than in machine shops. A number of machine tool building concerns, especially those who build grinding machinery, have, however, recently made some use of the flanged loose pulley. The theory of its construction is that as the belt is relieved of part of the tension when thrown onto the loose pulley, the latter is not so likely to heat up and cause trouble as it would if it were of the same diameter as the tight pulley.

There is a difference of opinion as to the merits of the drop flanged loose pulley. One concern has hundreds of them running in its own plant, and has adopted them as a standard of all the equipment it furnishes requiring tight and loose pulleys. Another concern speaks favorably of the advantages of the device for driving grinding machinery, although it suggests that relaxing the stress on the belt when running on loose pulleys causes the former to deteriorate and lessens its life.

Another concern, however, points out that the decreased tension of the belt is comparatively slight with long center distances. Suppose that the center distance is 12 feet and that the loose pulley is 3/8 inch less in diameter than the tight pulley; then the shortening of the center distance does reduce the tension of the belt, but ordinarily not so much but that the loose pulley is still under considerable pressure, sufficient to make it run at full speed. In fact, the drop face pulley almost invariably runs faster than normal speed, inasmuch as its diameter is reduced. From this it appears that the reduction of diameter to reduce the belt tension tends to increase, if anything, the danger of heating on account of the more rapid rate of rotation.

One well-known grinding specialist does not hesitate to characterize the drop face pulley as an example of mechanical quackery, and further adds that there is much of this sort of thing in wood-working machinery design. If a loose pulley heats, it is pretty good evidence of insufficient lubrication or length of bearing, or both. Altogether it would appear that the solution of the loose pulley problem in rapid running machinery is simply long bearings and provision for constant lubrication. When these are provided, it will be unnecessary to resort to dropping the face or any other expedient of like nature.

* * *

DYNAMIC BALANCING.

The article on another page of this issue on balancing cream separator bowls is, we believe, a contribution to general knowledge of a somewhat obscure subject. It is a brief description of the method followed in a large factory in adjusting the rotating part of a dairy machine, which runs at a normal speed of about 8,000 revolutions (say 10,000 feet at periphery) per minute. At so high a speed it is positively necessary that the rotating part be put in a state of dynamic balance. This may be a quite different condition from a standing balance, as every well-versed mechanic knows. An armature, for instance, may be in perfect standing balance, and still vibrate badly when run at speed. The reason is simply that somewhere within its length there is an excess weight on one side that is not balanced directly opposite or in the same plane at right angles to the shaft. The fact that there is an exact equivalent to the excess at some other point in the armature length on the opposite side of the shaft, does not answer. The effect of centrifugal force at high speeds is enormous in proportion to weight, and small fractions of an ounce, unsymmetrically located, may quite easily be sufficient to perceptibly spring a comparatively large shaft, this force being 1,500 to 4,000, or more, times the weight in cream separator apparatus. The discovery of the exact seat of trouble is not always a simple matter, and to remedy it is, indeed, often extremely difficult.

The fact that some cream separator makers claim to make bowls that do not require balancing by the *addition* of fused metal to the unbalanced portions does not vitiate the principles enunciated. The fact is that, no matter how accurately the machine work is done, the minute variations in homogeneity of all metals whether rolled, forged or cast, make it entirely necessary to balance by test. Whether it is done by addition or subtraction of material is merely a matter of practice to be determined by individual preference.

The article referred to is a shop man's description written for other shop men, and is a good example of the practical matter that MACHINERY aims to publish. It may easily be worth the price of several years' subscription to those who have to do with the balancing, and no mechanic knows how soon he may be called on to handle work of just this character.

THE STEEL TRUST AND THE TARIFF.

It has been said with a great deal of truth that the tariff is the mother of monopolies, although, of course, there are monopolies which are not fostered by the tariff. At the same time there are industries which remain competitive whether there be a tariff or not. These industries are those which depend mainly upon individual enterprise, skill, and hard labor for their existence. Such industries, however, which depend merely upon their access to natural resources, such as coal, ores or lumber, for instance, are likely to become monopolies when they have been able to corner the supply of a special necessity. In such cases the tariff is plainly the nurse of special privileges, and serves no other conceivable purpose than that of enriching the privileged few at the expense of the many. Consider for a moment the case of the steel industry of the country. There is no exaggeration in saying that it is virtually controlled by one single corporation, a gigantic monopoly, which can command its own prices from those who use the product, whether the users be the machine builder, the structural contractor, the railroad engineer, or in the last hand, the general public. This company produces from one-half to two-thirds of all the iron and steel used in this country. Of all Bessemer steel ingots and castings, for instance, the production of the United States Steel Corporation amounted to 67.4 per cent in 1905; of wire rods, 69.9 per cent; of rails, 53.6 per cent; of structural shapes, 54.6 per cent; and of wire nails, 66.1 per cent. This operation also controls the greater portion of the ore lands in this country, in fact, according to the best authorities, from 75 to 80 per cent of all the ore land of the Lake Superior region, which at present constitutes practically the only cheap supply of workable good iron ore in this country. The monopolized value of the control of these ore lands it would be futile to try to estimate. In view of all this, it seems as if we ought to be ready to recognize, as a nation, that the time has come when even the most avowed believer in protection cannot help but see the fallacy of our present course.

When protecting our output of steel and iron by a tariff, we protect no infant industry. Moreover, the steel mills of the country cannot at the present time supply the demand for their product. The country has reached the point of development where the domestic supply is insufficient. We have been forced to import steel and iron, tariff or no tariff. What a farce then to burden our legitimate industries with this import tax in the name of protection to domestic enterprise, when this latter cannot possibly supply the raw material necessary. The only purpose the tariff serves under such conditions is to permit the interests which practically control our enormous natural resources of iron ore to exact from the users of steel an unreasonable tribute. When it is possible for British makers of steel to ship it all the way to San Francisco, paying an ocean freight rate of $5.90 a ton, pay the tariff, and still sell in competition with our own steel monopoly, then it appears to be plainly in evidence that we are paying slightly more for our domestic steel than it is actually worth, and that a tariff which produces such abnormal conditions is worse than useless.

INVISIBLE ECONOMIES.

S. H. BUNNELL.*

The effect of distributing the shop expense among the various paying jobs is to obscure its details, particularly to obscure the proportion of wasted expenses, lost time and the like, which may be caused in particular by the doing of certain classes of work, but which are, by the general system of distribution, hidden from view and spread over all, with the result of increasing the computed cost of everything, and diminishing the profits on all. It is an important part of the manager's duty to investigate invisible losses of all kinds, and to conduct matters so as to reduce these as far as possible.

Among such losses are those due to faulty arrangement of plant, so that unnecessary steps must be taken by workmen. There is little difficulty in transporting material by tracks or cranes over almost any desired distance, and in shop work this expense is not a large item, though in the manufacture of steel and similar work, where the masses transported are enormous, it becomes of much greater importance to reduce unnecessary transportation by arranging the plant so that material may progress readily from one operation to the next. The steps taken by workmen, however, cannot be disregarded, and every unnecessary walk is so much unnecessary expense to the shop. Toilet rooms are often arranged at great distances; tool-rooms and storerooms are so located, in the endeavor to concentrate supplies and reduce the expense of caring for them, that many workmen have to walk long distances several times a day. It is easy to compute the loss in dollars and cents due to the time taken by an average man to walk one hundred yards and return. It will generally be found from such calculation that the expense of dividing tool-rooms is more than covered by the resulting saving, although this will never appear in dollars and cents on the books except as a reduction of general expense. In many cases the transportation of tools can better be taken care of by the use of cheap messenger boys, thus saving the time of the expensive men. Unnecessary writing on workmen's time cards, or requisitions for material, and on other reports which must be kept by workmen, more or less careless with such matters, but possibly earning good wages, may involve a large unnecessary expense. A computation of the number of seconds taken by a workman to find his bit of pencil and write a dozen words on a piece of paper or card held on his knee, or against a post, or some rough surface, may show that the employment of a special clerk to make out these cards would result in a large saving. Further, the cards written by the clerk could be more quickly handled, and necessary records made from them with small chance of error, while the time lost by the cost clerk's force in looking up errors and obscurities on time cards written by workmen will generally amount to much more than the cost of making out the cards in the first place.

The physical comfort of the workmen, due to spending their time in a well-lighted and comfortable shop with clean floors, and neatness visible everywhere, is a valuable adjunct in saving lost time. Mental satisfaction is also important. A raise of pay when requested may be expensive for the shop in one way, but the refusal of the raise is certain to be more expensive, as the workman will not equal his former efforts after a disappointment of this kind. Almost everything, however trivial, has its bearings on the expense of getting out the shop product, and too much care cannot be given to reasoning out the probable effect of each move, even though time cannot be afforded to go deeply into all such small matters. The outsider coming into a shop is often able to see chances for saving in what may be called "invisible expenses," which have entirely escaped the men employed there. It is a common occurrence that a city will refuse taxation sufficient to pave an important street and provide a good bridge, while a large number of its inhabitants are at the same time losing many times the amount that would be required for such taxes in hauling small loads, and in unnecessary wear and tear on their vehicles over this same street. The good roads agitation has brought this point clearly before the public, and the agriculturalist has been held up to ridicule for his refusal to assist the cause of road improvement, while he himself was losing every year fifty times the amount he would be called upon by the broadest scheme of road improvement to contribute to the general good. The man in the machine shop office should not have his point of view limited to the direct expense accounts, but the indirect expense should receive more, if anything, of the manager's time and skill, and the obscure and invisible losses should be sought out with the utmost persistence.

* Address: Watertown, N. Y.

* * *

We hear a great deal spoken of this or that new bridge as being the longest in the world. As a matter of fact, states *Railway and Locomotive Engineering*, the longest bridge is located in Sangong, China, and is called the Lion bridge. It extends five and a quarter miles over an arm of the Yellow Sea, and is supported by 300 huge stone arches. The roadway is seven feet above the water, and is enclosed in an iron network.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

According to a news item in the *Pittsburg Despatch* of July 1, the United States Steel Corporation intends to gradually replace the steam power for the blowing engines with gas engines, using blast-furnace gas.

The steel ship may properly celebrate its 50-year anniversary this year. It is stated that the first steel ship ever built was the paddle steamer *Ma Robert*, constructed in 1857 for the Livingstone expedition. The fifty-year anniversary is indeed worthily celebrated by the completion, in the same year, of three such giants as the *Lusitania*, the *Adriatic*, and the *Kronprinzessin Cecilie*.

According to *Page's Weekly*, the municipal council of Paris has adopted a resolution in favor of a project of making Paris accessible to large sea-going vessels by the construction of a large canal from Paris to the sea. The council has two schemes under consideration. The first would utilize the Seine, while the second consists in the creation of a maritime canal from Paris to Dieppe.

Some weeks ago the results of the experimental trials of the *Lusitania* were made public, and they are regarded by her builders as being extremely satisfactory. The vessel obtained a speed of 25 knots, and her engines performed splendidly. Taking into consideration the fact that the *Lusitania* was not running under full pressure at the time of the trials, the results are considered remarkably good.

The production of gold in 1906 was nearly double that of ten years ago, and materially larger than that of the preceding year. The world's production of gold is still on the increase, and it has been estimated that in 1907 the total output will be nearly ten per cent larger than that of 1906. Transvaal is producing the largest amount of any country, the United States coming in the second, and Australia in the third place.

It is reported by *Engineering* that the Russian government has decided to proceed with the construction of a double track on the Trans-Siberian railroad. This step has been taken because high military officers have arrived at the conclusion that if the Trans-Siberian railroad had been double-tracked during the war with Japan, the result of the conflict would have been different, as Russian troops could have been despatched to Manchuria much more rapidly.

In reporting to the American Foundrymen's Association upon tests made with cast iron containing nickel, James B. Webb states that the results of the tests do not indicate a marked improvement in the physical strength of the castings, and bear out the supposition that nickel in cast iron is either not distributed uniformly enough to do much good, or else will find its best use in special classes of the metal freer from the high percentages of impurities incident to the ordinary castings. These tests were undertaken on behalf of the association, and authorized at the convention last year.

In *Annalen der Physik* of July 5, an account is given by Mr. M. Gildemeister of some experiments which he has carried out in order to find how long a time it takes for the magnetism in an electro-magnet to disappear after breaking the circuit. He states that 1-300,000 second after breaking the circuit, the magnetism has gone down to one-half, and after 1-150,000 second to one-tenth its original value. After 1-50,000 second only the residual magnetism is left in the magnet. The core of the electro-magnet which was used for these experiments consisted of a great number of very fine low carbon iron wires.

An interesting comparison between the cost of operating automobile fire engines and horse-drawn engines has been made in Hanover, Germany. This city was the first one in that country to procure a complete automobile fire engine service. It appears that while the first cost of the engine and horses for the horse-drawn service is $11,050 as compared with $13,090 for the automobile, the cost of maintenance is so much less for the latter fire engine that already at the end of the first year the automobile service is the cheaper one, and at the end of five years there will be a total saving of nearly $15,000. If these figures be correctly arrived at, it would seem that the automobile would, before long, entirely occupy this field.

A new tube railway has been opened in London, having a total length of eight miles. This underground railway is remarkable in several respects. It rises 272 feet in its course, and at one point it is 250 feet below the surface, one station beiug 192 feet under the surface. This is the sixth underground electric railway in operation in London, and five more are projected or under construction. The subways in London differ from those of New York City in that all run at a considerable depth, from 50 to 100 feet below the surface being a common location. In so doing, the subways do not interfere with surface conditions, or conditions near the surface, such as gas and water piping systems, etc.

The British Thomson-Houston Company has supplied the *Times Engineering Supplement* (London), with the results of tests made upon one of four Curtis turbines installed at the Fisk Street station of the Commonwealth Electric Company of Chicago. This turbine, which is rated at 9,000 kilowatts, was tested at loads varying from 5,374 kilowatts to 13,900 kilowatts, or from 60 per cent load to 55 per cent overload. The steam pressure ranged from 176 pounds to 198 pounds per square inch, and the vacuum was fairly constant about 29.50. The steam was superheated 116 to 148 degrees, and the consumption in pounds of steam per kilowatt-hour ranged from 12.9 to 13.6. The constancy of the consumption over so wide a range of load is remarkable.

While speed indicators on railway trains do not seem to have met with great favor on American or British railroads, they are very commonly used in continental Europe. According to *Railroad Men*, in France every passenger engiue is equipped with this instrument. On nearly all the lines on the Continent their use is customary, and in some countries even main-line freight engines are so equipped, and the indicators are considered quite as important as steam gages and automatic brakes. It would seem that their use would tend to minimize accidents caused by fast running. The indicator not only shows constantly the speed at which the train is running, but records it in a locked box to which the engineer has no access. The trip record is taken to the office when the engine completes the run. There are said to be 20,000 indicators in use in Europe.

Since the use of concrete had been introduced in this country, the uses to which it has been put have been many and varied. One of the most remarkable departures in the direction of the use of reinforced concrete is that of making concrete telephone and telegraph poles from this material. Nearly a year ago experiments were begun at Richmond, Ind., with reinforced concrete poles. These poles were 30 feet in height, octagonal in shape, and tapered towara the top, provided with gains to be used in climbing and for the insertion of cross arms. A number of these poles were erected on one of the main lines of the company's road, and a short line was constructed wholly with concrete poles. After a year of service it has been found that these poles give as much satisfaction as do wooden poles, and that they have the additional quality of being almost indestructible.

Some interesting statistics are given in the *Archiv für Eisenbahnwesen* respecting railway mileage in various countries. It is estimated that the total length of lines constructed and open all over the world, down to the end of 1905, amounted to 562,436 miles. The annual rate of mileage increase varies from about 3.4 per cent to 2.3 per cent; the total increase in the number of miles open for traffic in the five years ended with 1905 was 10.9 per cent. America, North and South, naturally heads the list of the different continents with a gross total of 285,781 miles. Europe is but a poor second, with a total of 193,133 miles; Asia follows next, with 50,562 miles; then comes Australia, with 17,431 miles, and Africa brings up the rear, with 16,528 miles. It is stated that the cost of land and construction of the European railways is about double that of the lines in any other quarter of the globe. The assumed total expenditure for European railways amounts to about $23,000,000,000, and the cost of the railways in all other parts of the world nearly $22,500,000,000. The cost per mile of European railways averages about $120,000, and of the roads in the United States $54,000.

The use of electrical power in modern steel mills is now extended to cover practically all the machinery of the plant, the systems of telpherage, conveyors and practically all the appliances for handling the hot metal, being now universally driven from individual motors. At the Gary plant of the Indiana Steel Co., the rail mill will probably require the greatest amount of power. This mill is situated about a half mile from the power house in which the sixteen huge units will be housed, and will consume approximately 10,000 kilowatts to operate the induction motors which drive the main rolls. These motors range in capacity from 2,000 to 6,000 horse-power, and three of them have overload capacity of 9,000 horse-power for an hour. The breaking-down stands in the rail mill for reducing ingots to fair-sized blooms, will be driven by two 2,250-horse-power motors. The blooms will then go to the blooming mill, which is operated by one of the 6,000-horse-power motors, and from this they will pass to the mills driven by two 4,500-horse-power motors, receiving their finishing passes in the mill driven by a third 2,500-horse-power motor. All the tilting and feed tables for the various passes, all hot saws, hot and cold pull-ups, the transfer tables, straightening machines and cold saws, and all auxiliary machinery of the mill will be driven by electric motors.

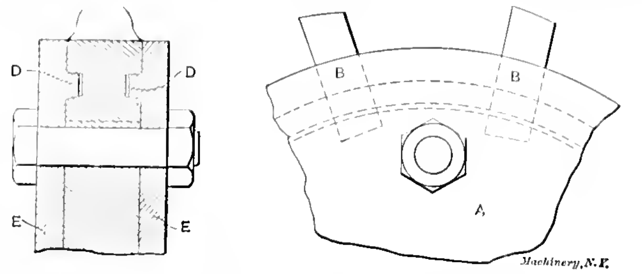
THE VALUE OF OLD VALVES FOR SCRAP METAL.

According to the *Brass World* there is no old metal, with the exception of copper wire, that commands so high a price from the brass founder as "old valves." A foundryman is always willing to buy them, as they are the best material he can obtain. There is no class of brass castings made with more care than valves. Not only must the metal be of a good bronze color, but it must cast well, so as to stand the pressure test. It must also contain sufficient tin to harden it and prevent its bending while being worked, or when screwed to the pipe. It is a pretty good metal that will stand these requirements, and a valve that has passed inspection must surely be of good quality. There may be said to be practically two standard valve mixtures on the market to-day. One of them is very extensively used and all ordinary grades of valves are made from it. The mixture is as follows: Copper 86 per cent, tin 5 per cent, zinc 5 per cent, lead 4 per cent. For the best grade of valve the following mixture is usually employed: Copper 86 per cent, tin 7 per cent, zinc 4 per cent, lead 3 per cent. Scrap cocks should always be carefully sorted from the valves, as the quality of metal used in them is inferior. In sorting over the material, also, the founder should take care that no iron wheels are included. The wheel is the only part of a brass valve that is made of iron, so that the rest may be thrown in indiscriminately. In general, however, if a first-class quality of metal is wanted, the best material will be found in valve bodies. There need be no hesitation in melting them up as they are, without the addition of any other ingredient.

IMPROVED INSERTED BLADE MILLING CUTTER.

The Mechanical Engineer.

The accompanying cut shows an improved method of securing the teeth of inserted blade milling cutters to the body. This arrangement is the joint patent of H. S. Moorwood of Onslow House, Brocco Bank, Sheffield, and J. M. Moorwood of Millhouses Lane, Millhouses, Sheffield, England. The body *A* of the cutter is provided with slots *B* to receive the cutter-blades as usual, but the lower ends of the cutter blades, as well as the portions of the body between the blades, are grooved to receive the annular projection *D* of two disks *E* which are screwed tightly to the body, thus holding the blades



Improved, Inserted Blade Milling Cutter Design.

in place. The groove in the blades as well as the annular projection on the side plates are slightly tapered on the inside so that the inserted blades are drawn inward and held firmly against the bottom of the slots for the blades in the body, when the bolts are tightened. While, without modification, this method may have its difficulties, and may be rather expensive, the idea involved is commendable, and may serve to suggest something of better practical application.

SECURING UNIFORMITY IN PHOSPHOR-BRONZE SPRINGS.

The Brass World, April, 1907.

Among the copper alloys, there is none which is surrounded with so much uncertainty as phosphor-bronze. This is particularly true of springs made of this material. If a spring of a material other than steel is desired, phosphor bronze is usually specified. If the mixture is rightly made, such a spring cannot be surpassed by anything except steel. The action of the phosphorus in phosphor-bronze is to reduce the oxides of copper and tin that are formed in melting. Any amount over and above this quantity acts deleteriously and injures the metal. Experience has taught that if the phosphorus in rolled metal exceeds 0.05 per cent, the bronze is injured.

The greatest variation in rolled or drawn phosphor-bronze, however, is caused by the tin content. A bronze which contains only 3 per cent of tin is inferior to one which contains 8 per cent, though both may be phosphor-bronze. On account of the difficulty in the rolling or drawing of phosphor-bronze containing a high tin content, manufacturers will substitute a lower percentage if it is possible to do it. The presence of zinc is also an unsatisfactory condition. A good spring should contain only copper, tin, and a very small quantity of phosphorus.

Those who have had trouble with phosphor-bronze springs should ascertain whether their troubles are not caused by the absence of the necessary amount of tin, or the presence of zinc. When rightly made, phosphor-bronze is an excellent spring metal, but if not, it is inferior to yellow brass. The "temper" is produced by cold-rolling, of course, but unless plenty of tin is used in the mixture, the requisite "temper" cannot be produced, no matter how much the metal is rolled.

GENERAL CONCLUSIONS FROM THE A. C. A. SEALED BONNET AUTOMOBILE CONTEST.

Albert L. Clough, in the *Horseless Age*, June 26, 1907.

On June 19 the Automobile Club of America arranged what has been termed a sealed bonnet contest; that is, all the machines taking part in the contest were completely equipped before the start, and then seals were affixed to all operating parts. The contest consisted of a run over a more than 600 mile long route, accomplished without adjustment or repairs of any kind, and lasted for four days. The outcome of the

contest shows that 41, out of 47 cars entering it, accomplished the feat of being driven the distance mentioned over good roads without suffering any derangement in their machinery. This is a remarkable showing, and a demonstration of the present reliability of modern motor cars. It is a result which is believed to have been unattainable one year ago, and which two years ago would seem to have been absolutely impossible. The mileage equals that which the average private car covers in an entire month, and is, in fact, in excess of the mileage which a locomotive or trolley car covers without being laid off for attention and repairs. But, of course, the result of the contest must not be understood to mean that 87 per cent of all modern motor cars are capable of covering 600 miles without adjustment or repairs, for the cars concerned in this test were of higher grade than the average, comparatively few of the lower priced cars having entered the contest. Nor can it be said to be a marked distinction for the 41 cars, out of the 47, that they accomplished the feat, or that they were of superior make to the remaining ones, for the element of chance in a contest like this is greater than in a contest of any other kind.

The conclusions reached are more as to the general reliability of motor cars as at present manufactured than in regard to the distinct superiority of the cars that accomplished the feat. One car, for instance, built by a company of established reputation, and known as being reliable, suffered the breakage of an inlet valve spring. It is hardly likely that the inlet valves of this engine were inferior to those of many of the other cars, or that in this engine there would be, in say 10,000 miles of running, any more broken valve springs than in the other cars in the same period of service. It would therefore be unjust, indeed, if any one draws the hasty conclusion that because a particular car has been unsuccessful in this contest, it is necessarily inferior to any of the successful ones. A good showing for the automobile was that in only two instances were cars crippled by the breakage of any essential part, and in one of these cases the breakage happened after due warning. The final conclusion of the sealed bonnet contest, for this reason, is simply that it furnishes the strongest vindication that we have ever had of the adaptability of motor cars in general, but that it throws no certain light upon the reliability of different makes. If another contest of this sort is ever run, it is obvious that much harder roads will have to be selected, and the contest must be prolonged greatly in regard to mileage.

STANDARD GERMAN TAPER SHANKS.

Zeitschrift für Werkzeugmaschinen und Werkzeuge,
July 15, 1907.

Since a long time back the Association of German Machine Tool Manufacturers has been endeavoring to establish a standard system of taper shanks, based on the metric system, to replace the Morse system, which on account of its irregularities and its basis of English measurements is not considered desirable in Germany. With the exception of a few machine tool builders who fear the effects of such a move, particularly on their export trade, the proposition has met with favor not only on the part of machine tool manufacturers, but on the part of their consumers as well, and many governmental officers and state railway shops have pronounced themselves in accord with the movement for a metric standard taper shank, based on a constant taper for all sizes. The difficulties that necessarily must follow the introduction of a new standard are duly appreciated, but the final gain is expected to be great enough to outweigh the unfavorable influences. The introduction would be gradual, and thus cause as little disturbance as possible.

The taper of the proposed standard is *one in twenty* or 0.6 inch per foot, which, in fact, is the same taper as proposed by Mr. Oscar J. Beale in the Jarno taper system, and also the same as in one of the Morse standard tapers, the No. 1. In the accompanying tables are given the dimensions for the proposed standard system of taper shanks, both with and without tang, and the dimensions for the hole in the socket. All dimensions are in millimeters. The first four sizes, Nos. 1 to 4, correspond closely to Nos. 1 to 4 Morse standard taper. From and including No. 5, the system is based on the formulas given, but the *first four sizes do not conform to these formulas.* No dimensions have been given in this standard system for unessential details, such as the radius of the cutter for milling the tang, etc., as this was not considered necessary.

THE WORKING OF LARGE GAS ENGINES.

Times Engineering Supplement.

At a meeting of the British Society of Engineers, Mr. George Moore read a paper dealing with the working of large gas engines. It was pointed out that while the use of large gas engines had increased remarkably during the past few years, very little information had been given as to the characteristics and behavior of these engines while in operation. Continental engines are divided by the author into three different types: the double-acting 4-cycle type, the Oehelhaüser and Körting types. The Körting and Oehelhaüser engines possess the advantage over the Otto cycle type that there is no need of water cooled exhaust valves. The thermal and mechanical efficiencies of the Körting type, however, are comparatively low. Trouble has arisen in this engine, as well, in regard to the piston, owing to its great size and weight, and certain designers make a piston in three pieces to overcome certain difficulties in this respect. The complicated form of the cylinder head of the Körting engine renders it liable to crack, and experience has shown that the greatest wear takes place in the middle of the cylinder near the exhaust ports. Gas engine designers are still in doubt about whether it is expedient to chamber the tail rods, and practical experience seems to bear out that the tail rod itself is not of any great advantage on engines of less than 500 horse-power. In the actual running of large gas engines it has been found that one of the most persistent troubles is the liability of pre-ignition, and with large engines having cylinders of about 24 inches in diameter, pre-ignition is never entirely absent when using producer gas. The author's experience is that Mond gas is satisfactory for larger engines if reasonable care is taken. Gases containing a high percentage of hydrogen are not very suitable, because the hydrogen ignites at a comparatively low temperature, and a high percentage of this gas is liable to cause pre-ignition. The question of the value of positive scavenging has not, as yet, been settled in regard to the four-cycle type of gas engines. In regard to various methods of governing, it is pointed out that the by-pass governor valve, commonly used on the Körting engine, does not work satisfactorily with producer gas.

POWER REQUIRED FOR MILLING MACHINES.

S. Streiff, in *Werkstatts-Technik*, January, 1907.

The following experiments for finding the power required for driving milling cutters have been carried out on a special milling machine. The results are given in the accompanying table. Only the results of such experiments where the power required was determined definitely are taken into consideration. A number of experiments, where either the time

of cutting was insufficient to get a good average, or where some other disturbing factor entered in the experiment, have been left out of consideration. The milling cutters used were made from high speed steel. It will be seen from the table that a proportionally higher amount of power is required for light milling than for heavy, a result that is rather natural, as the running of the machine itself, irrespective of the work being performed, would require practically the same amount of power in either case. It will also be seen from the table that the depth of the cut does not increase the power required in the same proportion as does the width of the cut, and that work with a heavy feed and a deep but comparatively narrow cut requires far less power for the amount of metal removed than does a slow feed, and a cut of moderate depth, but wide. In general it seems as if a slow feed is particularly uneconomical in the use of the milling machine. The figures in the table have been transformed into the English system of measurements, to facilitate comparisons.

PRECISION GRINDING.

Paper by H. Darbyshire, read before the Engineering Conference of the British Institution of Civil Engineers.

Speaking comparatively, the gratifying advantages that may be obtained from the use of high speed steel are limited to a certain point, that point being where a fractional quantity of material must be left, and extreme care exercised in arriving at the precise dimensions. For this final finishing I claim that the grinding machine is the most rapid and economical tool to use, for the following reasons: It removes this fractional amount of material in the shortest comparative time; it arrives at the desired dimensions by a series of rapid and minute chips which cover the whole surface repeatedly, and whose depth is under perfect control; any variation in its shower of sparks is instant and visible evidence of its change of form, either through distortion or accident; and, finally, it allows of the actual surface finisning being the last operation, thereby removing all those errors and distortions which are a result of keywaying or other operations. To those who are not conversant with the more modern development of the grinding machine, the first of these reasons may appear an exaggeration; but an inquiry into what is being done in the matter at the present time will only serve to substantiate the statement. For the correcting of hardened work it has long been considered a necessary part of the engineer's equipment, but its use for general finishing purposes has been, and is still, considered by many to be indulging in a luxury.

As instances of the amount of stock which may be removed by a modern grinding machine, I may quote the following examples of work done: Several cast-steel bars, 10 feet in length and 1 15/16 inch in diameter, were reduced 0.080 inch in an average time of 75 minutes, the greatest variation in diameter being 0.0004 inch. A chilled-iron roll, 4 feet long and 17 inches in diameter, was reduced 5/16 inch in diameter in 7 hours. A cast iron roll, 4 feet by 6 1/16 inches, was reduced 1/16 inch in diameter in 25 minutes, the greatest variation being 0.0005 inch. These examples will convey some idea of the amount of material which may be removed in a given time by a grinding wheel; and in the first two examples it was found more economical to grind outright from the rough black bar and casting than to turn and grind. I find the leaving of a grinding allowance of 0.015 inch to 0.030 inch on the diameter to be the most economical for general work. These broad limits allow the lathe hand to use coarse feeds and work rapidly. In order to keep within these limits, rough tolerance gages are desirable, for if the maximum amount given be exceeded, waste of both grinder's time and abrasive material must ensue. The fact that a ground surface is superior to that produced by a file or water-cut is indisputable, and the rapid manner in which a fixed dimension may be obtained is a further recommendation; that the result is effected by a series of minute chips with a visible index of their depth is another point in its favor. In order to start a finishing cut in the lathe and control its size, the length of its traverse requires a sense of touch which may have taken years to attain; to obtain a similar result, but a better surface in the grinding machine, is an easier matter, because another sense is enlisted, and the work is simplified. Given a few days' practice with a grinding-machine, an operator can judge to 0.001 inch the depth of the cut he is taking, by the shower of sparks displayed. In actual practice, where accurate results are necessary, the following points must receive attention. The first in importance is that there must be an abundant supply of water delivered at the grinding

point. Secondly, hard bonded wheels should be avoided, as they do not cut freely, and may well be compared to a dull milling cutter; they are mostly chosen through mistaken ideas of economy.

Where a high degree of surface finish is required for appearance only, the grinding machine is superior to hand labor, for various reasons; it is more rapidly done, and leaves a surface more uniform and pleasing to the eye. This latter recommendation may seem a trivial one if we fail to remember that this method of finishing secures the most accurate results; it yields cylindrical work which is both truly round and concentric with the center points on which it is held, and this is always an advantage. Again, in the finishing of plane surfaces the easiest method of holding the work to the machine table is that which will give the most precise results; thus a slide or similar body would be outwardly finished by clamping its scraped and finished ways to packings ground in position. This insures absolute truth of outer alignment, which would be of great value to the operator of the future built-up machine, and its beauty of finish would probably be a means of insuring his care that its accurate condition be maintained. The great advance that has been made in grinding practice recently has been mostly in work of cylindrical form, and for this purpose its claims to attention are undeniable. Personally, I see no reason why the same advantages cannot be obtained in the grinding of plane surfaces with a suitably designed machine.

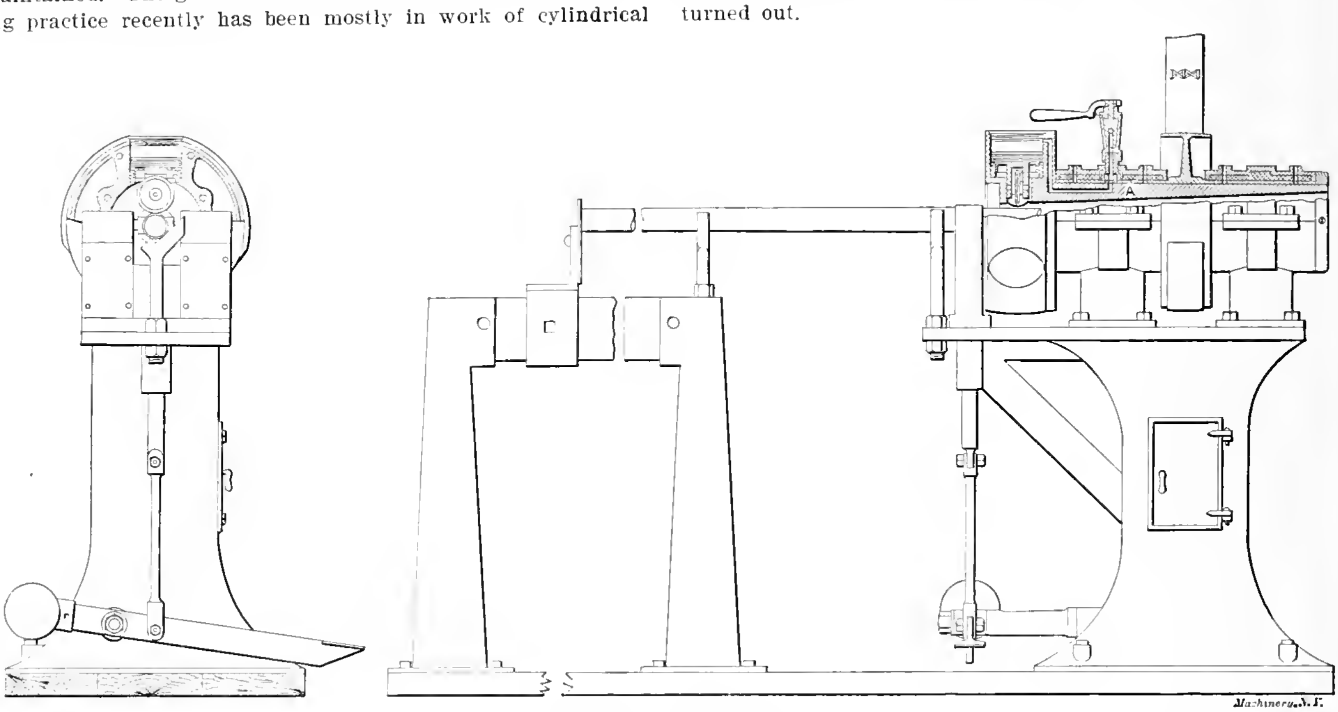
PNEUMATIC TUBE AND PIPE CUTTER.

Railroad Gazette, August 2, 1907.

A pneumatic tube and pipe cutter of interesting design is used in the shops of the Seaboard Air Line at Portsmouth, Va. This machine can be easily operated by one man, and can cut three two-inch locomotive tubes per minute with an air pressure of 50 pounds per square inch. If the air pressure is increased, the machine will perform its work even more rapidly.

The machine consists of a sleeve *A* turning in long bearings and driven by a pulley keyed near its center. At the end of the sleeve is an enlargement containing three cylinders to which pistons are fitted. These cylinders stand on radial lines and the pistons have roller cutters attached. There are ports through the sleeve, as shown, that lead to the outer end of the cylinders, through which air is admitted by means of a three-way cock. Stops for the tube and Y-supports are provided beyond the end of the machine. After the machine is started the tube is placed in position to be cut, resting on the supports and shoved back against the stop. It is clamped by pressure on the pedal shown, and the handle of the three-way cock is turned to admit air to the outer ends of the cylinders. This forces the pistons in and the cutters against the tube. As the circular head revolves the cutters roll around the tube and are forced in, and cut off the piece in a few revolutions.

The piece cut off passes out at the back end through the hollow tapered spindle. When the tube is cut, the air valve is moved to exhaust, and the cutters open by centrifugal force to receive another tube. As the tube is clamped by the pedal it can be fixed and released instantly without loss of time, and as the tube does not revolve, the machine is practically noiseless. In addition to these advantages the boiler maker does not have to mark each tube where it is to be cut, as the length is fixed by the adjustment of the stop. The cutters are of steel, ⅛ inch thick and 3 inches in diameter. One set of cutters in the Seaboard Air Line shops has been in service for four months and has made 24,000 cuts, without grinding, on 2-inch tubes, approximately ⅛ inch thick. Previous to building this machine, the number of engines that could be turned out of the shop was dependent on the tube work; but since its installation the amount of tube work to be done is not considered in deciding upon the number of engines to be turned out.



Pneumatic Tube and Pipe Cutter.

PREPARATION OF ENGINEERING ARTICLES AND TECHNICAL PAPERS.

Proceedings, American Society of Mechanical Engineers, October, 1906.

In preparing an article for publication, or for presentation before a professional society, there are some general principles, the observance of which will add greatly to the value of the work. These principles do not relate to the subject matter directly, but rather to the manner of presentation. In the first place, as a paper generally does relate to some especial department of work with which the author has had experience, he is very apt to assume many things as matters of common knowledge, when in fact they are not nearly so familiar to most of the readers as they are to himself. It is not usually a mistake to be too clear, or too definite, particularly in the preliminary statements. If, therefore, the author avoids undue assumptions as to the familiarity of his readers with the subject in hand he will add greatly to the value of his statements. The rules to follow for the presentation of the subject itself may then be given as follows:

State first, in a brief and clear manner, just what the article is about, what the author is endeavoring to show, or what he expects to prove. This introductory statement should be *very brief*, and having been made, it should be kept in mind throughout. A paper should be about but one thing at a time, and that one thing plainly stated at the start.

Then should follow the general treatment; description of work, of experiments, of opinion, etc., this portion constituting the matter usually forming the body of technical articles or papers.

After this should come what may be called "proof," that is, a statement showing how the general matter immediately preceding has demonstrated what the author set out to show.

Finally there should come a very condensed summing up, in such a form that a brief glance would enable a casual reader to grasp the substance of the article, and decide without reading the whole, whether or not he wants to examine it in detail.

The introductory statement, and the final conclusions, should in every case, enable the reader to get at the kernel of the whole matter, of which the bulk of the article should be the detailed and expanded treatment.

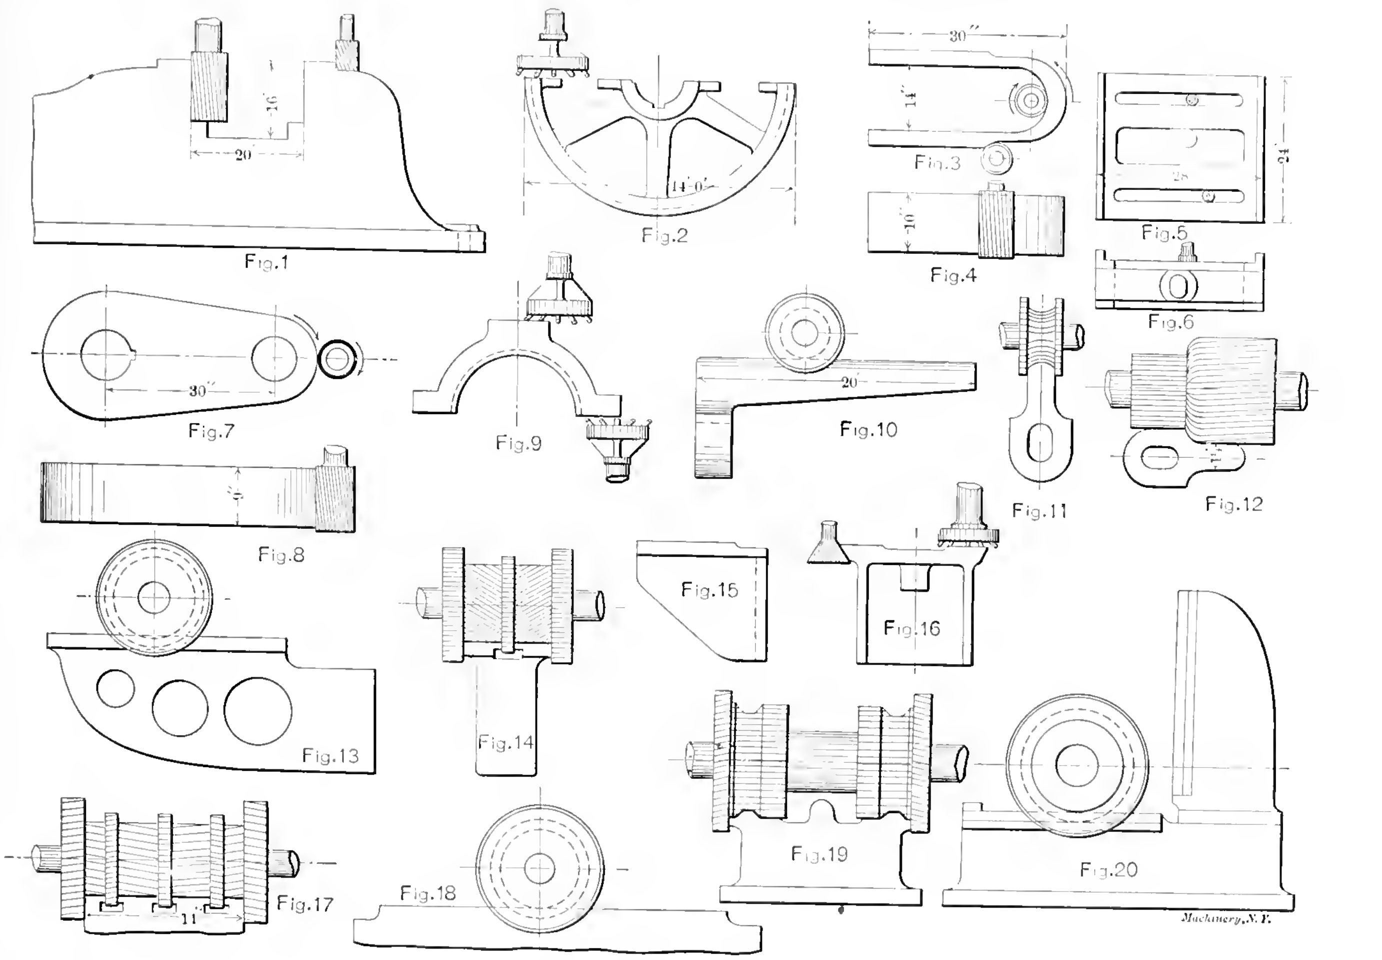
The following rules should be adhered to in regard to the mere mechanical preparation of copy for publication. Write plainly, on one side of the paper. Number the sheets consecutively in the upper right-hand corner, and have them of a uniform size. Put full name and address on all manuscripts. All sketches, drawings and tables should be made on separate sheets of paper. In selecting photographs or making photographic prints for illustrations, it should be remembered that the glossy solio prints are better suited for reproduction than velox, or other matted surface paper; besides, they bring out all the detail in the negative to the best advantage. Photographs should not be printed too deep, and the reproductions are better made from prints of a slightly reddish tone than from those over-toned to a bluish tint.

All copy intended for illustrations should be clearly marked with the title, subject and author's name, a reference to the manuscript to which it relates, and all other data of interest. This had better be written on the back in pencil; ink is apt to show through, especially when written on the back of light portions of a photograph. If the illustrations be many, a list of them, giving their titles in brief, should properly accompany the manuscript.

THE RELATIVE VALUE OF MILLING AND PLANING.

Walter Duckitt, in *The Engineering Review*, July, 1907.

The relative merits of milling and planing processes is a subject which has received the attention of some of our most capable engineers and machine tool builders during the past few years. Speaking broadly on the question, it must be admitted that the field of operation of the planer is comparatively small compared with that of the miller, the latter machine having developed, during recent years, to such an extent as to bring it into the front rank of machine tools, and to render it an indispensable acquisition to the shops. It has by no means, however, displaced its older rival, the planing machine, which has to be considered in its redesigned and appropriately named "high speed" type. One of the chief and most advantageous features of the planing machine is the comparative cheapness of its cutting tools and general equipment, as compared with those required for its more modern competitor, the miller. The former, when belted up, can generally be set to work at once, as any tool smith can easily forge the general run of cutting tools that are required, whereas, in the case of the miller, a large equipment of cutters and fixtures is required, sometimes amounting in value to a thousand dollars or more.



Examples of Milling Operations.

The milling machine, therefore, in some respects, is at a disadvantage as compared with the planer, namely, that whereas the former requires a good tool-room to keep its equipment in thorough order, a tool smith and a simple grinder suffice for the latter. Even with this to be said in favor of the planer, however, it must not be taken that it scores as heavily as at first appears in the matter of cost of equipment, as most of the leading brands of high speed cutting steel now on the market are very expensive, and in a full set of tools for a planer, therefore, there is a large amount of capital sunk in the weight of steel alone, to say nothing of the labor.

Milling machines which enter the field of competition with the planer may be classified under vertical and horizontal types. Of the horizontal spindle type there is the small hand

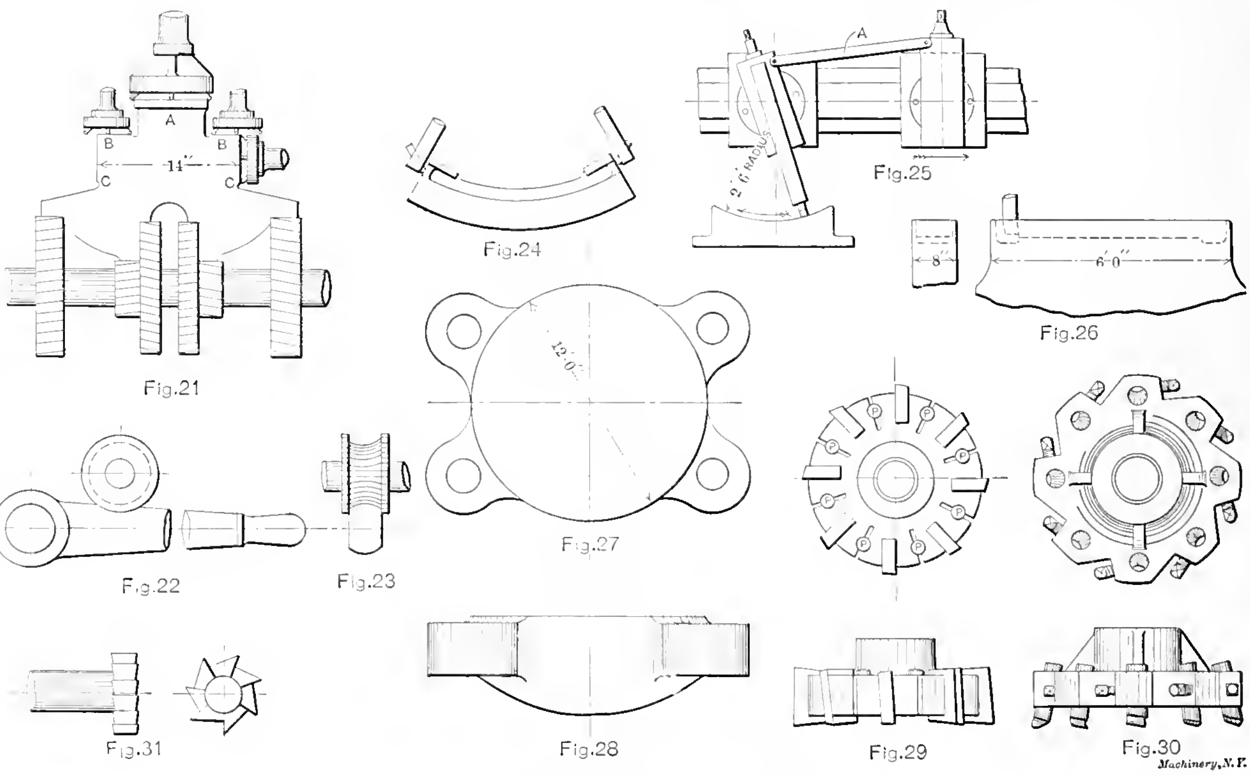
feed class, which can scarcely be said to come into actual competition with the planer, except for milling keyways into shafts, spindles, etc., which, if of any length, was formerly done entirely on planers. For keyway cutting, the milling machine may fairly claim to have scored heavily, and of late years has taken this class of work entirely off the planers, as with the latter machine a highly skilled man is required to cut the keyway to its proper dimensions, whereas with a miller, all that is required is a simple keyway cutter of the required width, and the only dimension the operator has to watch is the depth. A comparatively unskilled, and, therefore, much lower rated man can accomplish this.

Coming to the Lincoln type of miller, this machine is chiefly used for manufacturing operations of the medium and light trades, such as automobiles, small arms, sewing machines and bicycles; indeed, it is in a great measure due to this type of machine that these trades have developed to their present magnitude, enabling the various small operations to be performed by cheap labor by the aid of jigs and fixtures, coupled, of course, with good supervision. A very large variety of operations can be performed on the Lincoln miller for a mere fraction of the cost that would be involved were a planer used.

correct radius as shown. These levers are milled on both edges in exactly fifteen minutes each, at a cutting speed of 46 feet per minute, and a table feed of 3 inches per minute. Of course there is not much to remove, but it would take a planer at least one and one-half hours to perform the same piece of work to a very indifferent finish.

Figs. 17 and 18 show a gang of cutters operating on a plain milling machine table. The two outside cutters finish the table to width, the four small cutters operate on the top of the table, while the three narrow cutters finish the T-slots to width, leaving them to be finished with the T-slot cutter, Fig. 31, on a vertical machine. The gang cutters when not used for the job, are stored away complete with their arbor, because, if used singly on general work, they would lose their size, owing to the necessity for constant grinding and resharpening. This is a very important item with expensive gang cutters, which should be borne in mind. It formerly took twelve and one-half hours to plane up this table; it is now milled in four hours at a cutting speed of 35 feet per minute and a table feed of $1\frac{1}{4}$ inch for the roughing and $1\frac{3}{4}$ inch for the finishing cut.

Figs. 13 and 14 show a planer housing arranged to be gang milled on the face on a heavy horizontal slab miller of



Examples of Milling and Planing Operations.

We then come to the upright plain miller with overhanging arm for support to the cutter arbor and adjustable knee or table support. These machines are adaptable to a wide range of work to which the planer formerly claimed a monopoly, effecting, in the majority of cases where they are employed, a very considerable economy.

Examples of Saving Afforded by Milling.

A very good example and typical piece of work suitable for either the Lincoln or upright plain types is the forged steel cotter shown in Figs. 10, 11 and 12. Machined all over for the connecting-rod ends of a large stationary Corliss engine, this is a difficult piece of work to perform on the planer, due to so many curved surfaces and radius corners for forming the head. It formerly took nine hours to plane, and then only resulted in a very imperfect job, necessitating several hours filing and fitting to finish it. A boy now completes it in a miller in $4\frac{1}{4}$ hours, representing a clear saving in labor cost of over 250 per cent. Another example of milling suitable for the Lincoln and upright plain type of machine is the brake lever for an automobile shown in Figs. 22 and 23. This is a mild steel stamping, with round edges, 2 feet 6 inches long, formed with a simple form cutter of the

the Ingersoll and Newton types, at a table feed of $2\frac{1}{2}$ inches per minute. This is done with about 60 per cent economy, as compared with the planer. Figs. 19 and 20 show a very excellent piece of work done on a heavy slab miller. The work is a bed for a gear hobbing machine, only four cutters being required for the operation, including the finishing of the sliding ways for the table on each side. These ways are completed with the two form cutters shown, spaced the exact distance apart, which is a very vital point, and saves a lot of bedding when fitting the table. The latter is also gang milled, with suitable cutters, to fit on the ways. The housing shown in Fig. 20, and also the head for carrying the cutter spindle, are milled in a similar manner. Fig. 1 shows the crank-shaft end of a large stationary engine bed, the adjustable bearing gap being milled out to size by a large and extremely powerful machine of the milling and boring type. The cutter is fed to the work, the latter remaining stationary; the bed end is milled complete for the bearing and cap in ten and one-half hours, a performance that would be very difficult to duplicate on a planing machine, however powerful.

Fig. 2 shows part of a large rope driving fly-wheel, cast in halves, being milled across the joint in the same machine with an inserted tooth cutter. In this case also a great

saving is effected as compared with the planer. The latter machine has to travel across the entire face, and thus fully 75 per cent of the stroke is wasted, as reversals and very short strokes on heavy planers are not to be recommended; whereas with the miller, only the surfaces actually operated on are traversed. The keyways are also cut at the same time with an end milling cutter the same diameter as the width of key, and thus much time is saved in that direction also. Fig. 9 shows an eccentric strap being milled in the same manner, at a great saving compared with planing.

The vertical spindle miller has been developed to include a large field of operations from keyway cutting up to work of very large dimensions. Figs. 3 and 4 show a large forged steel strap for a connecting-rod, milled all over on a vertical spindle machine. The top and bottom are milled first with inserted tooth cutters, the strap being then finished inside and out, in the manner shown, at a cutting speed of 45 feet per minute and a feed of 2 inches per minute. The time taken is now twenty-one hours, whereas formerly, to plane and slot these straps took twenty-nine hours. Figs. 5 and 6 show a large double-ported slide valve, the ports of which are milled to size in a vertical spindle machine, after the valve has been planed all over, on a high speed planer, cutting at 35 feet per minute. This is an instance where both the planer and the miller can be used to advantage on the same piece of work for different operations, as it has been found that, excepting the port holes, these pieces can be planed cheaper than milled.

Figs. 7 and 8 show two large steam engine cranks of forged steel, planed top and bottom, and then finished all round on a large vertical spindle machine with a circular milling attachment. This machine has two spindles, the crank shaft and pin holes being bored both at the same time after the milling is completed, thus saving the time of extra handling, no small item where heavy weights are involved. Figs. 15 and 16 show a knee or table support for a milling machine, being milled on a vertical spindle machine, the angular cutter operating on the sides as shown. In Fig. 21 one of the most remarkable examples of milling is shown. It consists of an aluminum crank case for a 30 H.P. motor car engine, 2 feet 6 inches long. The top face marked *A* is first milled, the faces *B* being operated on at the same setting. The surface *A*, is then bolted against an angle plate, and the cam shaft cover faces *C* are completed. The cutting speed is 580 feet per minute, and the feed 10½ inches per minute. The case is then taken to the slab miller, and the bottom milled out complete with gang cutters as shown. These engine cases, which formerly took twelve hours to plane, are now milled in 5 hours. The milling machine is far better adapted for working aluminium than the planer, because of its having a much wider range of speeds and feeds.

The universal milling machine can fairly claim to be the king of millers, if, indeed, not of all machine tools, but being chiefly designed for tool-room work, it can scarcely be said to enter the field of competition with the planer. American tool makers, especially, have paid particular attention to this type of machine, and it is chiefly due to their efforts that it has reached its present high state of perfection.

Examples of Work More Advantageously Planed than Milled.

The design of the planer has, however, been much modified during the past few years, chiefly due to the advent of high speed steel. Whereas a few years ago it was considered good standard practice to work at a cutting speed of 20 feet per minute, and return at 40 feet, it is now no uncommon thing to see planers cutting at 40 feet, and in some cases 50 feet per minute, and returning at 200 feet per minute. Machines of this type can, on certain work, hold their own against the milling machine, and on this account will continue to keep up their established position in the shops. More particularly does this apply to the heavier branches; for instance, an example is shown in Fig. 24, which represents a segment of a large rope-driving fly-wheel rim being operated on at both ends at the same time by two saddles on the cross-slide. Eight of these segments—sufficient to build a wheel—are placed in a row on the machine table, being thus planed all at one setting, thereby ensuring extreme accuracy, cutting at 25 feet per minute and returning at 50 feet, using high speed tools. This is a very heavy piece of work which no milling machine could perform in the time taken to plane them. Fig. 25 shows a very interesting piece of work in the shape of a former plate, 10 feet 6 inches long, for a vertical plate bending machine, being planed out to a radius of 2 feet 6 inches in the manner shown. The left-hand tool box is set centrally above the work and the swivel head-bolts slacked; the saddle is then locked in position, and the rectangular bar, *A*, is connected to both the tool boxes. The right-hand tool box then commences to travel in the direction shown by the arrow, and by so doing drags the cutting-tool through the required arc. This is a job which no milling machine could accomplish satisfactorily with such primitive equipment.

Fig. 26 shows the slides of a horizontal engine which are planed to advantage, as milling cutters cannot be got in at the end, owing to insufficient clearance. Figs. 27 and 28 show a large hydraulic press top cover weighing 50 tons, which is planed on a large machine operating four cutting tools at the same time, two in each tool box on the saddle. There has not yet been found a quicker method. The concluding sketches, Figs. 29 and 30, show two types of inserted milling cutters for use on heavy milling machines. Fig. 29 is a type largely used on vertical spindle machines; the cutters are given 5 deg. forward rake, and are held in position by the taper pegs, *P*, driven into holes, which are gashed through with a slitting saw as shown, to give the necessary spring under the wedging action. This cutter gives good results, if ground accurately, on certain classes of work, but is more expensive to make than that shown in Fig. 30, which has simply round cutters secured by screws. The holes for carrying the cutters are not bored with any forward rake, that being ground on the cutter itself. This type of cutter is largely used on heavy rough work and also in smaller sizes on aluminum, where it scores heavily over the flat-tooth variety. The latter is not designed to allow of sufficient clearance on the bottom which is absolutely necessary on aluminum, otherwise the chips get under the cutters and produce a very rough finish on the work.

Weighing the profit-earning qualities of the planing and milling machines, it is generally conceded that the miller predominates, but at the same time, the planer still leads, on certain classes of work, such as long straight surfaces, plate edge planing, and lathe-bed planing, more particularly on the larger sizes, also planing the slides of their own beds, as well as tables, etc. It may safely be concluded that although the milling machine is pre-eminent, the planer will always find favor on certain classes of work.

* * *

MEASURING SCREW THREAD DIAMETERS.

WALTER CANTELO.*

It is always advisable when measuring screw thread diameters to measure them in the angle, in addition to testing their diameter on top of the threads and at the bottom of the thread groove, but unless calipers made expressly for the work are at hand, the measurement in the thread angle is apt to be omitted. The tables in the supplement were worked out by the writer in 1902 for convenient application in the inspection of screw threads in connection with ordnance inspection for the United States army. The method is known as the three-wire system of screw measurement, because three wires, of the diameter called for in tables, and applied as shown in the diagrams in the supplement, are used in connection with an ordinary flat point micrometer. The dimensions for the standard threads of the systems shown are given in the tables mentioned. For threads of special size or pitch, the values for the various thread parts are easily computed from the formulas given for the kind of thread under consideration It is especially necessary that the wires used be as nearly round in section as possible, and of uniform diameter.

Two methods of measuring are shown for the 60-degree V, U. S. standard and Whitworth threads, and for each method a formula and table of values are given. The three-wire method

* Address: 1181 Noble Ave., Bridgeport, Conn.

is preferred by the writer, because the error in the thread groove—if any be present—is taken into consideration twice, while by the single-wire method errors are liable to be introduced by the surface on top of the threads not being exactly concentric with the thread groove. It is evident that for each of the threads the wire to be used in any thread groove is limited in regard to diameters as follows:

The 60 Degree V Thread.

Maximum diameter of wire $= \dfrac{p}{0.866} = 1.155\,p$, if p equals the pitch of the thread.

Minimum diameter of wire $= 0.577\,p$.

The U. S. Standard Thread.

Maximum width of thread groove $= \frac{7}{8}\,p$.

Maximum diameter of wire $= \frac{7}{8} \times \dfrac{p}{0.866} = 1.010\,p$.

Minimum diameter of wire $= \frac{7}{8} \times 0.577\,p = 0.505\,p$.

The 55 Degree Whitworth Thread.

Let $p_1 =$ distance across thread groove at point where radii are tangent to angle.

Radius on thread $= 0.1373\,p$, and arc forming top of threads contains 125 degrees.

Then $p_1 = p - 2 \sin 62° 30' \times 0.1373\,p = p - 2 \times 0.887 \times 0.1373\,p = p - 0.243\,p = 0.75\,p$, approx.

Maximum diameter of wire $= 0.75 \times \dfrac{p}{0.887} = 0.84\,p$.

Minimum diameter of wire $= 5/6 \times 0.6068\,p = 0.505\,p$.

The dimension D_1 (see diagram in supplement) has to be considered for both the single-wire and three-wire methods and has values as follows:

For the 60 deg. thread: The depth equals $0.866\,p$ and as the apex of the thread angle and root of thread groove are at the same point, it follows that $D_1 = D - 0.886\,p \times 2 = D - 1.732\,p$ or $= D - \dfrac{1.732}{n}$.

For the U. S. Standard thread: The depth equals 6/8 of the 60 deg. V thread, being flattened on top and filled in at the root an amount equaling one-eighth of the V thread depth and the distance from the top of thread to apex of thread angle at root, therefore, equals $\frac{7}{8}$ of the V thread depth, or $\frac{7}{8} \times 0.866\,p$ and $D_1 = D - \frac{7}{8} \times 0.866\,p \times 2 = D - 1.5155\,p$ or $= D - \dfrac{1.5155}{n}$

For the Whitworth 55 deg. thread: The depth equals 4/6 of the 55 deg. V thread depth, being filled in at the root and cut away on top an amount equaling 1/6 of the V thread depth. The depth of the 55 deg. V thread would be $0.96045\,p$ and the distance from top of Whitworth thread to apex of thread angle at root equals $5/6 \times 0.96045\,p$ or $0.8004\,p$ and $D_1 = D - 2 \times 0.8004\,p, = D - 1.6008\,p$, or $= D - \dfrac{1.6008}{n}$.

From the foregoing it will be seen how the formulas $x = D_2 + 2b + a$ for the three-wire system, and $x_1 = \dfrac{D}{2} + \dfrac{D_2}{2} + b + 2a$ for the single-wire system are produced, and also, it will be readily seen how easily the formulas $x = D - \dfrac{1.732}{n} + 3\,a$ for the 60 deg. V thread and $x = D - \dfrac{1.5155}{n} + 3\,a$ for the U. S. Standard thread, as given in the article by E. A. Johnson in the January, 1907, issue of MACHINERY, may be arrived at.

The Acme 29 Degree Screw Thread.

For this thread I prefer to use a separate wire for each pitch, of such diameter that when laid in the thread groove of the tap or thread plug gage, it will be flush with the tops of the threads when they are of correct dimensions, and when laid in the thread groove of the screw it will extend 0.010 inch beyond the tops of the threads.

The Brown & Sharpe 29 Degree Worm Thread.

For this thread also I prefer to use a separate wire for each pitch that will be flush with the tops of the threads when laid in the finished thread groove.

NICKEL STEEL.*

E. F. LAKE.†

Nickel steel is used to a large extent in the construction of high-grade machinery, and can be purchased in the open market, to-day, in almost any percentages of nickel from nothing up to 35 per cent, and with the carbon component varying between 0.10 and 1.00 per cent. Thus it covers a wide field of usefulness in which greater strength, wearing qualities and other properties are demanded, than can be obtained in the ordinary carbon steels.

Nickel Prevents "Sudden Rupture."

Nickel was added to carbon steel as the result of investigations which were started for the purpose of overcoming the "sudden rupture" that is inherent in all carbon steel product. This property or tendency of carbon steel to rupture is the subject of numerous investigations by the railroads of the country at the present time, owing to the many accidents that have occurred in the past few years being blamed to broken rails. Nickel added to steel largely overcomes this tendency, and we see it used successfully for parts of machinery that have to withstand high shock and torsional tests, such as the crank-shafts and connecting-rods of explosive

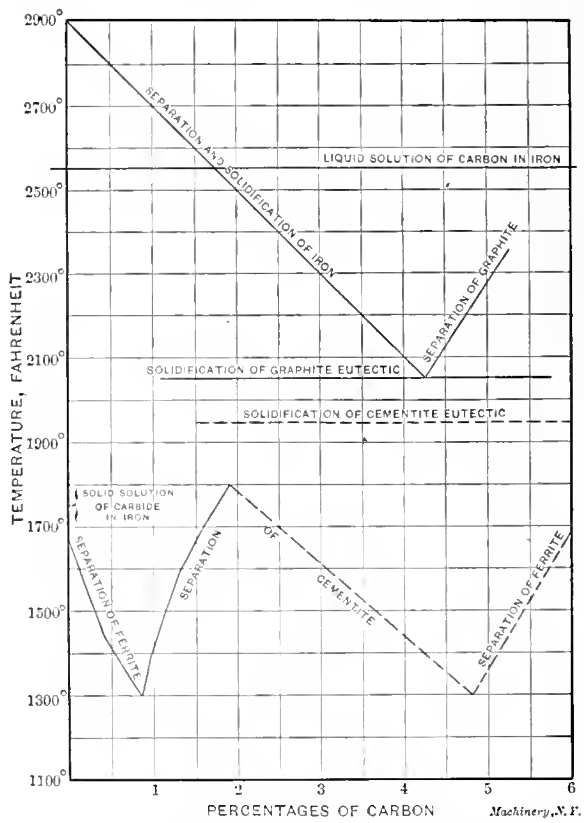


Diagram of Characteristics of Nickel Steel.

engines, propeller shafts for marine and automobile use, and other parts of a similar nature which have to withstand similar strains and stresses.

Effect of Nickel Not Uniform.

Nickel gives to steel one peculiar property, in that it can be added in percentages up to 8, and the tensile strength and elastic limit will be raised by so doing, but in percentages from 8 to 15 these become nil, as a zone of brittleness is produced and no tests can be applied, but at 16 per cent the strength and elastic limit are returned, and from there on these gradually decrease, while the extensibility increases.

Beneficial Effects of Nickel in Heat Treatment.

The qualities of carbon steel are susceptible of change by heat treatment the same as alloy steels, but the higher the carbon content is, the more liable it is to burn and thereby reduce its strength, and it is extremely difficult to case-harden steels which contain more carbon than does mild steel with-

* For additional information regarding the manufacture and characteristics of this and kindred steels, see the article in the July, 1907, issue of MACHINERY: Nickel-Chrome Steel, and previous articles referred to in the same issue.

† Address: 414 Crane St., Detroit, Mich.

out destroying their good qualities and strengths. By the addition of nickel the tendency to burn is largely overcome, and the extent to which it can be swayed by heat treatment is remarkable. This is best illustrated by Table I in which the steel was given different degrees of hardness. Its composition was as follows:

Nickel, 3 per cent; carbon, 0.30 per cent; manganese, 0.40 per cent; phosphorus, 0.05 per cent; sulphur, 0.04 per cent.

TABLE I. STRENGTH OF NICKEL STEEL AT DIFFERENT DEGREES OF HARDNESS.

Hardness.	Tensile Strength, pounds per sq. in.	Elastic Limit, pounds per sq. in.	Elongation in 2 inches, per cent.	Reduction of Area, per cent.
Annealed..........	88,000	60,000	28	58
Medium Hard.....	130,000	130,000	20	6
Hard...............	220,000	190,000	12	37
Very Hard.........	225,000	225,500	8	19

A good quality, open-hearth, 0.30 per cent carbon steel, as received from the mill in the untreated state, shows the same strength as the untreated nickel steel in Table I, but it cannot be raised to much more than one-half of the strength of the nickel steel in its hardest state, and even then it is much more liable to fracture under shock tests.

What the Microscope Reveals in Testing Steels.

Steel subjected to different heat treatments shows different properties when examined under a microscope, and microscopy is becoming one of the methods of examining and testing different steels. If we take a piece of steel containing less than 0.85 per cent of carbon, polish it, attack it with a few drops of picric acid and examine it under a microscope, the results will be widely different according to its composition and the treatment it has undergone. In a piece of steel that has been cooled slowly, small dark masses will appear which are more numerous the closer the carbon is to 0.85 per cent, and for this percentage the small dark masses occupy the entire surface with alternate layers which are iron—called ferrite—the dark masses being called cementite, they being an iron carbide. When nickel is added to carbon steel, this latter element has the appearance of mother-of-pearl, and is called pearlite.

Nickel steel containing less than 0.85 per cent carbon is, therefore, composed of ferrite and pearlite, and the proportion of the former grows smaller as the carbon content is reduced. If the steel contains more than 0.85 per cent carbon it will show, and is composed of pearlite and cementite, and the cementite increases as the carbon content is raised. These pearlitic steels may also contain chromium and manganese.

Next heat this steel to 1,400 degrees F., or a dull red, and quench in water, then polish, attack with picric acid, examine under the microscope as before, and it will show extremely fine lines intersecting each other in the direction of the sides of an equilateral triangle. This constituent is called martensite, and is found in all carbon steels quenched in an active bath after heating to the above degrees.

If the temperature is increased to 2,200 degrees F., or a bright orange, and the steel quenched in a very cold bath, as, for instance, one that is made 32 degrees F., by a salt-and-ice solution, there appears, in addition to martensite, another component called austenite, and this is easily scratched with a needle.

Then if the steel is quenched, during its transformation or above this point, in an oil bath, or one of little activity, a component is obtained that appears jet black, and is very easily colored with picric acid. This is known as troostite.

Therefore by annealing or heating and quenching this steel we can change its components from troostite to austenite, martensite, or pearlite, or *vice versa*, and its condition is readily determined by the aid of a powerful microscope.

If we take a large piece of steel in which a microscopical examination always indicates martensite to be present in the surface layer, different constituents will be shown at a certain distance beneath the surface and often very close to it. These constituents are only slightly colored by picric acid and are known as troostite and sorbite. In this case the transformation is not as complete as in the small piece, and there has been a sort of partial return to the normal state.

Other Effects of Heat Treatment.

Other molecular changes take place in heat treating steels and some of these are governed by the carbon contents. These changes are shown by the accompanying diagram.

If certain steels are given the heat treatments as described above, the average blacksmith would try them with a file, and if the file bites as well as it did before heat treating he would throw the steel out as not hardened, yet transformations have taken place which would show by tests that the tensile strength and elastic limit have been raised while the elongation and reduction of area were reduced. In the case of the nickel steel of which Table I shows the test, these transformations have been given a range for strength—*i. e.*, from 88,000 pounds to 225,000 pounds per square inch—that would have been considered impossible a few years ago.

Thus annealing, hardening and tempering steel are resorted to for raising the tensile strength, elastic limit, and its ability to withstand shock and torsional tests, as well as to put a fine cutting edge on tool steels. For another example of this, a nickel steel containing silicon was heat treated as shown in Table II, and with the resultant strengths as shown.

Need for Annealing.

In heating treating steels for strength, and especially nickel steel, it should always be remembered that hardening by quenching produces internal strains which can only be removed or destroyed by tempering or drawing after it is quenched. Thus nickel steel cannot be used in its hardest state, and in which it has the highest tensile strength and elastic limit, for crank-shafts, connecting-rods or other parts of machinery that have to withstand similar strains and stresses, but the piece must be tempered, thereby reducing the strengths and increasing the elongation in order to reduce the brittleness as well as the internal strains caused by hardening. These internal strains may also be caused by forging, hammering, or working, and the best results will be obtained if the steel is annealed after each important operation.

Liability of Nickel Steel to Warp, Decarbonize and Crack.

Three things work to the detriment of nickel steel and should always be taken into consideration when hardening it. First it nearly always warps in quenching; second, it may be decarbonized in heating; and third, fissures and cracks might occur in quenching.

TABLE II. EFFECT OF HEAT TREATMENT ON NICKEL STEEL OF THE FOLLOWING COMPOSITION

Nickel, 2.51 per cent; Silicon, 0.26 per cent; Carbon, 0.33 per cent; Manganese, 0.43 per cent; Phosphorus, 0.023 per cent, Sulphur, 0.032 per cent

Treatment.	Tensile Strength, pounds per sq. in.	Elastic Limit, pounds per sq. in.	Elongation in 2 inches, per cent.
Quenched at 1600 F.................	225,000	208,000	4
" " " tempered at 600 .	215,000	201,000	6
" " " " " 800	190,000	150,000	9
" " " " " 1000 .	170,000	145,000	12
" " " " " 1200 .	155,000	125,000	14
" " " " " 1400 .	135,000	98,000	17
" " " " " 1600 .	104,000	65,000	24

There are several rules which can be followed to minimize the tendency of steel to warp in quenching. If a piece is cut from stock that has been subjected to some mechanical treatment, it is very liable to be deformed on being heated, and it is undeniable that of the deformations attributed to the hardening process, a large part is due to the heating which precedes quenching, and results from the use of metal which has been mechanically worked. To overcome this, the steel should be thoroughly annealed before it is machined to size, so that the metal will be in a state of repose, and even then the tools used in machining may cause depressions in the metal that will cause warping when it is hardened.

In quenching, the piece should be immersed in the bath in the direction of its principal axis of symmetry, so that the

liquid can cover the greatest possible surface, and it should never be thrown into the bath. Thus a shaft should be immersed vertically and a gear wheel perpendicular to its plane. The piece should also be agitated in the bath so as to destroy the coating of vapor which usually forms around the piece and prevents its cooling rapidly.

To reduce the tendency to decarbonize, it is necessary to provide against oxidation, therefore the atmosphere within the furnace must be kept as far as possible reducing, and the pieces must be prevented from coming in contact with the gases.

This can be done by placing the pieces in a protecting retort, or in using a metallic heating bath, such as one of lead.

Fissures or cracks which occur in hardening are caused by the different parts of the piece cooling unevenly, thus producing internal stresses of enormous proportions which sometimes produce brittleness and consequently fissures or cracks, as nickel ferrites have a lower degree of molecular cohesion than plain ferrites. These fissures may be prevented, by reducing the rate of cooling, in three different ways. One method is to cover water with oil from one inch to one inch and a quarter in depth. The second is to cool the pieces in a bath of a comparatively limited volume, so that the cooling is followed by a slight tempering, and the third is to withdraw the piece from the bath before it is completely cooled. This last requires considerable skill to obtain uniform results.

Nickel Steel Well Adapted for Gears.

Nickel steel is one of the best steels on the market for gears, when carbonized, as different tests have shown that 2 per cent of nickel added to the ordinary carbonizing steel will double, and in some cases more than double, the tensile strength after carbonizing, and these tests would prove that nickel steel should be used for carbonizing wherever the difference in price will warrant. It is from 2 to 2½ cents per pound higher than the ordinary carbonizing steel, but the greater safety in manufacturing, and a consequent decrease in the number of spoiled pieces, will largely overcome this difference in price.

If a 2 per cent nickel steel is carbonized so the surface layer contains 1 per cent of carbon, it will show pearlitic, when examined, but if a 7 per cent nickel steel is used it will show a surface layer that is martensitic with a core pearlitic, or, in other words, the periphery has the same constitution as if it had been quenched and hardened while the core was in the annealed state.

The different materials used in carbonizing have different effects as to the penetration of the carbon and the time required for a certain penetration.

But a general rule for the rate of penetration at different degrees of temperature is as follows, the time being eight hours:

F. Degrees of Temperature	Depth of Penetration.
1,300	0.000 inch.
1,475	0.0195 "
1,565	0.039 "
1,650	0.0625 "
1,700	0.08 "
1,750	0.110 "
1,800	0.125 "
1,850	0.165 "
1,900	0.195 "

Thus it will be seen that a rise in temperature of 150 degrees doubles the rate of penetration, and in one case a rise of 90 degrees has doubled it.

With the temperature held stationary at 1,850 degrees the speed of penetration is as follows:

Time	Depth of Penetration
¼ hour	....
½ "	0.02 inch.
1 "	0.31 "
2 "	0.40 "
4 "	0.50 "
6 "	0.80 "
8 "	1.20 "

The steel used for carbonizing should not contain over 0.2 per cent of carbon, and the manganese component should be low, as this has a tendency to produce crystallization in annealing, and cause brittleness.

The cement used should be of a definite chemical composition which does not act abruptly, such as 60 per cent powdered charcoal and 40 per cent carbonate of barium, and two rules might be followed in treating; one being to carbonize at 1,600 degrees F., cool to 1,400 degrees, and quench; and the other is to carbonize at 1,850 degrees, quench first at 1,650 degrees, and the second time at 1,400 degrees.

Nickel Steel Not of as High Grade as Nickel-chrome Steel.

Nickel steel is not of as high a grade as nickel-chrome steel or the newer vanadium steel, but it stands a good second to these, is about two-thirds the price, and is so much easier machined and forged than nickel-chrome steel that it is used in preference to the higher grades.

Care Required in Forging and Working.

In forging, great care must be taken to keep this steel at a high full forging heat and never hammer or roll it below this temperature, as cracks are then liable to occur. A great deal of talk is heard among the users of nickel steel about its cracking badly and being defective, and if defects occur in the bloom, they are pretty sure to show up somewhere in the finished product, but if the steel is properly rolled and forged these defects and cracks will not appear. Where carbon steel has been used for automobile axles and given way from fatigue, crystallization or other causes, heat-treated nickel steel has been substituted, and has given perfect satisfaction.

TABLE III. INFLUENCE OF DIFFERENT PERCENTAGES OF NICKEL IN NICKEL STEEL.

Per cent of Nickel.	Tensile Strength, pounds per sq. in.	Elastic Limit, pounds per sq. in.	Elongation in 4.72 in. per cent.	Treatment.
1 to 1½	78,000	48,000	18	water tempered at 1650° F.
2½ to 3½	97,000	82,500	15	medium hard.
2½ to 3½	80,000	68,000	20	" soft.
2½ to 3½	85,000	60,000	23 to 13	" hard, structural.
2½ to 3½	71,000	50,000	28 to 16	" so t, "
4½ to 6	102,000	74,000	15	hard, for strenuous work.
4½ to 6	121,000	107,000	12	" but annealed at 1600° F.
4½ to 6	88,000	63,000	20	medium hard
16 to 18	199,000	114,000	6	annealed at 1650°.
22 to 26	110,000	45,000	40	" " "
22 to 26	114,000	50,000	35	" " "
30	80,000	28,000	44	" " "

Proportion of Carbon Important.

We frequently hear the boast of different manufacturers that they use 2 per cent nickel steel for various parts of their machines, but this means nothing, as its properties depend as much upon the carbon content as on the nickel. To illustrate, one nickel steel that is largely used, and is the best for certain purposes, contains 2 per cent of nickel and 0.12 per cent of carbon. It has a high tensile strength and very little elongation, while another nickel-steel equally good for other purposes contains 2 per cent nickel and 0.9 per cent carbon, and gives a high tensile strength with a great elongation.

Table III shows the different percentages of nickel in steel turned out by one manufacturer, and their strengths under different treatments.

These steels have percentages of carbon ranging from 0.10 to 1.00 per cent, and those with the highest percentages of nickel are used mostly for valves, owing to their heat-resisting powers combined with a great strength. Sometimes from 1 to 3 per cent of chromium is added to these valve metals to increase the elastic limit and mineral hardness.

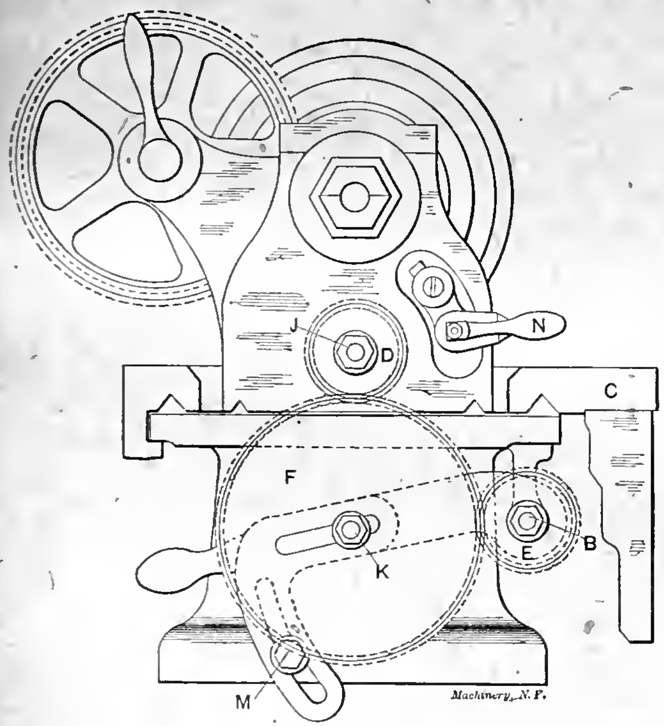
* * *

A contemporary, in describing a new form of electric meter, makes use of what it calls an "exploded view" of the apparatus. In this view the parts are shown slightly separated, thus giving a better idea of the construction of the device. Presumably, a charge of powder is supposed to have been set off beneath the apparatus, and the picture represents a snapshot taken about 0.0000001 of a second after the explosion. The expression is a graphic one, but it sounds very queer.

PUNCH PUNCH PUNCH PUNCH PUNCH PUNCH

SHOP OPERATION SHEET NO. 13.

Oscar E. Perrigo. MACHINERY, September, 1907.



To Cut a Thread having the Same Pitch as the Lead-screw of the Lathe.

1. Rotate the spindle of the lathe one revolution by hand, and observe the movement of stud J, to see whether it makes one revolution or one-half, per turn of the spindle.

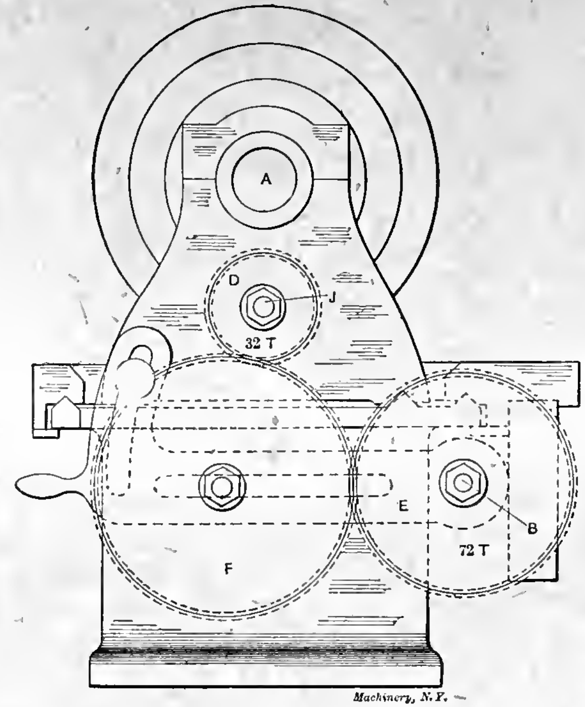
2. If stud J revolves one turn for one of the spindle, select from the set furnished with the machine two gears having equal numbers of teeth. Place one of them, D, on the stud J, and the other, E, on the lead-screw B. If the stud is geared to revolve at one-half the speed of the spindle, gear D on the stud must have twice the number of teeth possessed by gear E on the lead-screw.

3. Place on the intermediate stud, K, a gear F of any convenient number of teeth. Adjust it in position to mesh properly with gears D and E, and fasten it in position by the clamp screws or bolts at K and M.

4. With the nut on the carriage C thrown into mesh with the lead-screw, start the lathe up in the forward direction. If the carriage moves toward the headstock, the lathe will cut a right-hand thread of the same pitch as the lead-screw. If the carriage travels the other way, a left-hand thread will be cut. To change from right to left or *vice versa*, shift lever N, or make such other adjustment as is provided by the design of the lathe.

SHOP OPERATION SHEET NO. 14.

Oscar E. Perrigo. MACHINERY, September, 1907.



To Cut an 18-Pitch Thread in a Lathe having an 8-Pitch Lead-screw.

1. Observe whether the stud J revolves once for every turn of the spindle or for every two turns. If the latter, proceed as if the lead-screw were twice the pitch given, or 16.

2. Form a fraction having for the numerator the number of threads per inch of the lead-screw, and for the denominator the number of threads per inch to be cut. Reduce this to its lowest terms. Finding in Step 1 that stud J and spindle A are geared to run at the same rate, we have $8/18 = 4/9$.

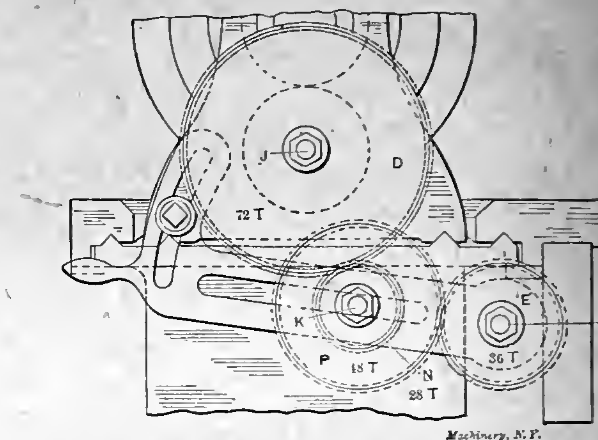
3. Find two gears from the set furnished with the lathe such that when one of them is used as the numerator of a fraction and the other as the denominator, this fraction, reduced, will equal that found in Step 2. Finding gears with 32 and 72 teeth, we have: $32/72 = 4/9$.

4. Place the first gear on stud J, as shown at D in the cut. Place the second gear on lead-screw B, as shown at E. Connect them by any suitable intermediate gear F.

5. To prove the correctness of the gears selected, multiply the number of teeth in gear D on the stud, by the number of turns per inch in the thread to be cut. Divide the product by the number of threads in the lead-screw, observing the rule given in Step 1 if the stud is geared 2 to 1 with the spindle. The result should be the number of teeth in the gear on the lead-screw, thus: $32 \times 18 \div 8 = 72$.

SHOP OPERATION SHEET NO. 15.

Oscar E. Perrigo. MACHINERY, September, 1907.



To Cut a 3½-Pitch Thread in a Lathe having a 6-Pitch Lead-screw, using Compound Gearing.

1. Observe whether the stud J revolves once for every turn of the spindle or for every two turns. If the latter, proceed as if the lead-screw were twice the pitch given, or 12.

2. Form a fraction having for the numerator the number of threads per inch of the lead-screw, and for the denominator the number of threads per inch to be cut. Reduce this to its lowest terms. Finding that the lathe in question has the stud geared 2 to 1 with the spindle, we form the fraction thus:

$$\frac{6 \times 2}{3\frac{1}{2}} = \frac{12}{3\frac{1}{2}} = \frac{24}{7}.$$

3. Next find four gears from the set furnished with the lathe, such that when the product of two of them are used for the numerator of a fraction and the product of the other two for the denominator, this fraction reduced, will equal that found in Step 2. Finding gears with 72, 48, 36 and 28 teeth, we have:

$$\frac{72 \times 48}{36 \times 28} = \frac{24}{7}.$$

4. Place either of the two gears in the numerator of the fraction in Step 3 (72, for instance) at D on stud J. Place either of the gears in the denominator (28, for instance) in mesh with it at N on stud K. Place the other gear, in the numerator, at P on stud K, meshing with the remaining gear of the denominator, 36, on the lead-screw B at E.

5. Prove the correctness of the calculation by multiplying together the numbers of teeth in the driven gears N and E, and the number of threads per inch of the lead-screw (taken at double its value in this case, as called for by Step 1). This product must equal the product of the numbers of teeth in drivers D and P, multiplied by the number of threads per inch it is desired to cut. Thus:

$$28 \times 36 \times 2 \times 6 = 12{,}096.$$
$$48 \times 72 \times 3\tfrac{1}{2} = 12{,}096.$$

HOBS FOR WORM GEARS.*

JOHN EDGAR.†

In the August, 1907, issue of MACHINERY, Mr. Flanders gives a very good treatment of both the worm and worm-gear, but he has very little to say regarding the hob. It is the desire of the writer to supplement his remarks by a few suggestions on the design and proportions of the hob.

If we were to make an extended collection of hobs from various sources, we would find a great variety in design and proportions. It is generally accepted as a fact that the hob need only be a duplicate of the worm, with the exception that it should be slightly larger in diameter in order to give a clearance at the root of the gear tooth. That such hobs are used and appear to give good results, is their only claim to existence. When we come to think that the teeth of the gear are dependent on the hob for their shape, and that the smooth-running qualities depend also on the same tool, it must be conceded that a little thought and care put into the production of the hob would not only repay for any extra trouble, but would be a source of longer life to the gear.

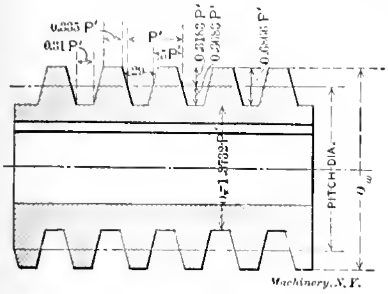


Fig. 1. Dimensions of Worm.

If a worm and gear of standard proportions are brought into mesh, we have at the bottom of both the thread of the worm and teeth of the gear a clearance equal to one-tenth of the thickness of the thread or tooth at the pitch line. The clearance at the root of the gear tooth is obtained by enlarging the hob over the diameter of the worm, by an amount equal to two clearances, while the clearance of the tooth in the thread bottom is taken care of by the proper sizing of the gear blank.

While it may be customary practice to make the hob an exact duplicate of the worm, except in the one item of outside diameter, a hob proportioned as suggested in Fig. 2 is recommended as one that will give much more satisfactory results, and be found to be well worth any additional trouble in construction required beyond that for the style ordinarily used. The peculiar feature of this hob is that it is an exact opposite of the worm with respect to the proportions of the thread shape; the depth below the pitch line in one case being equal to the height above the pitch line in the other. The object of this is to have a hob that will form the complete outline of the tooth and make it absolutely certain that the standard proportions of tooth and clearance are obtained. Thus, should the diameter of the blank be large, the hob will trim off the top of the gear teeth to the proper length, when the proper center distance is maintained.

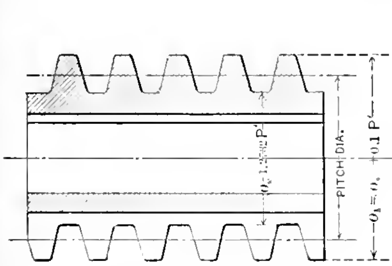

Fig. 2. Dimensions of Hob.

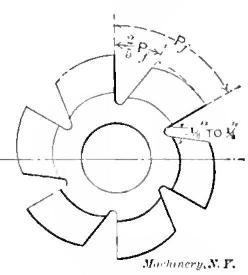

Fig. 3. Data for Fluting Hob.

There is another point that is generally overlooked, and that is the necessity for having the corners of the thread rounded over, and for providing a liberal fillet at the root of the thread. The radii of the rounded corner and the fillet may be as large as the clearance will allow, which would be one-twentieth of the circular pitch of the thread.

The effect that this fillet and rounded thread have on the shape of the tooth is something that greatly increases the quality of the gear and the strength of each individual tooth. The rounded corner on the thread points does away with any tendency to scratch the surface of the tooth in the cutting action, and leaves a much larger fillet at the root, greatly increasing the strength. The fillet at the bottom of the thread rounds off the top of the tooth in the worm-gear, removing any burrs, and leaving a nicely finished product. This fillet also removes the dangerous tendency of the hob to develop cracks in the hardening process—a common source of trouble even where care is taken. Fig. 1 shows the proportions of the worm in comparison with the hob in Fig. 2.

In forming the hob, much can be gained by making a special form tool of correct proportion that will leave no chance for error; the only dimension needing care then is the diameter. Such a tool is shown in Fig. 3. The figure is dimensioned by formulas, so that a tool for any pitch can be easily proportioned from it. This tool may be made by using a gear-caliper without resorting to the protractor, or the protractor may be used in laying out the angle. This tool may be made without side clearance, providing that the sides incline in the same direction and at the same angle that the thread takes, but under ordinary circumstances, where only one hob is to be made, little is gained by having no side clearance. Clearance may be made from 5 to 10 degrees from the angle of the thread. [Grinding a tool like this of course changes its form, so it must not be used indefinitely in making large numbers of similar hobs.—EDITOR.]

The number of flutes that should be provided in the hob is a point on which very little is said, various authorities differing widely. Where the hob is to be used in an automatic hobbing machine in which the hob and blank are positively geared together, the number of flutes may be a comparatively small number as compared with a hob that is to be used in connection with ordinary processes of hobbing worm gears. In the process in which the previously gashed worm-gear blank is swung loosely on centers and revolved by the hob as the latter rotates, the hob should have a larger number of flutes.

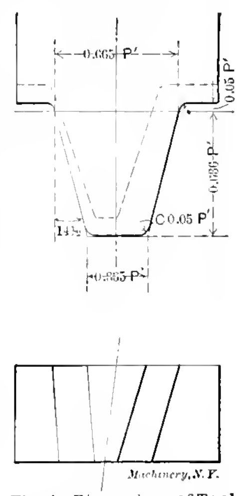

Fig. 4. Dimensions of Tool for Threading Hob.

A rule that checks up well with present practice is as follows:

To find the number of flutes in a hob, multiply the diameter of the hob by three, and divide by twice the circular pitch.

The above rule gives suitable results on hobs for general purposes. When the result gives an odd number of teeth, take the next smaller even number, to facilitate calipering.

Some authorities on worm-gearing state that the number of flutes in a hob should in no case be an exact multiple of the number of threads. Their reason for this rule is that the hob so gashed will produce a much smoother tooth and one nearer correct in shape, because no tooth in the hob passes the same tooth in the gear twice in succession, so that any little imperfections in shape of the individual hob teeth are counteracted by one another. Another authority is strong in his advice not to have the circumferential distance from flute to flute equal to or equally divisible by the circular pitch of the hob, for the same reason as stated regarding the former rule. From these statements, it is seen that to obtain a rule that would be at once simple and yet take all conditions into consideration, would be a difficult proposition. [So far as we can see, only the first of these two rules is a logical one. Owing to the fact that hobs have teeth only, instead of full surfaces matching the worm, the curved outlines of the wheel teeth are merely approximated by a series of tangents. If the number of flutes in the hob is a multiple of the number of threads, the hob teeth will "track" after each other, giving wheel teeth only roughly approximated by a comparatively small number of long tangents.—EDITOR.]

The cutter used in gashing the hob should be about 1/8 inch thick at the periphery for hobs of ordinary pitch, while for those of coarser pitch a cutter 1/4 inch thick would be much

* For further information regarding worm gearing, see MACHINERY, August, 1907: Calculating the Dimensions of Worm Gearing, and other articles referred to in that issue.

† Address: 7 Webster St., Hyde Park, Mass.

better. The width of the gash at the periphery of the hob should be about two-fifths the pitch of the flutes. The cutter should be sunk into the blank so that it may be from 3/16 to 1/4 inch below the root of the thread. Fig. 4 shows an end view of a hob gashed according to these rules.

Where a hob is to be used to any great extent, and is subject to much wear, it would be advisable to increase the diameter above the dimensions given from 0.010 to 0.030 inch according to its diameter and pitch, to allow for decrease in diameter due to the relief, and caused by grinding back the cutting face in sharpening.

Hobs are generally fluted parallel with the axis, but it is obvious that they should be gashed on a spiral at right angles with the thread helix in order that the cutting face may be presented with theoretical correctness; but the trouble encountered in relieving the teeth on the ordinary backing off attachment is the cause of the common mode of fluting. When the pitch or lead is coarse in comparison with the pitch diameter of the hob, so that the angle is correspondingly steep, it may be best to flute on the normal helix, and if the hob cannot be machine relieved, it may be backed off by hand.

The amount of relief depends much on the use for which the hob is intended. A hand hob for hobbing a gear in position may be made with little or no relief, while hobs used on hobbing machines may have much more relief than those used on the milling machine.

In closing, I would suggest that Mr. Flanders' model drawing give the full data relating to the thread, such as the whole depth, the width of the thread at top and the space at the bottom. The pitch diameter would also be handy to have, as would also the center distance.

WITH THE REPAIR GANG.

A. P. PRESS.

Down at one end of the O. C. R.R. round-house there was a long L where they did the repair work, and where we used to hang out when there wasn't much to do. There was a boilermaker, a few machinists, and two or three blacksmiths. Jim Haven was the boss of the smiths, and did the hiring and firing for the lot. One day in came a big, stout fellow and he asked Jim if he wanted a good blacksmith.

"Can you weld two pieces of iron together?" asked Jim.

Now this was equivalent to asking a bookkeeper if he could write, and the man was mad. He didn't say much but remarked: "You just give me a chance and I'll show you whether I can or not." "All right," said Jim; "it's almost 12 o'clock and I am going to dinner, but the power runs all the noon time, and there's fire and there's plenty of stock here. See what you can do while I am gone."

"Can you weld two pieces of iron together?"

He waited until Jim got washed up and out of the shop. Then he picked out two pairs of the biggest and best tongs in all the bunch. He gripped the jaws right into each other, put a ring on each end of the tongs, put them in the fire, brought them up to a good heat, put them under the hammer and made as pretty a weld as ever you saw! Taking a stamp we use to mark O. C. R.R. on all the tools, he struck it on four sides of the job, laid it on Jim's anvil, washed up and got out.

Well—when Jim got back, the air was blue, for Jim wasn't any Sunday-school teacher and he could say things that I don't want to write, and you wouldn't print them if I did, but after he cooled off, he said: "Well, that's a good job; if he comes along again, I'll hire him."

One day old 76 ran her nose into a snow-drift up on Long Plain Hill, and buckled up her side-rods. You see the front drivers stalled in the snow, but the rear ones didn't; they sent us up there, and we towed her down to the house for repairs. We took off the rods and carried them in to Jim to straighten up.

There was a smell of burned leather.

He took a heat on them, worked out the kinks, lined them up on the centers. When they were all done he told the helper to set them away over in the corner, and then go and tell the round-house boss that they were all right. They were "black hot" and the helper took a pair of tongs and lugged them over to the corner and set them up.

Now there was a kind of "kid-glove" apprentice out in the round-house on whom we thought it was all right to put up a job any time, and Jim thought the round-house boss would send him in after the rods—and he did. The "kid-glove" fellow used to wear a pair of gloves most of the time, and I suppose that is why we were down on him. In he came, gloves and all, and asked Jim where the rods were.

"Over there in the corner," Jim replied.

He went over and grabbed a rod. There was a smell of burned leather, a string of swear words, and Eben came back to the smith's part.

"Why in the dickens didn't you tell me they were hot?" "Why any boy could tell they were hot; even my boy Tommy, coming in there with my dinner, could tell it." "It is a lie," said Eben. "It is, is it? Tommy, come over here and see if you can carry one end of that side-rod with Eben."

Now Tommy was wise, and he knew his father a good deal better than Eben did. He went over to the corner, wet his finger in his mouth and touched both ends of the rod. Then, taking hold of the cold end, he waited for Eben to take hold of the other, which he did with the tongs.

Bill put some oil on Eben's hands and cooled off the rods for him, but Eben went off with a look on his face that said: "I'll get even with Jim some time," and he did, as I will tell you later.

A DRAFTING APPRENTICESHIP COURSE.

Something more than a year ago the need for young draftsmen trained in locomotive detail work became so imperative, and the difficulty of getting them so great, that the engineering department chiefs of the Schenectady plant of the American Locomotive Company organized an apprenticeship course in mechanical drawing and locomotive design with the object of making their own men instead of depending upon the uncertain and generally unsatisfactory general supply. The move was made for no philanthropic motives whatever, but simply for the very good business reasons that have caused other large concerns to organize apprenticeship courses in shop work. This course also includes shop instruction, but it is simply given to round out the graduate draftsman's knowledge of locomotive construction and shop methods, and give his training the practical turn required of a first-class man. The result after one year's work is very satisfactory. About twenty young men are taking the course, and some are now working over the board in the general drafting department. These young men are doing good work in the main.

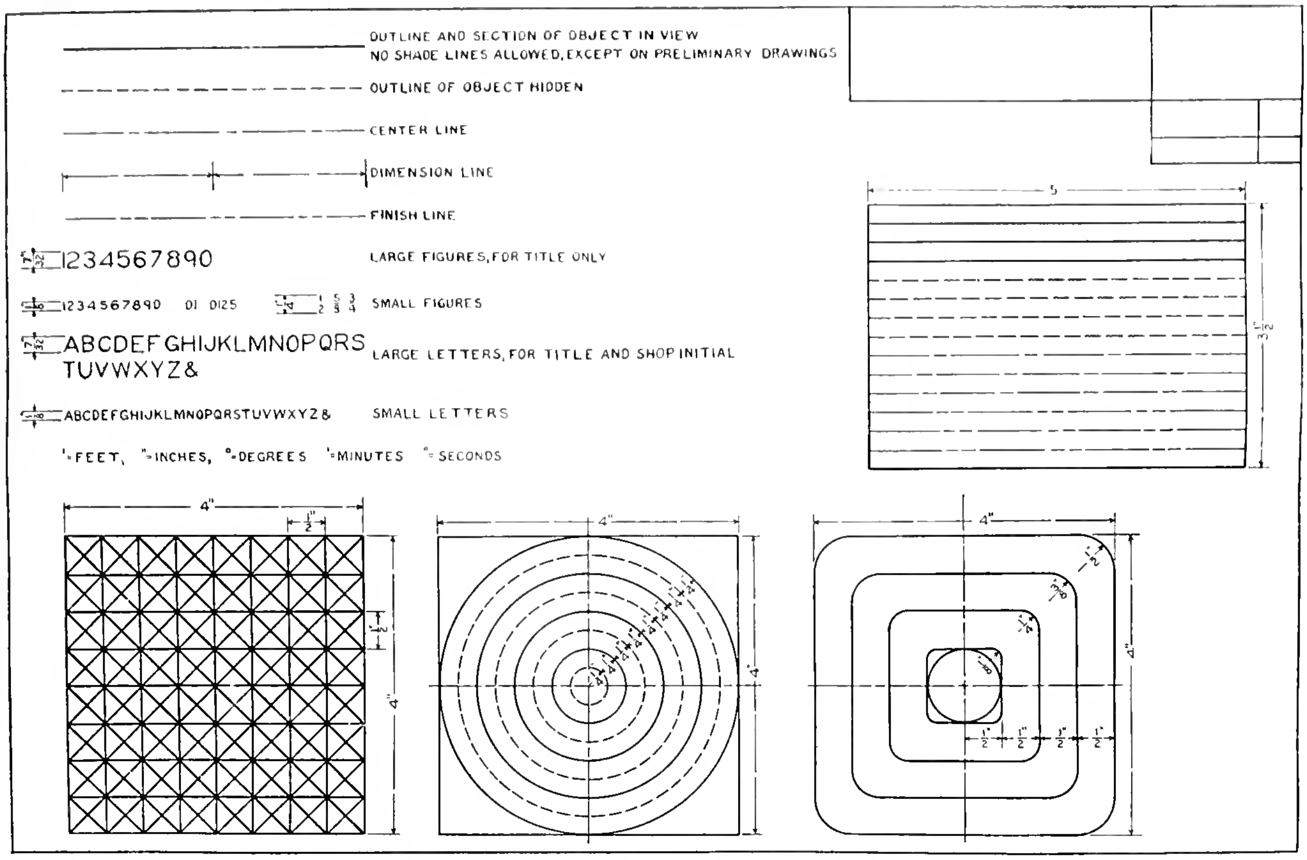

Fig. 1. First Drawing Exercise in American Locomotive Company's Drafting Apprenticeship Course.

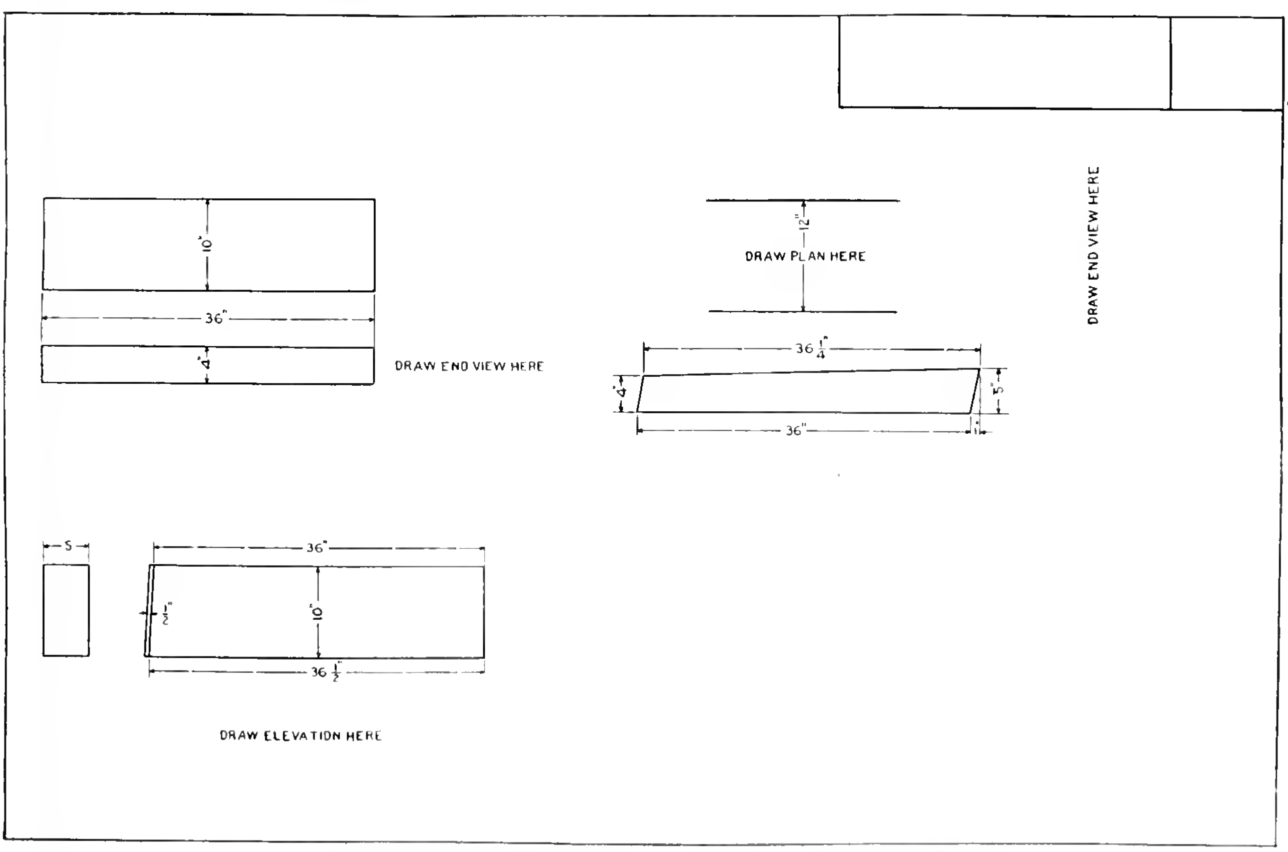

Fig. 2. Second Drawing Exercise in Course, subject being a Locomotive Fire-brick.

and are building themselves up into just the kind of men which the course was designed to provide.

The apprenticeship course in drafting is offered to a limited number of young men between the ages of sixteen and nineteen who can read, write, and answer certain simple questions in oral arithmetic. They are taken in on one month's trial, and then, if satisfactory, are admitted to the regular four years' apprenticeship course upon signing an indenture. The first, third and fourth years are to be spent in the drafting office, and the second year in the shop, receiving instruction in the use of tools and erection of locomotives. The first three to six months are spent in the blue-print room, making and fixing blue-prints, etc.

The apprentices, while at work in the drafting office, are given regular instruction, during working hours, in drafting, algebra, geometry, trigonometry, descriptive geometry, applied mechanics, strength of materials, and machine design, and they are taught the general application of these subjects to drafting room and engineering problems. The apprentices are divided into small classes for receiving instruction, in order to get the benefit of close contact with the instructor.

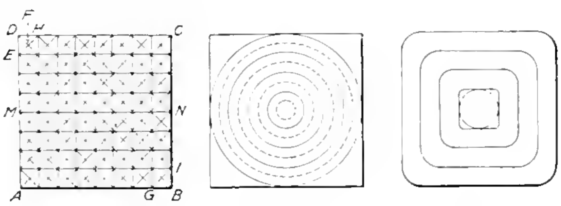

Fig. 1. Fig. 2. Fig. 3.

For dimensions of these figures see drawing exercise No. 1.

Fig. 1

1. What is the area in square inches of ABCD?
2. What is the area in square inches of the triangle ABD?
3. What is the area in square inches of the triangle DEF?
4. What is the length of the line DB?
5. What is the length of the line EG?
6. What is the length of the line EH?
7. What is the area of the rectangle EHIG?
8. What is the area of the rectangle MNBA?
9. What is the area of the triangle EHD?
10. What is the area of the figure HDEGBI?
11. What is the area of the figure DBGE?

Fig. 2

12. What is the area of the largest circle? (in square inches)
13. What is the area of the ring between the circle whose diameter is 3 inches and the circle whose diameter is 2 inches?
14. What is the area of one of the four corners spaces between the square and the inscribed circle?
15. What would be the diameter, in inches, of a circle circumscribed about the square?

Fig. 3. Examination Paper Based on First Drawing Exercise.

Each apprentice devotes four hours a week to recitation during the three years spent in the drafting office, but during the year spent in the shop the recitation hours are omitted, it being considered better policy not to interfere with regular shop routine. After the completion of the course the apprentices will be given a bonus of $150 over their regular wages, and they will be encouraged to remain in the employ of the company.

The instruction is of a strictly practical nature, the subjects being treated so as to have an immediate application to the regular work of the drafting office. There is no long preliminary course during which the students become discouraged because they do not see the use of the things taught.

The first drawing exercise is illustrated in Fig. 1. When this is satisfactorily accomplished the apprentice is given work of a simple nature to do in the apprentice drafting class. While this exercise is of a very simple nature, it contains the practical basis for future work including lettering, dimension lines, center lines, etc. Fig. 3 is a reproduction of a sheet using the same figures for an elementary examination paper on areas, etc.

The second drawing exercise illustrated in Fig. 2 has for its subject a locomotive arch firebrick which is kept in the recitation room and which forms the subject for numerous questions relative to its area, weight, density, volume, etc.

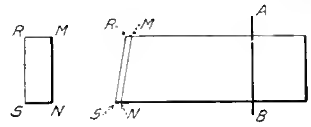

Fig. 12.

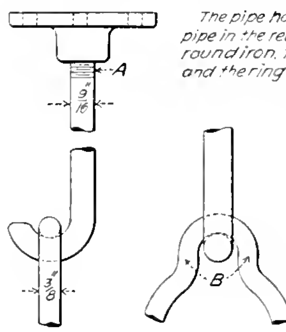
For dimensions of this brick see drawing exercise No. 2.

1. What is the area of the upper surface of the fire brick shown by fig. 12? (as shown by the plan view)
2. What is the area of the bottom surface?
3. What is the area of the cross section at A-B?
4. What is the length of the line from M to N?
5. What is the length of the line from R to S?
6. What is the length of the line from R to M?
7. What is the length of the line from S to N?
8. What is the area of the end surface of the brick which is beveled?
9. What is the area of each side of the brick? (as shown by elevation views)
10. Supposing the brick to have been originally 37½ inches by 10 inches with all corners square, how much bottom surface (expressed in square inches) was cut away by bevelling the brick?
11. How much was cut away from the upper surface?
12. How much was the area of the end which was bevelled increased by the process?
13. What are the cubical contents of the brick of fig. 12?
14. Supposing the brick to have been originally 37½ inches by 10 inches by 5 inches with all corners square (a rectangular parallelopiped), what was its original volume and how many cubic inches were cut away in bevelling it?
15. How much does the brick of fig. 12 weigh, if fire brick weighs 120 pounds per cubic foot?

Fig. 4. Examination Paper Based on Second Drawing Exercise.



The pipe hangers which support the water pipe in the recitation room are made of 9/16" round iron, threaded (see sketch and hanger) and the ring is made of 3/8 round iron.

1. If the thread is U.S. standard, what load will each hanger support before there will be a tensile stress of 6,000 lbs. per square inch at A?

2. What load could be supported by the hanger before there would be a tensile stress of 6,000 lbs. at B? (½ of the load is supported by each side of the ring).

3. Suppose the load upon the hanger to be 1,200 lbs., what would be the fibre stress due to tension at A and at B?

4. If the ultimate strength of the material is 54,000 lbs., what is the factor of safety with a load of 1,200 on one hanger?

5. If the load upon one hanger were 1,200 lbs., what would be fibre stress due to tension at A?

6. If the ultimate strength of the material is 54,000 lbs., what is the factor of safety with a load of 12,000 lbs. on a hanger?

7. With an ultimate strength of 54,000 lbs. per sq. in., and a factor of safety of 6, what load could be put upon each hanger? (Assume the weakest point to be at A)

8. (a) Suppose each foot of pipe, including fittings and the contained water, weighs 7½ lbs., how long a portion of the pipe would each hanger support before there would be a tensile stress of 6,000 lbs. per square inch at A?
(b) Approximately, what length of pipe does each hanger support at the present time?
(c) Approximately, what load is upon each hanger at the present time?
(d) Using the load as obtained under (c), what is the stress due to tension at A?
(e) With the load as found under (c) and an ultimate strength of 54,000 lbs., what is the factor of safety?

Fig. 5. Examination Paper on Strength of Materials.

The nature of these questions is shown in the reproduction of an examination paper, Fig. 4. The sheet shown in Fig. 5 illustrates practical examples in strength of materials. The few examples chosen will serve to give some idea of the nature of the instruction.

LETTERS UPON PRACTICAL SUBJECTS.

PUNCH AND DIE FOR ARMATURE DISKS.

The accompanying cut shows a compound die for armature disks for the cores for electric motors. The punch and die are shown in plan views and also in cross sections in Figs. 1 and 2. The die holder *A*, Fig. 1, is of cast iron, and is first planed on the bottom. It is then strapped to the face-plate of a lathe, and faced and bored to receive the plate *B*. This plate is also first faced on the bottom. It is then turned over and bored to the outside diameter of the disk to be punched; the depth of the bored hole is about 1/4 inch. The die sections *C* are all milled in a fixture; they are then drilled and tapped for 1/4 inch flat-headed screws. After this, the sections are hardened and tempered. The plate *B* and the sections *C* are then assembled, and after being assembled the sections are ground. The inside ring *D* is now machined. The keyway and marking notch are tapered one-half degree for clearance; the large hole for the shaft in the armature tapers also one-half degree.

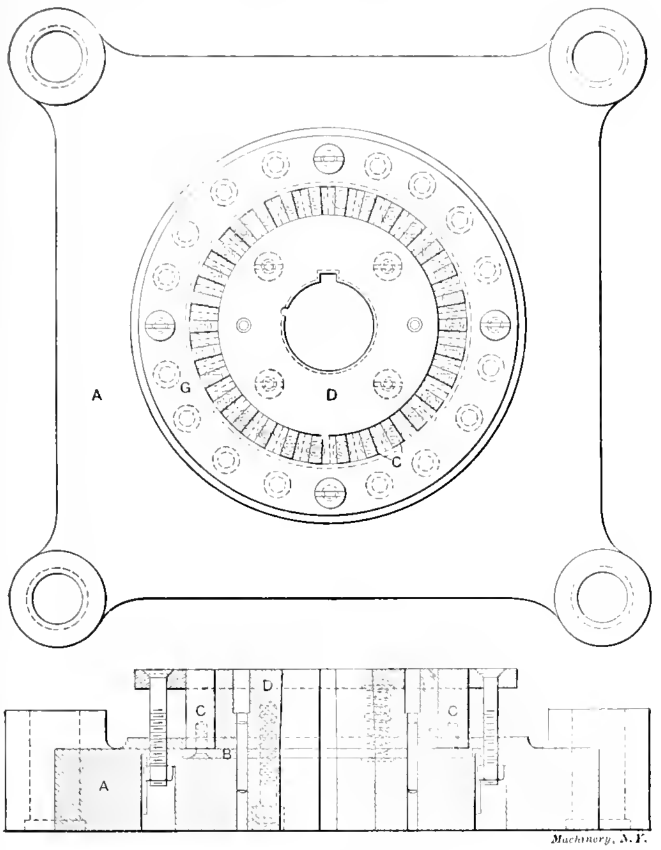


Fig. 1. Die for Making Armature Disks.

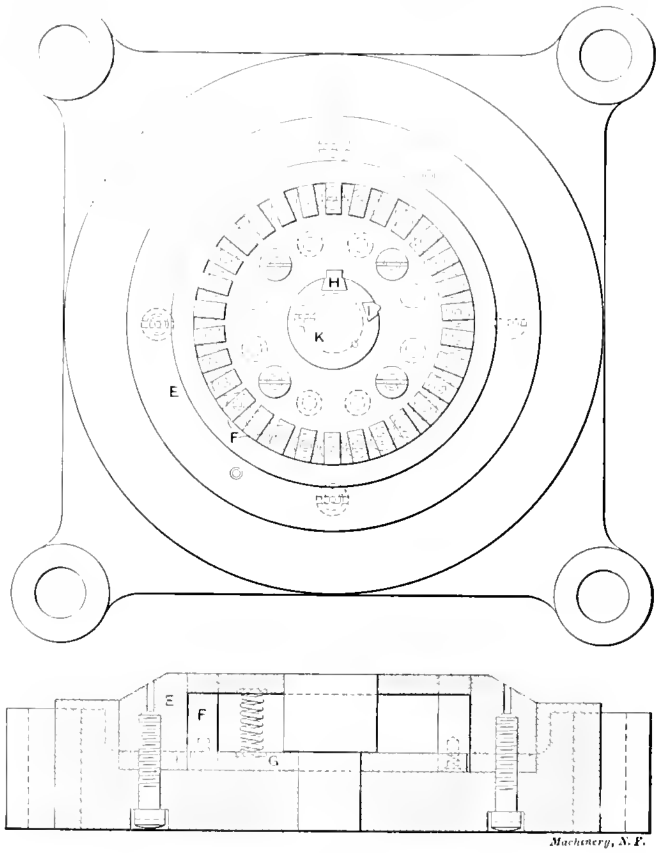

Fig. 2. Punch for Armature Disks.

The ring is drilled and tapped for four 1/2-inch screws, and drilled and reamed for two dowel pins. After this the ring is hardened, tempered and ground to a very close fit in the circle formed by the sections *C*. The center hole is also ground to the required dimension. The stripper is now made, the working of which is plainly seen from the cut, and the whole is assembled, and the die is ready.

We are now ready to proceed with the punch. In this, *E*, Fig. 2, represents a tool steel ring, which, after it is machined, drilled and tapped, is hardened and ground. Punch sections *F* are located in the plate *G* which is milled with the proper number of slots. The punch sections should be left a little softer than the die, because the punch and die will wear much longer and give much better results if this is the case. The sections *F* are held in place by a ring *J* which is shrunk on the outside at the bottom. At *H* and *I* are shown the punches for the keyway and the marking notch. These are fitted into the center punch, being dove-tailed into this. They taper from the bottom up when the punch is in working position, and are driven in so that when punch *K* is assembled they cannot work out. The holes for the sub-press pins are drilled and reamed with the punch and die together, and the holes in the die counterbored to a depth of about 3/8 inch. The pins should be a driving fit in the die and a working fit in the punch.

M. J. W.

ECONOMY WITHOUT DISCRETION.

The following incident shows the mistake of letting a non-practical man have charge of the red tape. In a certain small-sized manufacturing company, which had always paid fair dividends, the management thought that things could be run more economically, and as one of the directors knew a man who was considered an expert in weeding out all unnecessary expenses, it was decided to give him a trial. A few days after this a little sharp-nosed man came bustling around the shop asking every imaginable question in a snappy manner—he was the expert. His new methods were first noticed by Ed., who came down on the 6:55 train, and thus could not get to work before 7:05 A. M. He found he was being docked one-half hour every morning for being late. Ed. had been with the firm for over eight years, and was a good, conscientious workman, who kept first-class time, other than the five minutes late every morning, and then he always stayed until 6:15 P. M., because his train did not leave until 6:30. It made no difference, the expert said, their time was 7 A. M., and train or no train Ed. must be there or be docked half an hour. Things went fairly well until Saturday, when the expert came in about ten minutes before quitting time and caught the boys just starting to clean their machines; then there was a roar. "Ten minutes is too long to take to clean up; in the future only five minutes will be allowed," and he walked out. The following week the supply of files, hack-saw blades, waste and oil was cut to about half the usual amount, and more than that would not be given out, no matter how urgent the need; next, notices were put up saying that from the first of the month all work would be given out on time limits, and every man must keep within these limits. The result of this was that all jobs were faked up just enough to get through the shipping department without defects being noticed. The expert did not think of appointing any inspectors.

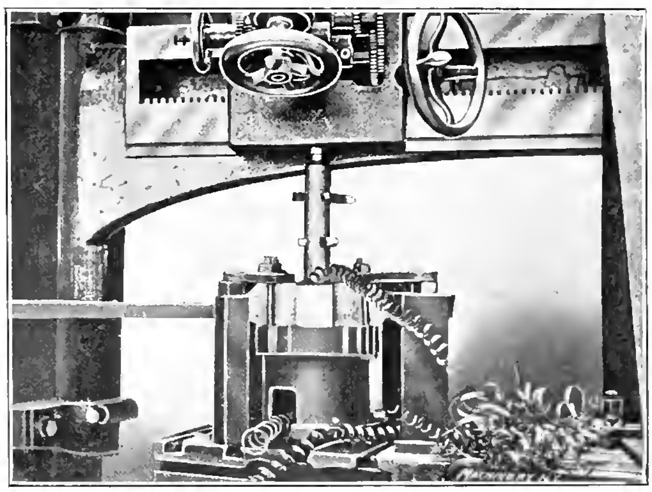
A few weeks after this a lot of tool steel came in, and then

the trouble began in the hardening department. The new steel was of the "cheap" kind, and after the die makers had spent days of work forming it into dies, it would crack or spring badly when it came to the hardening room. The final result of all this was that the working expenses were higher than ever, and the expert said that the general foreman was trying to "do him," so he had him fired for inefficient results. This caused a general strike, and the directors held a special meeting and had the whole matter investigated, and found out where the real trouble was, so they fired the expert, and reinstated the foreman, and since then there has been no more false economy in the form of cheap steel, insufficient supply of files or any other little meanness—and the firm has not lost by the change. PENNSYLVANIA.

BORING LOCOMOTIVE RODS.

The cut herewith shows an old Pond radial drill press fitted up temporarily for boring new locomotive side rods for bushings. This machine has been in constant use for twenty years, several years of this on a double shift. To the extreme right in the cut a triangular brace is shown, bolted at the base to the table of the machine, and clamped to the radial arm at the top to give greater rigidity to the machine.

A special cast iron jig was made as shown for boring the rods, having provision made for bolts to hold the rods down, and high enough to allow the three one-inch square high speed steel tools in the bar to pass through the rod without coming



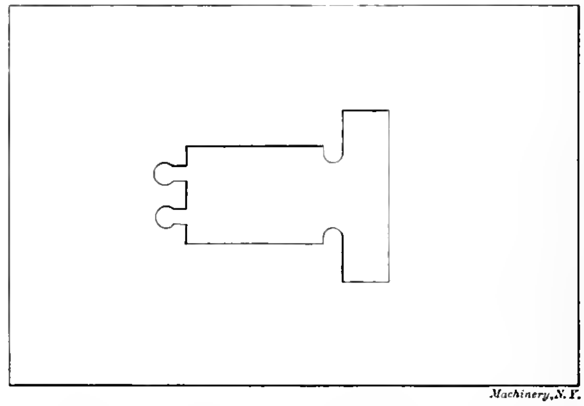
Device for Boring Locomotive Rods.

in contact with the table of the machine. The boring bar is three inches in diameter and extends through a hole in the table. The tools are sufficiently far apart so that just as the first one leaves the cut, the next one is starting a fresh cut. These tools are set out so that each one is $\frac{3}{4}$ inch further out than the preceding one, and consequently the hole will be enlarged from 3 inches to $7\frac{1}{2}$ inches by passing the bar through once. Special attention must be given to grinding the tools with enough top rake, and very little front clearance. If this is done, and the belts kept in good condition, it will be surprising what a large amount of chips can be removed in one hour. Next to having one of the modern two-spindle two-thousand dollar rod boring drills installed, I would recommend fitting up one of the old radials as shown.

Port Huron, Mich. M. H. WESTBROOK.

CONSTRUCTION OF DIES TO PREVENT BREAKAGE IN HARDENING.

Having read an article which appeared in the March, 1907, issue of MACHINERY relative to hardening dies with small projections or tongues, in which the possibility of breakage is large, I herewith give the method of practice in some shops where I have been employed. We will take, for instance, the die that was shown in the article to which I refer. This die I propose to make in the following manner. The die is first filed or machined in the regular way, with the exception that the two tongues are left out. In line with the center of the tongues and at a certain distance from the cutting edge, holes are drilled larger than the width of the tongues. These are taper reamed from the top with a standard taper reamer. A slot is then cut from the hole into the die the same size as the tongue, when the die would look as shown in cut. We now make two pieces to fit in the holes, and extend out the required distance, making sure that they will be a drive fit after hardening. It is best if the pieces are 1/32 inch longer than the thickness of the die, so that they can be ground flush after being driven into place. While this may increase the cost of producing the die, yet, if from any accident, one or



Method of Making Dies to Prevent Breakage in Hardening.

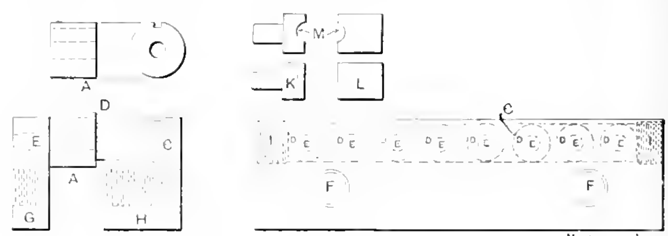
both tongues should be broken, they are easily replaced without the necessity of annealing the die. While I do not wish this article to be taken in the nature of a criticism, it is to the interest of all readers if some discussion of such subjects is entered into.

We do not use the same method of holding punches in the punch pad as the writer referred to, as the necessity of turning the punch from large stock to leave the head large enough is an expensive operation. We make the punches 0.001 inch or 0.0015 inch larger than the holes in the punch holder, and just before they are driven home, we rivet the upper ends of them, which are drawn soft enough for the purpose. If the punches are set properly, it will be impossible to pull them from the holder, for the friction on the body of the punch is greater than it would be in any metal on which the punch would stand up. K. L. ROSS.

ST. LOUIS, MO.

PUMP VISE JAWS.

The accompanying cut shows a handy device for use on a milling machine for slotting pieces such as shown at *A*, and also for slotting screw heads. The vise jaws *G* and *H* are made out of tool steel, and are left soft; they are placed in a milling machine vise, and the piece *A* to be slotted is placed between the two jaws, as shown. The chamber *C* is a cylindrical hole into which are drilled holes from the side for the cylindrical plungers *D*. The chamber *C* is filled with tallow,



Equalizing Vise Jaws.

and, as the pieces *A* are clamped in between the plungers *D* and the vise jaw *G*, the tallow provides an equalizing effect until all the parts are held equally firm. This means permits pieces of a slightly uneven length to be held securely. The plungers *D* must, of course, be a very good sliding fit in the holes running down to the chamber *C*. The pin *E* simply serves the purpose of locating the piece *A* by entering the hole in its center. The holes *F* are tapped to receive screws holding the jaws to the milling machine vise. Pieces *E* and *D* should be made of tool steel and hardened. When screw heads are slotted the parts *K* and *L* are used instead of *D* and *E*. The screws are then held in the semi-circular grooves

M, the operation of the device being the same as when slotting pieces *A*. The screws *I* in the ends of the circular chamber *C* simply serve the purpose of preventing the tallow from escaping at the ends. S. OLIVER.

Great Barrington, Mass.

TO FIND THE NUMBER OF CUTTER FOR SPIRAL GEARS.

The calculations of spiral gearing has been fairly well discussed in these columns, and many formulas and time-saving methods have been presented, but these all had reference to the determination of the dimensions of the gears themselves, while the method of determining the proper cutter to be used has not been simplified.

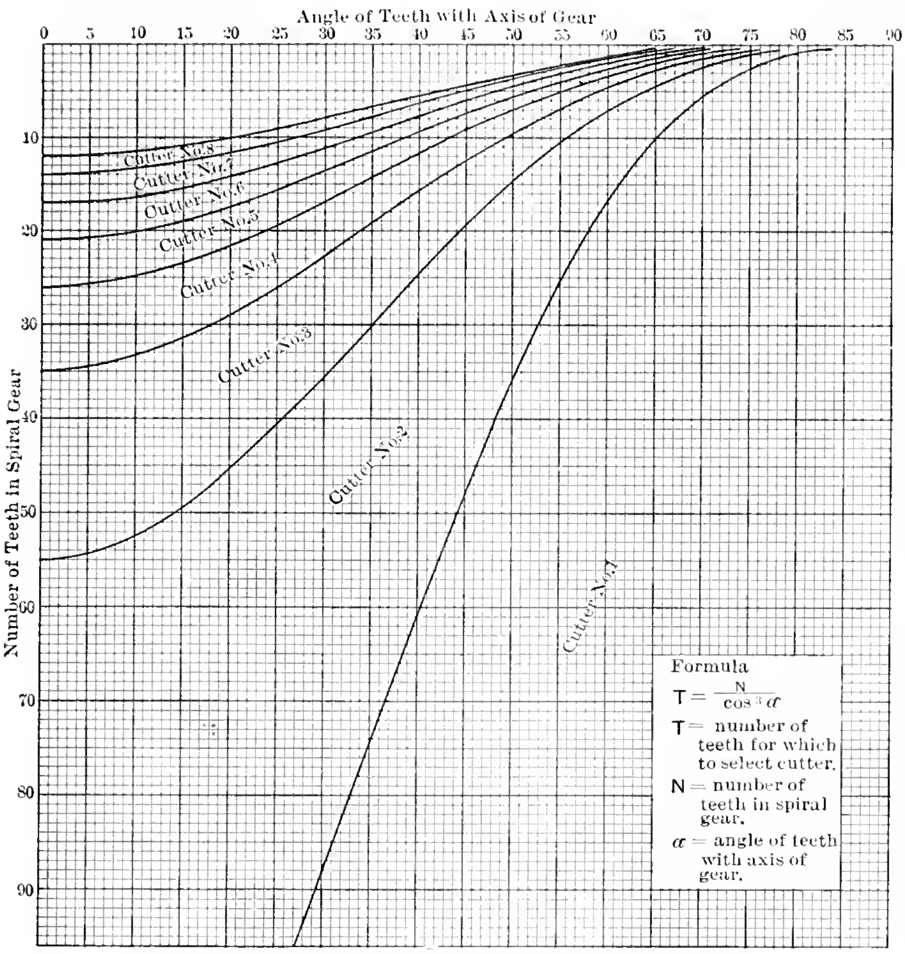


Diagram for Finding Number of Cutter to use for Cutting Spiral Gears.

The cutter used in milling spiral gears is, of course, understood to be a standard spur gear cutter, the only difference being, that the *number* of the cutter used to cut a spur gear of, say, thirty teeth, will not necessarily be the same number of cutter that is used to cut a spiral gear of thirty teeth, it of course being generally known that the angle of the teeth with the axis of a spiral gear is another factor affecting the tooth form, and, therefore, the number of the cutter. However, spiral gears are correctly cut with spur gear cutters, the problem being, to find the proper number of cutter to use.

The selection of the cutter has been determined by the formula:

$$T = \frac{N}{\cos^3 \alpha},$$

in which

N = actual number of teeth in the gear,

α = angle of teeth with the axis,

T = number of teeth for which to select the cutter.

This number, T, is sometimes called the "apparent" number of teeth in a spiral gear.

This relatively unimportant operation of calculation often involves more labor than the determination of the pitch diameter, etc., inasmuch as we have to cube a cosine. The result, moreover, is to merely give the "apparent" number of teeth in the gear, and from this result, we look up the table of cutters, to find the actual number of cutter to use.

Each cutter number covers a "group" of teeth, as for example, No. 2 cutter cuts from 55 to 134 teeth in a spur gear; therefore, by plotting a series of curves, we can represent the group covered by each cutter, by the field between two of the curves.

The accompanying diagram enables one to determine the number of cutter to mill a spiral gear, without any calculation, by simply locating the point corresponding to the actual number of teeth in the gear, and the angle of the teeth with the axis. This point then falls within the area of one number of cutter. This diagram, unlike most diagrams, gives exact, and not approximate, results, because of the fact that we are dealing with groups instead of definite quantities or amounts.

The writer has found this a great time-saver, and hopes that it may be of assistance to others.

ELMER G. EBERHARDT.

Newark, N. J.

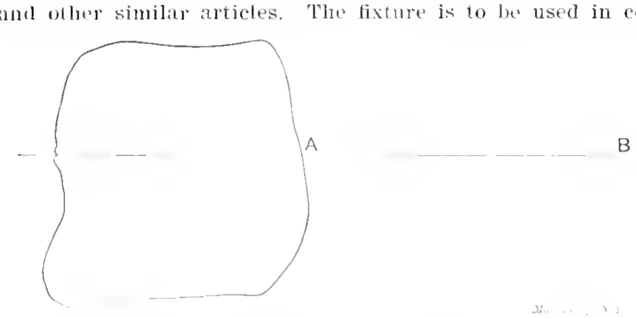
POCKET KNIFE PLANIMETER.

The following application of the knife as a planimeter is very useful and accurate to one or two per cent. I have never seen the method published, and think that it might be of interest. As shown in the cut below, a straight line is first drawn through the figure, the area of which is to be found. A common penknife or jackknife, having at least two blades, is then opened so that the large blade is entirely open, and the small one perpendicular to it. The knife is then placed on the paper with the plane of the blades perpendicular to it, the small blade at the intersection of the figure and the straight line, and the large blade on the straight line. With the left hand holding the large blade lightly against the paper, the small blade point is made to follow the outline of the figure with the right hand. When the starting point is reached, the distance of the large blade from the line multiplied by the distance between the points of the knife will be the area of the figure. H. D.

[The accuracy of the "hatchet" planimeter, of which the pocket knife used in the form described is an example, depends very largely upon the alignment of the knife edge and the tracing point. The prolongation of the axis of the blade section in contact with the paper should pass exactly through the point of the little blade used for tracing. The ordinary pocket knife seldom fulfills this condition, hence the method is more interesting than useful.—EDITOR.]

SCREW SLOTTING FIXTURE.

The cut on next page shows a fixture designed to slot screws and other similar articles. The fixture is to be used in con-

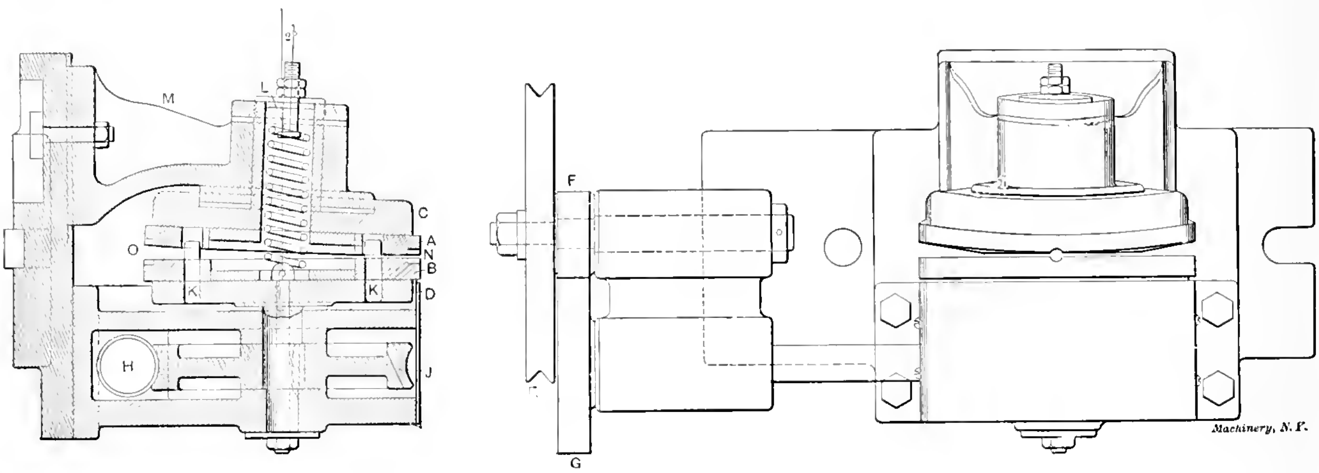


Using a Pocket Knife as a Planimeter

nection with a milling machine. At *A* and *B* are shown two rings of machine steel, case-hardened, with holes drilled on

their peripheries suitable to grasp the work to be slotted. The number of holes will vary according to the speed at which the fixture is run and the work being slotted. The rings are held and located on the holders *C* and *D* by screws and dowel pins not shown in the cut. Holder *D* is driven by means of a belt from the countershaft to grooved pulley *E* and through spur gears *F* and *G* and worm and worm-wheel *H* and *J*. Holder *D* is made in one piece with the worm-wheel shaft. Holder *C* is in turn driven by holder *D* by means of pins *K* held in holder *D*. Spring *L* takes care of any variation which may exist in the size of the pieces being slotted.

To locate and drill the holes, which retain the work, in rings *A* and *B*, they are screwed and doweled on the holders, and the fixture placed on a drill press in such a manner that an equal section of the hole will be drilled in each ring. The rings are then case-hardened. For different pieces of work it is merely necessary to make different rings to suit the conditions of the piece. The bracket *M* is adjustable forward and backward to allow different thicknesses of rings to be used. The hole in bracket *M* is bored at an angle of 2 degrees, and the plate *A* is also faced off at the same angle, so that it



Screw Slotting Fixture.

will be parallel to ring *B* at *N*. By boring the hole at an angle, it will be readily seen that at the point *O* the space between the two rings is the greatest, and at point *N* the least. In operating the fixture, it is placed on the milling machine so that the slotting saw will pass directly through the center of the piece, and directly over the center of the rings. The fixture is then started, and the operator only inserts the work in the holes. As will be seen, the piece is gripped firmly while passing under the saw, and automatically dropped when reaching the bottom.

Montreal, Canada. FRED R. CARSTENSEN.

WHAT A FOREMAN SHOULD BE.

A man may hold a position as foreman and still possess few of the qualities that go to make up an ideal one, and on the other hand a man may possess many of the qualities of the ideal foreman and still remain in the ranks all his life. Luck, push or pull may have put the first man into the place, but these alone seldom keep a man there. On the other hand, it may be the lack of push alone that has deprived the second man of his birthright. My experience has been confined mainly to machine shops, but the principal qualities that make a successful machine shop foreman are the same that are required in other branches of business. Leadership, experience, tact, self-control, foresight and system, are among the qualities that *should* be present, but often several of these are absent, and the man still counted a success from the employer's point of view. A man may be a brute to the men under him and still make money for his employers, but I am not going to discuss this.

In the first place a foreman, as the word implies, should be a leader, that is, a man who naturally leads others, and in this connection a good physique is a great aid, though not always a necessity; then comes experience, for a man can hardly be successful in solving the problems that constantly arise, and which require instant decision, without a certain amount of experience to back his judgment, and nothing so quickly shakes a man's confidence in his foreman, as the latter's lack of sound judgment. However, good judgment and common sense will make up for the lack of a vast amount of experience. Common sense prevents a man giving orders which are absurd on the face of them. An instance occurred in a shop not long ago that illustrates this. Some iron collars were to be shrunk onto pins, turned for the purpose. The foreman, a new man, ordered the pins heated and driven into the collars. As a result of this foreman's order a lot of pins were spoiled and he was made the laughing stock of the whole shop. It is needless to add that this kind of a foreman "lasts quick," as the saying is.

As for tact, it enables a man to get along where a lack of it has caused strikes and discontent. A tactful foreman does not give orders to the skilled, high-class mechanic in the same tone that he uses in ordering about a lot of meddlesome boys, or in telling the "roustabout" to do a better job of sweeping. This kind of a foreman studies his men, studies their little weaknesses and pet ideas. One man he asks about the ball score and another if he has read that piece in the last magazine about hardening steel. A certain man, or two, gets all the particular jobs, while another who likes brass work is given the preference in goods of that class whenever possible. Thus it goes all through the shop, placing work where it will be done the quickest and best, and keeping the human machinery oiled as well as the other kind. In order to get the best results from his men, a foreman must not only command their respect in regard to his judgment, but also as to his personal habits. A dirty, slovenly, drunken boss, no matter how good a mechanic, cannot hold the respect of his men, and the shop will reflect his personal habits.

Again, in order to keep the shop going so that no time is wasted, he must plan ahead. He must keep watch of his men and calculate accurately when a certain man will finish a given job and have another ready for him. He must watch his supply of material and order more, in good season, making ample allowance for delays in the order department both of his own shop and the one from which it is purchased, as well as for the time required in transit. All these things he must keep in mind, and look ahead as an engineer glances along the track to see if all is clear. Added to all this he must use system. He must have his machines grouped so that the work can travel from one to the other with the least possible difficulty in handling. He must have things so arranged that a record is kept of the original cost of a piece of work, and the amount of time that was taken to machine it, fit it, and put it in place. He must see that the machines are kept in repair, and that the workmen do not abuse them. He must have a system of inspection in order to know whether the work is properly done. He must have system in everything; if he doesn't, he is missing one of the greatest aids to success.

Briefly stated, the ideal foreman is one who gets all that is possible out of his men, keeps them contented and at the same time turns out the product of his machines at the lowest possible cost. The nearer a foreman comes to this description, the more valuable he is, and the further from it, the less he is worth. E. VIALL.

Decatur, Ill.

TOOLS FOR MOTOR CAR CYLINDER BORING.

The set of tools shown in the accompanying illustrations is used in a horizontal boring machine for motor car cylinder boring. These tools were designed by the superintendent of a large motor car factory in England. In Fig. 1 is shown a device for boring the two cylinders of an engine at one setting. A 6-pitch gear is mounted on the flange of the boring machine spindle. This gear meshes into gears on the spindles of the boring fixture. The spindles run in phosphor-bronze bushings, and the thrust is taken at the end by a ball bearing.

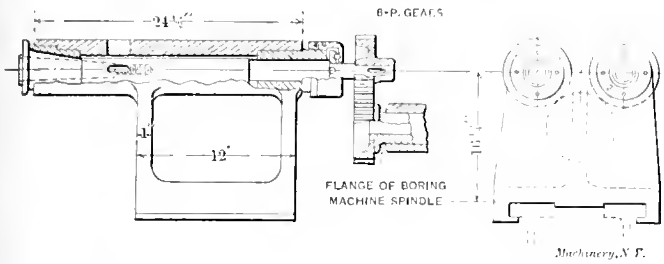


Fig. 1. Device for Boring Two Cylinders at One Setting.

The fixture has slots cut through at the front end to facilitate the removal of cutters, etc. This permits the spindle to be solid back of the hole for the taper shank of the tools used. The front end of the spindle bearing is tapered, and the back bearing is parallel. The fixture is held to the boring machine by straps. In Fig. 2 is shown the boring head. This has a tapered hole for the arbor, tapering ⅛ inch per foot. The rear end of the head is slotted for a key drive, and the front end is counterbored and a collar is placed in the recess secured to the arbor by a collar-head screw. This makes a firm and strong drive. Three Novo steel cutters are used in the head

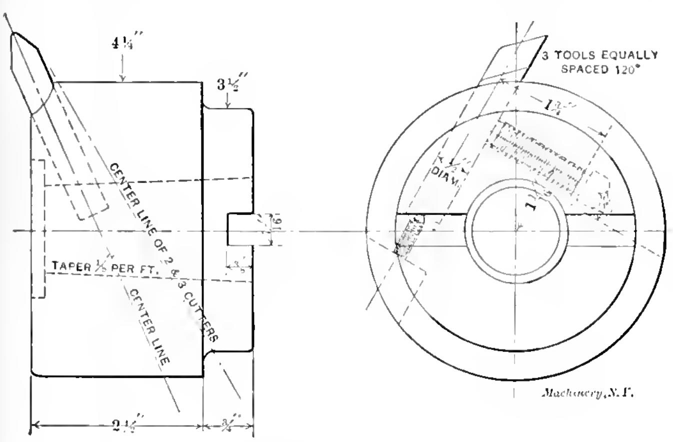

Fig. 2. Boring Head.

and are spaced 120 degrees apart, but are placed on two different centers in order not to weaken the head too much. The cutters are adjusted by small headless setscrews and are clamped in place by ⅜-inch square head screws, as shown. Two cuts are taken through the cylinders, the chips being blown out by compressed air.

In Fig. 3 is shown a facing tool holder. The facing tools are subjected to very heavy duty and must be held steadily. The hole in this holder is straight. On one end it is slightly countersunk on a 45-degree taper, and on the other side recessed to a 2-inch diameter for the spindle flange. Two keys are inserted into keyways on the spindle flange, making a positive drive. Flat tools of high speed steel are fitted into the slots in the head and are countersunk for the binding screws, so that when the screws are tightened, the cutters are brought down tightly against the back of the holders. These tools are nicked on the cutting edge in order to break up the chips. A steady rest which is used when facing the cylinders is shown in Fig. 4. The 1¾-inch diameter passes through the hole in the facing tool holder, and the ⅞-inch threaded part on the end screws into a threaded hole in the spindle. The 45-degree beveled face bears up against the 45-degree countersink, just mentioned, in the facing tool holder, and forces this

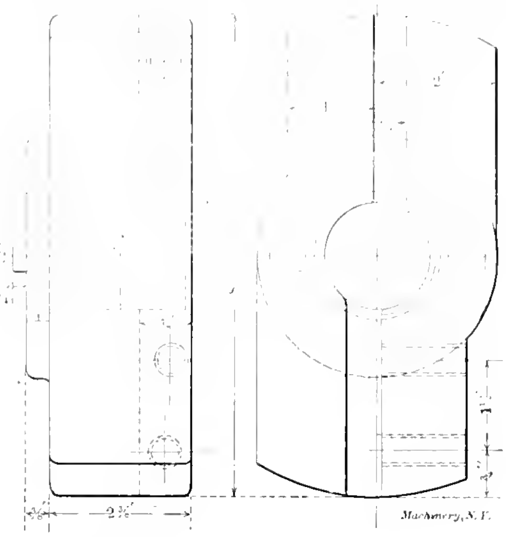

Fig. 3. Facing Tool Holder.

holder up against the flange of the spindle nose. The steady rest proper is made of cast iron and turned 0.002 inch smaller than the diameter of the cylinder. A felt washer is placed behind the cylindrical rest to permit it to give slightly.

In Fig. 5 is shown a valve boring and facing tool. The cutters for this are circular and keyed to the arbor. The pilot at the end enters into the hole already drilled for the

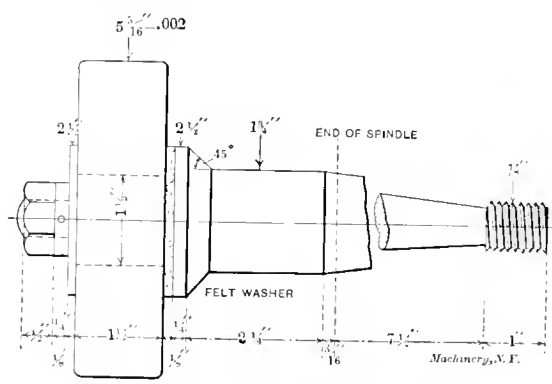

Fig. 4. Steady Rest used when Facing Cylinders.

valve spindle. In order to save space the end cutter is also made to act as a nut, and gashed for a spanner wrench. Two cutters are used for finishing the bore, one roughing and one finishing.

In Fig. 6 is shown a recessing tool which is used for recessing the groove shown at *A* in Fig. 7. A heavy center spindle which has a keyway and key in its upper portion, and then turned down to a smaller diameter, is milled at the lower end

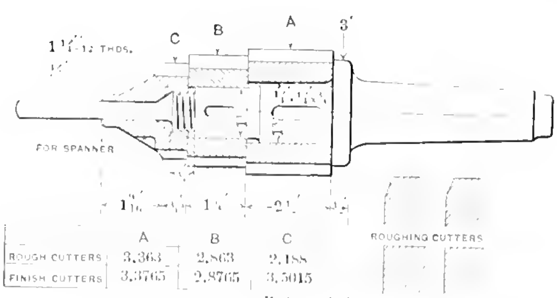

Fig. 5. Valve Boring and Facing Tool.

for a tool *D*, which is made of high speed steel and formed to the shape required. This tool is drilled for pivot *F* and slotted for pin *E*, which latter is milled flat on the sides. The stud *E* moves endwise in the slot in *D* until collar *B*, which acts as stop, comes up against bushing *C*. This bushing guides the tool and spindle in the cylinder and is beveled at the end

so as to easily enter the hole. The spring inside of the bushing allows the cutter to recede when the arbor is removed from the cylinder. BORER.

R. S.'S PERPETUAL MOTION EXPOSED.

In the July issue of MACHINERY, R. S. claims to have solved the problem of perpetual motion, but I regret to say that although it may prove financially a success—people have been known to subscribe for stock in things lots more foolish than this—his device will not be the motive power for very many factories, for the simple reason that it will not work. While it is one of the best perpetual motion devices on the market, it is easy enough to prove that there will neither be a per-

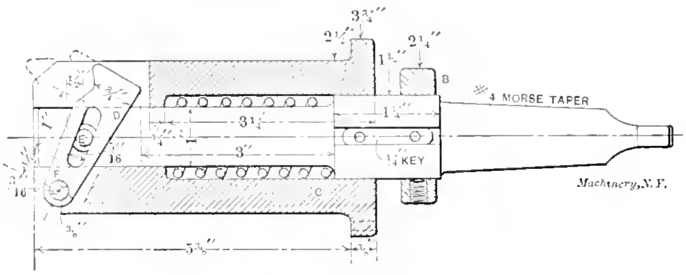

Fig. 6. Recessing Tool.

petual motion, nor even a temporary motion, except if caused by outside forces. This, of course, we all know, but an explanation why R. S.'s machine does not work may nevertheless be in place.

The explanation is simply this, that the work performed by the device when the leaden weights fall down and pull out the bags, thereby pushing the water aside, equals the work afterward done by the water on the bags. The water cannot be displaced without expenditure of energy, and the apparent gain of energy, as explained by R. S., is exactly equalized by the loss of energy due to displacing the water when the leaden weights pull out the bags. This can be exemplified by referring to the action of a cylinder in a piston under analogous circumstances. Suppose a piston and a cylinder of the same specific gravity as water were submerged in water to a depth of 10 feet. Assume the area of the piston to be 4.608 square inches. Then, a six-inch movement of the piston will displace 27.648 cubic inches of water, which weighs one pound, taking the weight of water to be 62.5 pounds per cubic foot. At a depth of 10 feet the hydraulic pressure will be 4.34 pounds per square inch. Consequently, the work done in pulling out the piston six inches and displacing one pound of water will be:

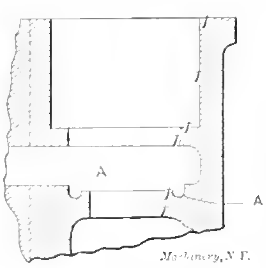

Fig. 7

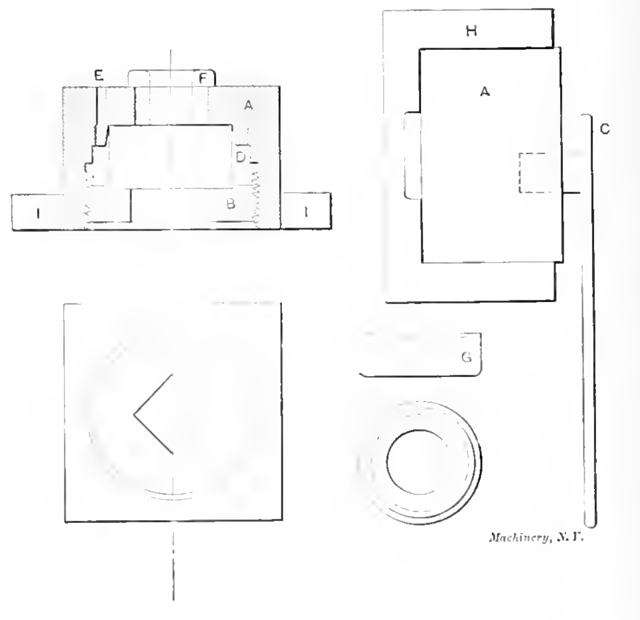
$$4.34 \times 4.608 \times 6 \div 12 = 10 \text{ foot-pounds.}$$

The piston and cylinder have, however, acquired a buoyancy of one pound, and in traversing 10 feet to the surface the work of lifting would be equal to 10 foot-pounds, or the exact equivalent of the work required to pull out the piston and create the buoyancy effect. N. MEYER.

New York.

INTERCHANGEABLE JIGS FOR DRILLING COLLARS.

The article in the June issue of machinery by Geo. T. Coles regarding the making of collars under the steam hammer, reminded me of the methods I adopted in the machine shop some time ago to reduce the cost and increase the output of a variety of sizes of collars. These collars are made of annealed tool steel in sizes varying in thickness as well as in diameter and size of hole. They are cut off on a cold saw by a boy who attends three machines. They were previously made from the bar in a monitor lathe, and the cost was far in excess of what it ought to be. Having a three-spindle gang drill in the shop, which was idle part of the time, I therefore decided to make use of it in the production of these collars. Four jigs like the one shown in the cut were made. They were made to take any diameter or thickness of collars within their range. The body of the jig is a square block of steel, with the hole to receive the collars exactly in the center. The lower end is threaded left-hand to receive piece *B*, which has a square hole in the center to receive wrench *C*. The ring *D* is bored taper, and fits the collar operated upon at the top end only, so that the collars will drop out of the jig easily. The rings are made to fit collars of different diameters, and are just an easy drive fit in *A*, the body of the jig. They are driven out with a soft punch through holes *E* in piece *A*. Drill bushings *F* are also interchangeable. Piece *G* is a distance piece used when drilling thin collars in order to avoid screwing piece *B* into the jig too far. It is apparent from the cut that these pieces are made to fit the collar at one end, and beveled at the other to center in piece *B*. The reason piece *B* is threaded left-hand is as follows: If the collar operated upon should turn in the jig, the piece *B*, taking the thrust, would also turn, and being threaded left-hand would thereby tighten the collar in the jig. Piece *H* is a channel iron the function of which is to hold the jigs while refilling. In operation, one of the jigs is placed upon the drill



Jig for Drilling Collars.

press table under each spindle between flat strips *I*, which keep the jigs from turning, at the same time leaving them free to be removed for refilling. It will be seen that by having four jigs, and a three-spindle machine, by timing them so that they will finish the holes one after the other, it will give plenty of time to refill the fourth jig, and thereby, with an extra drill or two, kept sharpened by the tool grinder, the machine may be kept in constant operation. This machine is equipped with a pump keeping a constant flow of cutting fluid on the drills. As this machine is also handled by comparatively cheap labor, a saving of almost 400 per cent was shown by actual test. C. G. H.

SOME AUTOMOBILE FACTORY WRINKLES.

A simple and effective method of finishing the big end bearings of the connecting-rods of gasoline automobile motors is in use at the factory of the Locomobile Company of America, at Bridgeport, Conn. The rods, which are of drop-forged steel, heat-treated, are bushed at the wrist-pin ends with solid bushings of hardened steel and the split big ends are lined with Parsons' white brass. Heretofore the custom at this factory has been to bore the big end bearings as accurately as possible in special boring machines and then fit each to its individual crank-pin by hand, with the aid of the scraper. The new method, which saves time in turning out the work and also makes a better job, consists in boring the bearing a few thousandths small, and then forcing through it a tapered mandrel of hardened and highly finished steel, the largest part of the mandrel being of course of the size required for the finished bearing. The mandrel is forced

through the bearing by means of a hand-press whose plunger is depressed and raised by a rack-and-pinion arrangement, worked through a ratchet by a hand lever. The mandrel is passed through twice, from opposite sides of the rod. At the completion of the operation the metal is somewhat compressed near the surface and is very highly polished, having a glaze such as it would acquire after running for some time in actual service under favorable conditions. The bearing is a very good fit on its crank-pin, and no hand fitting whatever is required, so that the polished surface is not broken. The compression of the metal, together with the glaze on its surface, apparently increases its ability to resist wear. Preliminary tests showed that bearings finished in this way would wear considerably less than carefully hand-fitted bearings run under exactly similar conditions. Of course the crank-pins must be very accurately finished, or the accuracy and high finish of the bearings will be of little benefit. Preparations are being made to finish the main bearings of the crank-shafts in the same way.

At the same factory the idea of giving new parts the same finish that is acquired by running under proper conditions is carried out in finishing the piston rings, which in a high-compression gasoline engine must be as well fitted as possible. After being finished on grinding machines, the rings are put into a holder which corresponds to the piston and holds the rings just as a piston does, and this is worked to and fro in a cast-iron tube bored and finished exactly the same as a cylinder of the motor, a small quantity of a fine abrasive substance being employed. The rings so finished bear all round when placed in their own cylinders, and also bear right across from edge to edge. The piston is tight from the first, and wears very well. Of course the tubes used in the finishing process are subjected to considerable wear and must be renewed frequently; but this is found to be a very unimportant detail as compared with the excellent results obtained by the employment of the process.

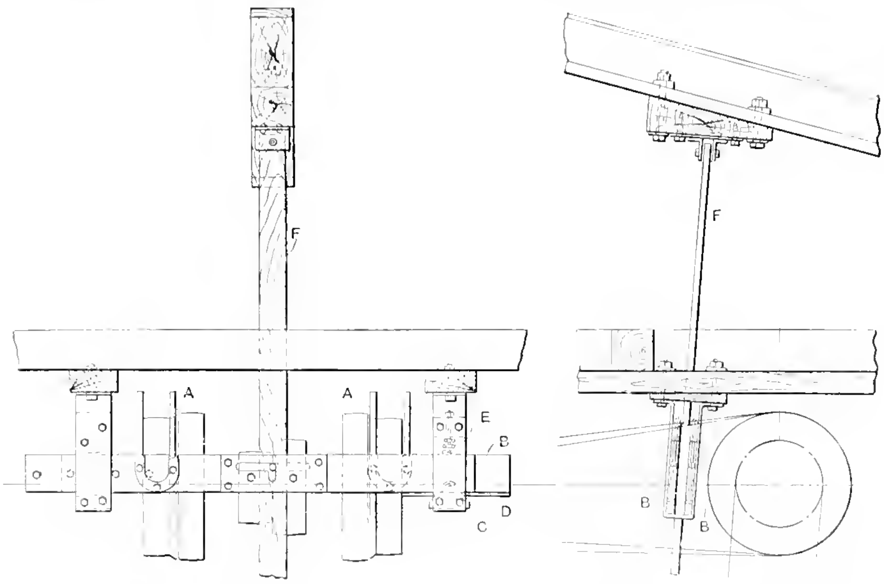
An interesting detail, which would probably not present itself to the mind of the average man, is that piston rings, after being ground on a magnetic chuck—a very widely used method in automobile shops—are more or less highly magnetized, and if allowed to go into the engine in this condition they will attract and retain any small particles of iron or steel that come near them, with unfavorable results in the matter of wear. Consequently it has been found necessary, in the factory in question, to install a demagnetizing apparatus which effectually removes this cause of trouble.

HOMER GREENE.

SHIFTING TWO BELTS WITH ONE LEVER.

The cut herewith shows a design for shifting two belts with one lever, which I think might be of interest to some of the readers of MACHINERY. The belt shifter fingers *A* are bolted to the sliding bars *B*. These bars are carried in the supports *C*. The bars have notches cut in one end. These notches are faced with the steel shoe *D*. The notches fit over corresponding wedge shaped blocks in the right-hand support, and are held down on them by the spiral springs *E*. The shifter lever of the machine is between the two sliding bars and carries a pin that works in a slot in the sliding bars. The bars are strengthened by the steel plates in their middle portion as shown. The action of the device is as follows. When the shifter lever *F* of the machine is in the position shown, both belts are on the loose pulleys. If the lever is moved to the right, the sliding bar nearest to the operator moves to the right, and the notches ride up on the wedge shaped blocks, lifting one end and causing the pin in the shifter lever to slide into the vertical slot in the bar. In the meantime the pin on the opposite side of the shifter lever has moved through the horizontal slot in that bar, shown by the dotted lines, without moving the belt shifter fingers on that bar. When the shifter lever is returned to the central position, it shifts the belt of the bar, nearest to the operator, to the loose pulley, because the pin is now working in the vertical slot. Continued motion of the lever to the left will cause the same operation to be repeated with the other shifter bar. Stops in the left hand portion of the bars keep them from moving too far to the right or left. This shifter has been working in the shop where it was made for some time, and has not given any trouble.

Norristown, Pa. WILLIAM L. AMBLER.



Arrangement for Shifting Two Belts with One Lever.

OBTAINING ANGULAR MOVEMENTS WITH THE INDEXING HEAD.

In the February, 1907, issue of MACHINERY appeared a table giving the movements of the indexing head of a milling machine for a series of angular measurements in degrees. The explanation of how to obtain the movement corresponding to a certain number of degrees did not seem as plain to me as it could have been made. I therefore present the following, in order to make the relationship between the movements of the index head and the angular movements as clear as possible.

As a matter of fact, we can obtain in the first place any movement in whole degrees, since the indexing of 360 is obtainable by simple plain indexing on any of the standard heads. This division is made by taking two holes in an 18-hole circle. Should it be desired to index, say, 27 degrees, we would multiply 27 by 2 and obtain the number of holes necessary for such a movement. As 54 is a greater number than the number of holes in the circle, we would have as the movement of the index crank 54/18 = 3 turns to make a 27 degrees division or indexing. Half degrees are obviously obtainable from the same source; as it requires a two-hole movement for a whole degree, it would be necessary to make but a one-hole movement to obtain the half degree. By substituting the 27-hole circle we may obtain a division of 20 minutes for a movement of each hole. Any row of holes that is divisible by 9 will give divisions of degrees and fractions thereof. Thus a 54-hole circle will give divisions as low as 10 minutes or one-sixth of a degree. This plate is furnished on some heads. By means of the differential index we may still further split up the fractions of a degree, but quarters or sixths of a degree are pretty close, and should be fine enough for even the closest jig work. Of course there are some jobs that one would encounter that might possibly call for much finer divisions, but they would then have to be accomplished by some other means than the one just considered. The above is by no means new, but was suggested by the table mentioned above.

The universal milling machine has become quite a factor in the production of small jig work, and is very handy on such work. When properly adjusted and carefully used very accurate results may be obtained by its use. However, good

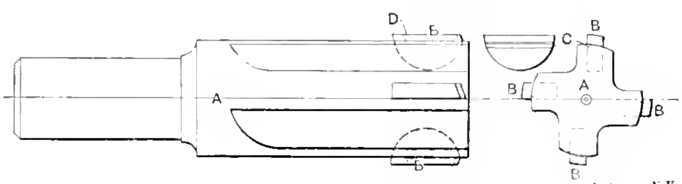
results must not be assumed to be possible from a machine that has been abused, and which is out of true; nevertheless, many unreasonable people think that they ought to be able to do so. Then, again, what is the limit that we may put on the accuracy of such machines? They are certainly far from being perfect even when just out of the inspector's hands. There is a tendency for some fussy individuals to split thousandths to an exaggerated degree even in the plain machines used in manufacturing. This is wandering some from my original topic, but it may be well worth saying.

Hyde Park, Mass. JOHN EDGAR.

INEXPENSIVE TOOLS WITH INSERTED HIGH-SPEED CUTTERS.

We are at the present time in need of cutting tools out of high speed steel, aud we would make them of this material if the price of the steel were not prohibitive in a good many cases. To overcome the objection of cost I have adopted a principle by meaus of which high speed tools can be made at a small fraction of the cost of solid tools. The principle is plainly shown in the cut, in which *A* is the body of a four-lip drill, made out of soft steel, and *B*, half-round disks inserted at the end of the flutes for cutters. The manner of inserting the blades is similar in principle to the Woodruff key system. The cutters *B* are cut off from round high speed steel bars, which have been turned to the exact diameter of the cutter, and are then split in halves with a hacksaw because of the stock saved by using this tool in preference to a saw in a milling machine. The cutters must be made to fit close in the milled slots, and for final binding a notch *C* is filed lengthwise in the cutters about the same height, or slightly below, the outside diameter of the body *A*. When the cutters are hardened and driven home, the soft metal of the body *A* is forced into the notch *C*.

The grinding and relieving is made in the same way as with a solid drill. When the cutters are ground back to about the distance shown by the dotted lines at *D*, the cutters are driven out and new ones inserted. This drill answers admirably for turret work where a boring tool follows



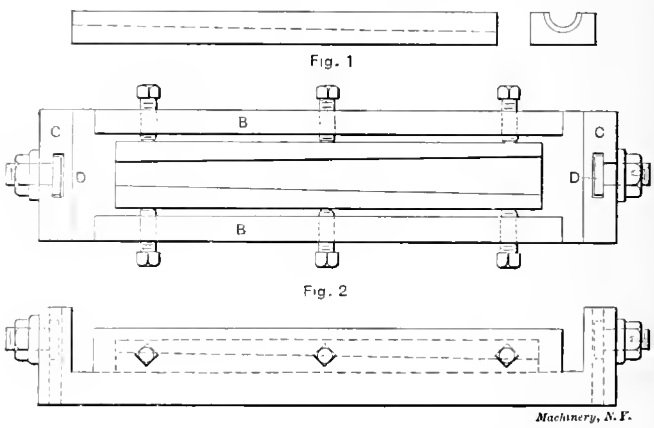
Inexpensive Inserted Blade Four-flute Drill.

for truing up the hole. For drill-press work another set of cutters can be set in back of the first set, so that when the first set of cutters is partly ground away, the second set will steady the drill. The same principle applied to a boring bar has several advantages, as there can be more than two cutting points put in the bar without materially weakening the bar, as is usually the case in small bars with the customary flat cutter and a slot through the bar. Coarser feed can then be used than with a two-point cutter. Another advantage is that on account of the small size of the cutters, it is possible to harden them very hard without risk of breakage, which would hardly be possible with drills of the larger sizes. The tools mentioned have been made, and have given perfect satisfaction, and there is no reason why this principle can not be applied to numerous other tools such as counterbores, milling cutters, and large reamers.

Lawrence, Mass. CHARLES THIEL.

FIXTURE FOR PLANING CONCAVE TAPERS.

Some time ago we had to make a number of semi-circular concave steel pieces as shown in Fig. 1, as well as quarter-circular concave pieces. These pieces were to be made so that if four quarter-circular or two semi-circular pieces were put together, they would form a round taper hole, the large end of which was to be $1\frac{3}{4}$ inch in diameter, and the small end $\frac{7}{8}$ inch in diameter. The extreme length of these pieces was 32 inches. They had to be made very accurate, and when put together must show a good fit on a tapered arbor. In order to plane these pieces a simple fixture was made, as shown in Fig. 2. The body of the device was a casting 40 inches long and $4\frac{1}{2}$ inches wide with two ribs *B B* and uprights *C C* at the ends. In these uprights two vertical T-slots were cored. The body was planed on the bottom between the ribs, and a number of holes drilled and tapped in the ribs for set screws to hold the work to be planed. Two 1-inch T-bolts with heads to fit in the T-slots *D D* were turned and threaded. The bolts were provided with very large centers in the threaded ends. These bolts were placed in the T-slots, a heavy washer slipped on, and the whole fastened by a nut. The steel pieces to be planed concave were now marked on the ends with their respective radii, and fastened by means of set screws in the fixture. The dividing heads were placed on the planer bed with the fixture between centers, the centers of the dividing head entering into the centers of the T-bolts. Then the fixture was adjusted between the centers. The T-bolts were set so that when the fixture was swung around, the radii at both the large and small ends would conform with the surface gage needle. The nuts and



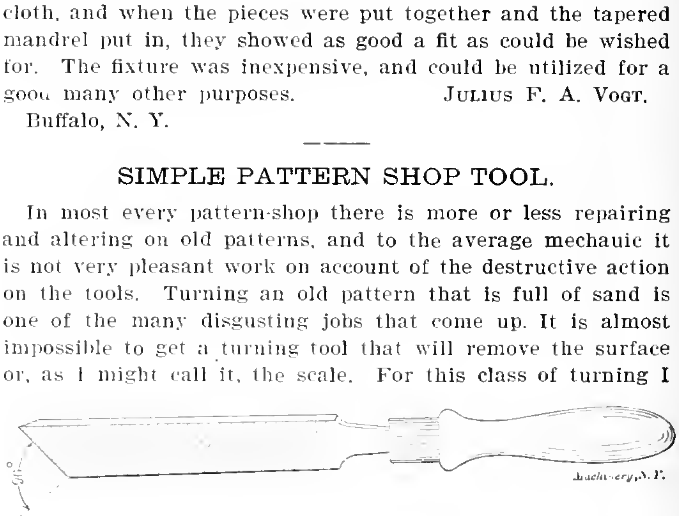
Fixture for Planing Concave Tapers.

T-bolts were then tightened. Now the end of the large radius was raised to the amount of the difference between the small and large radius, by adjusting the foot-stock end of the dividing head, and the work was ready to be planed. It will be seen that when turning the work between the centers, very accurate work could be done, and almost any taper within the range of the fixture could be planed. For final finish in this particular case the planed pieces were only rubbed with emery cloth, and when the pieces were put together and the tapered mandrel put in, they showed as good a fit as could be wished for. The fixture was inexpensive, and could be utilized for a good many other purposes. JULIUS F. A. VOGT.

Buffalo, N. Y.

SIMPLE PATTERN SHOP TOOL.

In most every pattern-shop there is more or less repairing and altering on old patterns, and to the average mechanic it is not very pleasant work on account of the destructive action on the tools. Turning an old pattern that is full of sand is one of the many disgusting jobs that come up. It is almost impossible to get a turning tool that will remove the surface or, as I might call it, the scale. For this class of turning I



Simple Pattern Shop Tool.

have two turning tools, made right and left, from flat, single cut files. The end is ground at right angles to the cut or tooth of the file, as shown in the cut, care being taken so as not to draw the temper in grinding. An old file will answer the purpose, but a new file is worth half a dozen old ones. Pattern-makers and millrights know what a job it is to turn an old or new split wood pulley. This tool will do the job easily. MILLWRIGHT.

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

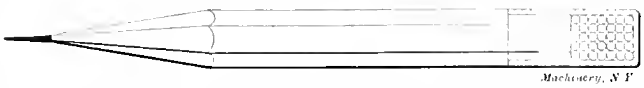
Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

CUTTING FIBER.

In a number of factories where I have been employed, fiber was used in the manufacture, and the cutting was done in the pattern-shop, either on the band saw or circular saw, destroying the cutting edge in a very short time. If rotary shears are at hand the work of cutting fiber into strips of any length and width can be done with ease, and accurately as to measurements, without in the least injuring the cutters. The edges are left clean as if cut with a sharp tool. A pattern-maker will excuse a nail cut into once in a while, but never the cutting of fiber. P. M.

TO PREVENT LEAD PENCIL FROM BREAKING.

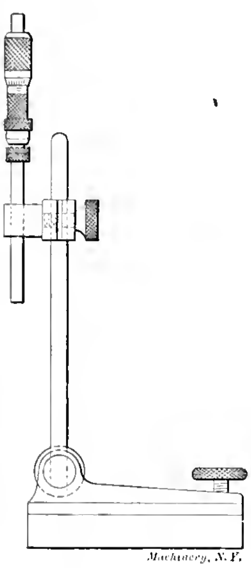
A small shell partly filled with a piece of lead, steel or shot, and forced on the end of a drawing pencil, may appear



to be a queer contrivance; but this end being the heaviest will naturally fall to the floor first, and will prevent the lead from breaking. Gordon F. Monahan.

Bridgeport, Conn.

INSIDE MICROMETER FOR SETTING CALIPERS.



The cut herewith shows an application of inside micrometers which is very handy. The hole for the scriber in the scriber clamp of a surface gage is reamed out to fit the rods used with inside micrometers. This forms a convenient holder for the micrometer when used for setting outside calipers to it. The calipers can be set easily and accurately at the same time, and where extreme accuracy is not necessary this arrangement is more handy than that of using large-sized micrometers. The writer has found that an accuracy of within one-quarter of 0.001 inch is obtainable in this way. Mistakes, in fact, are more easily guarded against than is the case when using the micrometers directly. Sirius.

GRADUATED STOP-COCK FOR OIL.

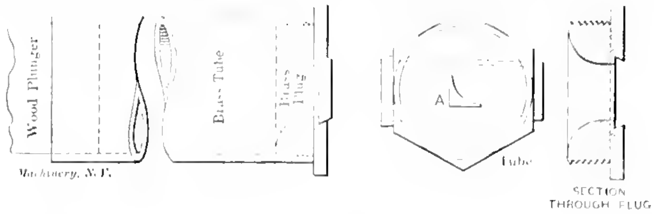
Having much fine planing to do on the milling machine, for which a very close regulation oil was necessary, one of our fellows conceived the idea of the graduated oil-cock, shown in the cut, which enabled him to regulate the flow

very closely and without the usual "turn and try." As the nature of the work was such that he could only continue at it intermittently, he would close the cock entirely when necessary to stop, and upon resuming would open it full for an instant to fill that portion of the pipe between the cock and outer end, and then turn to that graduation, which he would remember had before given the proper flow.

Springfield, Ohio. A. B. Christman.

TOOL FOR SHAPING WAX FILLETS.

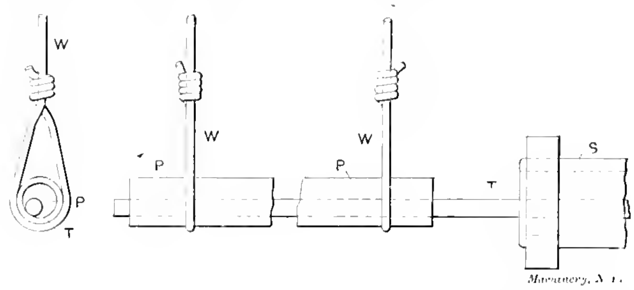
In the cut is shown a wax fillet tool that shapes the wax to a correct fillet instead of round as in all others that I have seen or read of. The brass tube is $1\frac{1}{4} \times 8$ inches, threaded at one end to receive a brass plug. This plug has a dovetail cut in it, as shown in the detailed view. In this



dovetail may be fitted brass plates, as many as are required for the various sizes of fillets. These are cut out as shown at A. By placing the fillet plate required in the brass plug, and heating the tube in the regular way, a much better fillet is made than with the round wax. Pattern-Maker.

STOCK SUPPORT FOR SCREW MACHINE.

Probably not one screw machine in a thousand has a stock support arranged as is the one shown in the cut, but for light stock it has advantages in the matter of economy of

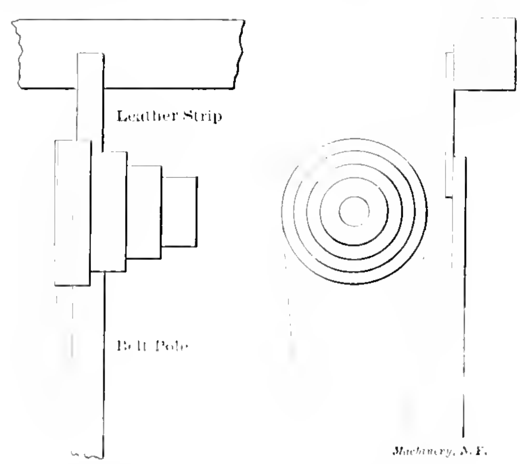


floor space, and can be swung up out of the way occasionally. In the cut, *S* is the spindle of a screw machine; *P*, a pipe; *W*, wires suspended from the ceiling, and *T* the screw-stock.

Springfield, Ohio. A. B. Christman.

BELT SHIFTER.

The cut herewith shows a handy and cheaply made belt shifter for the lathe or milling machine. It consists simply of a stick fastened to a beam by a strip of leather, about midway between the two largest steps of the countershaft



cone. In shifting the belt, the operator reaches through the belt and, grasping the stick, pulls it around against the belt to shift it to the desired step of the cone. For medium size cone pulleys the strip of leather which is fastened to the ceiling and to the stick should be 10 to 15 inches long, of single thickness, and about $2\frac{1}{2}$ inches wide. The pole is hung about $1\frac{1}{2}$ inch back of the largest diameter of the cone pulley. This shifter does away with the need of going after the usual belt pole. When correctly hung, it will shift the belt the whole length of the countershaft pulley. It is used quite extensively in the shops of the W. P. Davis Machine Co. Rochester, N. Y. C. Shaw.

Detroit, Mich.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

BECKER-BRAINARD UNIVERSAL INDEX AND SPIRAL HEAD.

The design of this head is the result of a desire to fill the need for a device that will answer the requirements of the heavier duty now imposed on the milling machine, and still retain the accuracy expected from such a tool. It has also been attempted to retain all the conveniences found in older designs of spiral head, and to add to these others that will increase the usefulness and convenience of the tool.

The prime considerations have been those of stiffness and accuracy. The spindle and worm-wheel are supported in a heavy block housed between two rigid uprights, in which the block swings in a vertical plane. Any angular adjustment required may be firmly held by tightening the nuts on clamping studs *M M* (see Fig. 6), which draw the outside plates securely against the uprights, making a rigid fastening for the head under the heaviest cuts, even when the work is not otherwise supported. The increase in strength thus obtained has in no way impaired the ease of handling.

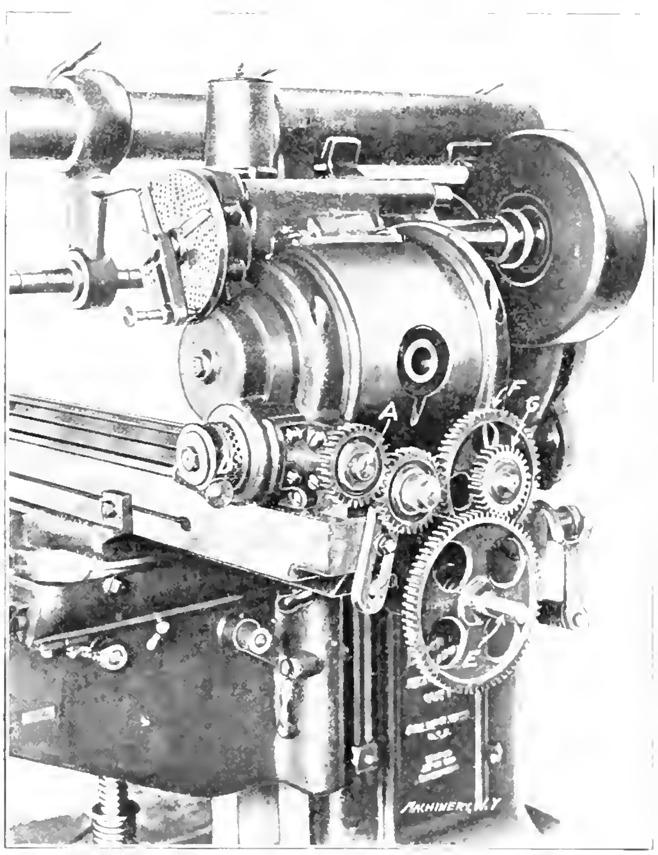


Fig. 1. Univeral Indexing Head in Place on Milling Machine.

The leading feature of the design so far as accuracy is concerned, is the large size of the worm-wheel which has been obtained. This is the largest that the respective swing of each size of head will allow, and the arrangement of the parts is such that in each case it is larger than that of any other head so far offered. Fig. 2, showing the back plate removed, gives a good idea of the unusual diameter of the dividing wheel. This adds greatly to the life of the worm and wheel teeth, as well as to the accuracy, since the wear due to the strain imposed by spiral milling is perceptibly reduced. The coarse pitch it is possible to use with the usual 40 teeth in a dividing wheel also allows of stronger gearing. Another feature is a provision for taking up wear in the worm and worm-gear so as to do away with all inaccuracies due to back lash. The worm gear, as may be seen in Fig. 6, is made in two sections, one of which may be rotated on the other to take up the wear. This method has long been used, and is a most accurate arrangement for making the required adjustment.

Elaborate provision is made for differential indexing. Unlike the arrangements commonly employed, this design provides for differential indexing under the following conditions: with the head in any position on the machine platen, with the work spindle at any angle with the cutter arbor; with work such as bevel gears, having conical surfaces instead of cylindrical; and in cutting helical grooves such as required in spiral gears, for instance. For all these conditions the full range of plain and differential indexing may be employed. Figs. 4 and 6 show best how this is accomplished. The change gears used in differential indexing are mounted on the rear side of the head, as shown in Fig. 4. As will be seen, they have no connection with the table at all, as is the case with ordinary index heads fitted for differential indexing. Shaft *B* carries on one end a gear meshing with the dial driving gear and on its other end the first of the train of change gears used, these being connected with stud *C* in the rear cover plate of the dividing head. Stud *C* carries on its interior end a bevel gear meshing with bevel teeth cut on the hub of the index wheel. It will be seen that this gearing connects the dial with the spindle in such a way as to give it a differential movement, of any degree required for the desired indexing. This is done in such a way as to make it possible to swing the spindle into any angular position desired, since the gears are all mounted on the swinging head.

To make the differential indexing universally applicable to helical work as well as to straight, was another problem this head has been designed to solve. The cutting of spirals makes it necessary that the plate be geared to the lead screw by suitable change gears. The connection between the lead screw and the index plate must be broken when making divisions, in order that the index plate may be free to make the differential movement with the index crank. This breaking of the connection is accomplished by means of an adjustable clutch (shown at *D* in Figs. 1, 3 and 6), which is withdrawn during the indexing operation. After the division has been made, the teeth in the clutch will be found to be in such a position in relation to the corresponding spaces of its mate that it is impossible to engage them. In order to bring the teeth and spaces opposite each other, half of the clutch is made adjustable, so that it may be rotated the required amount to bring the two portions into proper position for engagement. To effect this, one member of the clutch is connected to its shaft adjustably, by a worm meshing with a worm-wheel keyed to the shaft. This worm may be operated by hand by the knurled knobs shown. When these knobs are rotated, the clutch is slowly adjusted about its shaft, though still positively connected with it. By means of this, the lead screw and the indexing dial are again brought into connection with each other, after the indexing, without disturbing the setting of the work. But there is also another difficulty to overcome. The connection between the index crank and the dial through the worm, worm gear, spindle and change gears of the differential mechanism, would form a locked train when the index

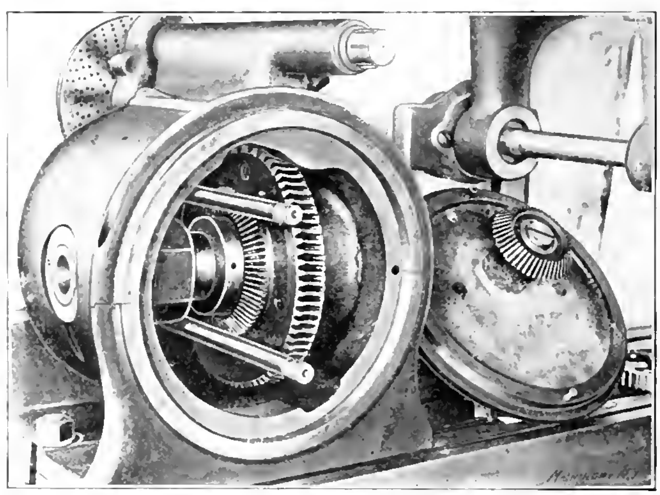

Fig. 2. Back Cover Removed, showing Clamping Bolts and Dividing Head.

pin is in mesh with a hole in the plate; so this must be released during the spiral cutting operation. This is accomplished by means of a knurled knob *H*, see Fig. 3, back of the index plate, which operates a friction clutch, so that the dial may be released from, or connected with, the differential gearing, as may be required. These various provisions make the differential indexing universal throughout the whole range of work of the machine.

Frequently it is desired to roll the work on its axis by a small amount without shifting the dog or loosening the position of the index pin, or sometimes the amount of adjustment may be such that if it is attempted to do it by the crank, the pin will not come exactly over the hole, as is necessary. If the attempt is then made to move both plate and crank in conjunction it will probably be found that the spacing of the holes in which the back pin enters is such that the required

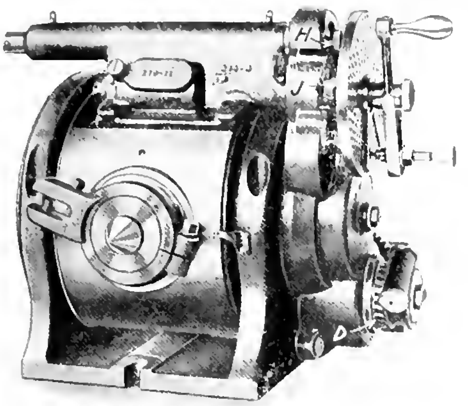

Fig. 3. Front View of Head.

adjustment cannot be exactly obtained. In this head the back pin is done away with, and the plate is held during the plain indexing by a friction clamp on the hub of the plate gear, which is thus gripped or released by a suitable bolt, *J*, conveniently located. By this means work may be set regardless of the position of the plate, which may be securely held in any desired location to bring the work to the position required.

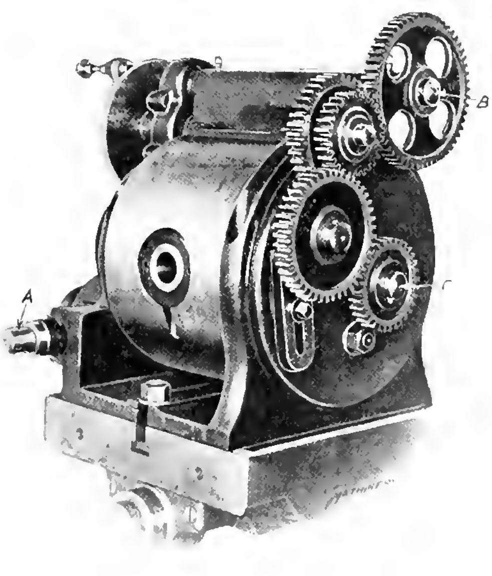

Fig. 4. Back View, showing Differential Gearing

It is believed that the doing away with the back pin, and the substitution of this more flexible clamping device, will be appreciated by milling machine operators.

Another convenience is an adjustable dial on the spindle nose for obtaining angular divisions directly in degrees, for work requiring no great accuracy. This is much preferable in ordinary cases to the cumbersome method of indexing degrees on the dial plate. A single reversible plate is used for all divisions, it not being necessary to provide a variety of these, with adequate differential indexing.

In recapitulation, the following results have been obtained in this design. It is of stiff and rigid construction, with a large worm and worm-wheel, giving accuracy and durability as well; differential indexing may be accomplished in any position of the head on the platen, on conical work as well as cylindrical work, and in the case of spiral milling; the spindle

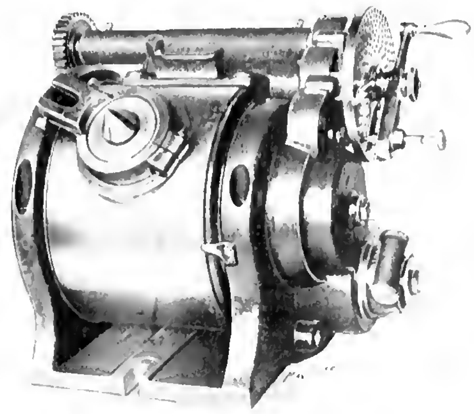

Fig. 5. Head Arranged for Differential Gearing with Angle Adjustment.

and work may be rotated independently of the lead screw when the change gears are set for spiral milling, making the setting of the work easier than would otherwise be the case; means are provided for taking up wear in the worm-gear or dividing wheel; but one reversible index plate is required for all the divisions within the range of the machine, and an adjustable dial is provided on the spindle nose for obtaining.

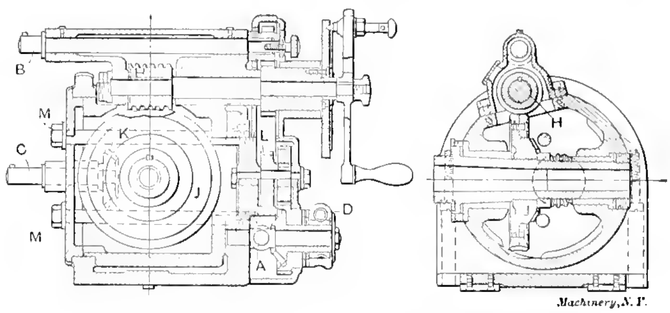

Fig. 6. General Construction of the Becker-Brainard Index Head.

angular divisions directly. This device is furnished with the universal milling machines built by the Becker-Brainard Milling Machine Co. of Hyde Park, Mass.

CUTLER-HAMMER LIFTING MAGNET.

The Cutler-Hammer Clutch Co., Milwaukee, Wis., has been experimenting on the design of electric lifting magnets for some years, in a quiet way. The company has now placed on the market the design illustrated in the three accompanying half-tones. This design is the result of these experiments, and of thorough testing in actual practice in factories, steel works and manufacturing plants.

Like all magnets of this kind, the construction is very simple, being composed of a steel core and frame work with enclosed coils of wire carrying the exciting current. There are a number of features, however, which are original with this design. A concave contact surface has been generally used as being the most efficient for handling loose materials of various kinds, such as punchings, scrap, etc. When, however, this same magnet is to be used for a load consisting of one or two large objects with plane surfaces, this concavity becomes objectionable, since an air gap intervenes between the inner pole and the object to be lifted. To obviate this difficulty an auxiliary pole piece is provided in this design. It is inserted in the concave face of the magnet with a stem passing through the central aperture in the frame. It is so designed that the inner pole is extended downward to the level of the outer pole, thus eliminating the air gap, and insuring intimate contact of both poles with the object to be lifted. The central aperture in which this auxiliary pole is fitted serves another purpose—that of ventilation. In magnets of the usual construction the concave pole face forms an air gap in which heat accumulates very rapidly, and from

which it is difficult for it to escape. The fact that there is a hollow central core through the frame obviates this trouble, making it possible to keep the windings cool at all times. The pole shoe of the magnet is the part subjected to the greatest wear and tear. This is removable, being fastened

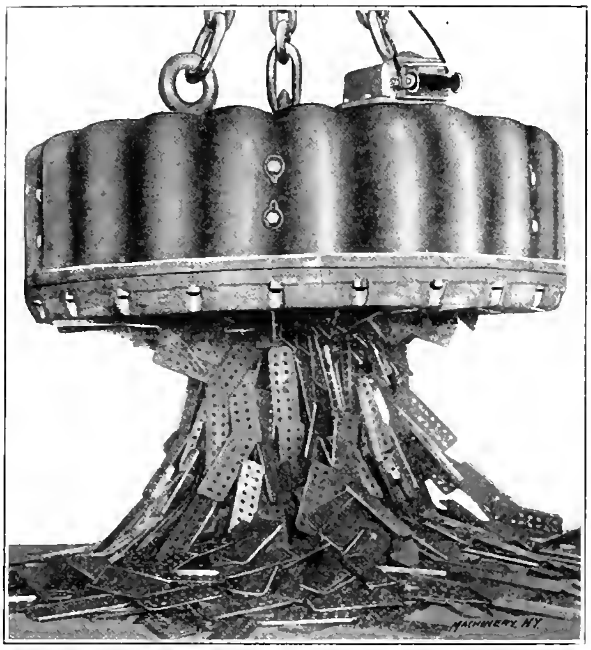

Fig. 1. Cutler-Hammer Magnet Lifting Punchings.

to the under side of the apparatus with through bolts and cap screws.

It will be noticed that the periphery of the frame is corrugated. This is done to furnish a greater radiating surface, and to protect, as well, the heads of the through bolts which fasten the removable pole piece to the magnet frame. The magnetizing coil, on which the efficiency of the magnet depends, is carefully built up of alternating layers of copper and asbestos, and is insulated from the cast steel frame by thick sheets of mica. No combustible material of any kind is used, so there is no danger of damaging the magnet if, by accident, it should be left connected with the circuit over night, as has actually happened. Under test, the coils of these magnets have been heated to 470 degrees F. without injury.

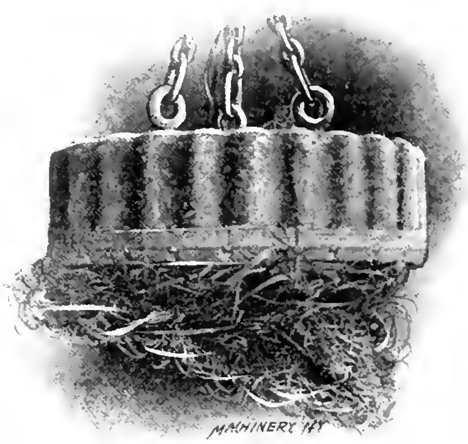

Fig. 2 Fifty-inch Magnet Handling Scrap.

This freedom from injury by heat is also of advantage in lifting and transporting forgings, castings, etc., which are as yet too hot to be touched by hand.

The half-tones shown illustrate two sizes of the Cutler-Hammer lifting magnet. Figs. 1 and 2 show the 50-inch size, and Fig. 3 the 10-inch size. The 50-inch size under favorable circumstances will lift as much as 20,000 pounds. Under other conditions the capacity of the same magnet may drop to 1,000 pounds or even less. This all depends on the nature of the load offered to it. Perhaps as unfavorable conditions as could be imagined were met with in a competition conducted by the Youngstown Steel & Tube Co. This was to determine the best form of lifting magnet for unloading pig iron from cars. The Cutler-Hammer magnet unloaded a steel gondola containing 109,350 pounds of sand cast pig iron in 2 hours 5 minutes. This was done entirely by one man, the crane operator. The average lift was 785 pounds, which was better by 43 per cent than the average made by a heavier competitive magnet. The Cutler-Hammer magnet was purchased and is now in use. The conditions which made this task difficult were the irregular surfaces presented by the sand cast pig iron, and the fact that the material was lifted from a steel gondola.

In Fig. 1, a 50-inch magnet is shown lifting a mass of steel punchings. In this case the auxiliary pole piece mentioned is used. The magnet was not lowered to the punchings, but was brought to within about 3 feet of them, when they arose to meet it as shown in the cut. In Fig. 2, a magnet of the same size is seen lifting plate and sheet scrap of weight not known. This scrap was originally in a pile about 4 or 5 feet high, and was crushed into a compact mass, as shown, by the weight of the magnet. In Fig. 3 the 10-inch size is shown lifting a Bliss car lighting dynamo weighing 800 pounds. The magnet itself weighs about 75 pounds.

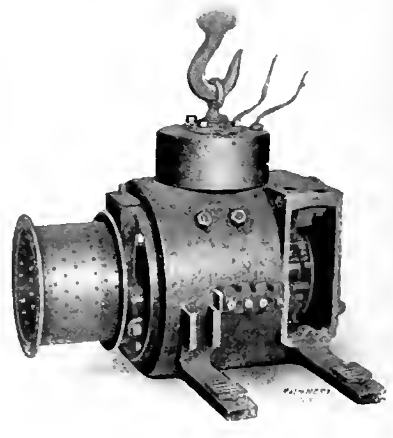

Fig. 3. Ten-inch Magnet Lifting a Weight Ten Times its Own.

The principal points on which the builder claims superiority above all competitors are first, that the weight of a Cutler-Hammer magnet will be guaranteed not to exceed that of any comparable magnet; second, that its lifting capacity will exceed that of any other with which just comparison can be made; and third, that the operating cost per ton of material moved will be less than with any other magnet.

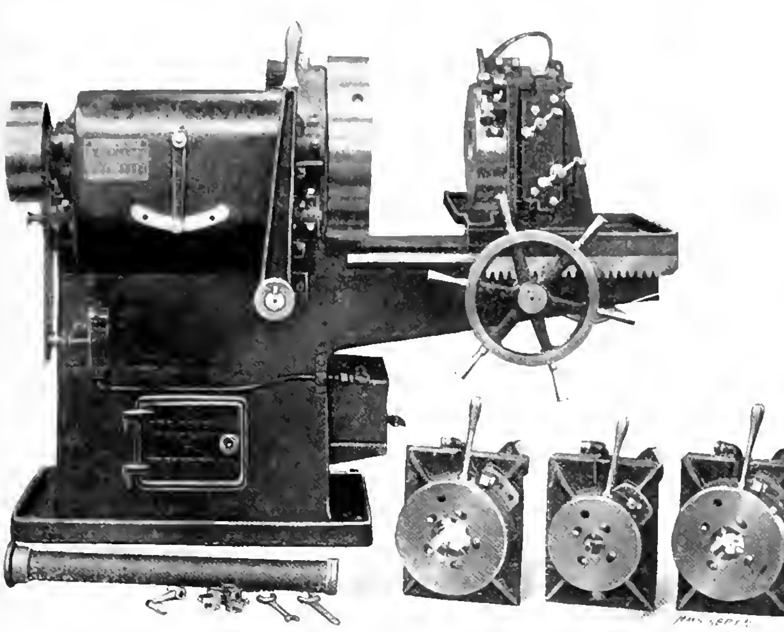
STOEVER LEVER PIPE THREADING MACHINE.

This machine, built by the Stoever Foundry & Mfg. Co., of Myerstown, Pa., is designed to cut off and thread pipe from 1/4 inch to 2 inches in diameter, inclusive. As shown in the half-tone, the bed and head-stock are cast together in one piece, insuring a rigid support for the bearings. This is particularly necessary in a machine of this kind, as the operation of the chuck brings a constant strain on the front bearings of the main spindle, which is not properly taken care of where these bearings are in independent castings, bolted to the bed.

The spindle has nine speeds, obtained from a single speed pulley, through sliding gears and clutches. This gives a sufficient range for cutting both steel and iron pipe of the sizes within the capacity of the machine. A speed plate is mounted on the head-stock, showing what speed should be used for each size, so the operator has no excuse for limiting the output through ignorance. The chuck is operated by a lever while the spindle is in motion; but little pressure is required, owing to the design of the linkage employed. The chuck presents a smooth surface, the actual gripping parts being entirely enclosed. Three jaws are provided, adjustable universally at any one of three points on the periphery of the chuck, one of which is within reach no matter in what position the spindle stops. All of the mechanism of the chuck is made of steel. The spindle gearing is completely enclosed, but can be exposed for inspection by removing the cover. A set of bushings is provided for supporting the various sizes of pipe. These extend clear through the spindle, with a bearing at each end, so that there is no trouble on the score of

having to center the pipe to enter the jaws when work is inserted from the rear end. An improved pipe and nipple holder is provided.

The die-head is mounted loosely in horizontal guides on the slide so that it can adapt itself to any eccentricity in the work. These horizontal guides are long enough, also, so that the head can be pushed entirely to one side, in which case the cutting-off tools can be brought very close to the gripping chuck, cutting off work flush with the jaws. In this position, also, pipe can be inserted in the machine from either end equally well, without requiring it to be dragged over the cutting edges of the chasers. A steel cam is used for adjusting the interchangeable steel chasers; hardened steel parts are used throughout in this mechanism to reduce the wear. The front face of the head swings open, so that the chasers may be removed by simply picking them out and inserting others in their place; the whole interior of the head is thus exposed for cleaning or inspection. Two cutting-off tools are used, both being operated by the same handle. A balanced feed is provided, so that both will always be cutting. The machine may be equipped in two different ways, either with a single head and chasers of various pitches, which are changed as the work requires, or with a head and inserted chasers for each pitch. This latter plan, though requiring a more extensive equipment, is the best for jobbing shops, where each operation may be on work of a different size. The length of the horizontal ways in the holder is such that two heads may be mounted at a time, it not being necessary to remove the one in place, if a short job has to be done on another size.



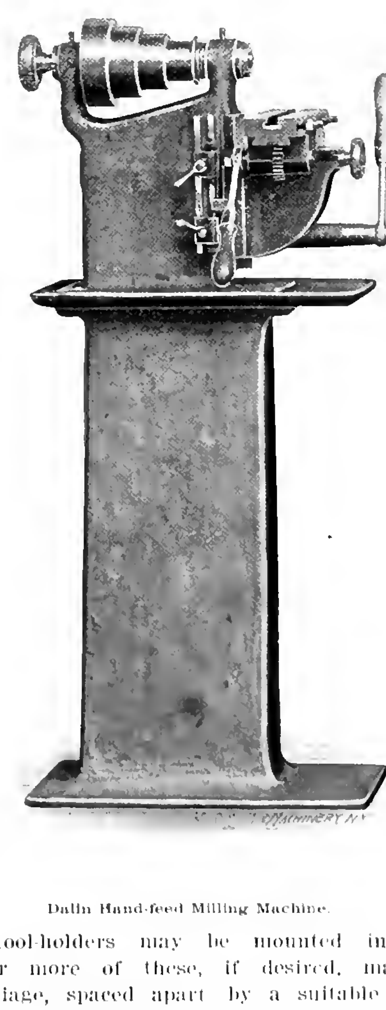
Stoever Lever Pipe Threading Machine.

The oiling system is carefully planned. The pump is driven by a steel chain from the constant-speed pulley. It is of the geared type, and will deliver oil when running in either direction. The oil flows back from the dies and cutting tools to the bed of the machine, and then through strainers into the tank below. The machine is made with a cabinet base in which dies, nipple holders, wrenches, etc., are kept. A large oil pan is also cast around the base. The weight of the belt driven machine, with one die-head, dies, countershaft and bushings, is 2,500 pounds.

NO. 1 DALIN MILLER.

The hand miller shown in the accompanying half-tone is built by Dalin Bros., Rockford, Ill. It is designed for small work, and is especially adapted to the demands of interchangeable manufacturing, being well built, carefully fitted, and very heavy and rigid for a machine of its size. The table has a long bearing, giving a good wearing surface. The vertical movement of the knee on the column can be limited in either direction by the stops shown, clamped in the T-slot on the side of the column. Fine pitch screws are provided for close adjustments, and the abutting surfaces are so placed as not to be subject to error from the accumulation of chips. Stops are also provided for the traverse of the table. The spindle is regularly fitted with a drawing-in sleeve and a half-inch collet or chuck for straight-shanked arbors and end mills. The machine is driven by a 4-step cone for a 1½-inch belt. If desired, it will be provided with a 3-step cone, and the spindle may be bored to a No. 7 Brown & Sharpe taper if the customer so requires. The machine is sold with or without base.

The height from the table to the center of the spindle is 4⅝ inches. The cross adjustment of the saddle is 2½ inches. The table, which has a working surface of 3½ x 12 inches, has a travel of 7 inches. The weight of the machine, with countershaft and base, is 295 pounds. If required, a vise will be provided, with jaws 1 inch deep, 3½ inches long, and with an extreme opening of 1½ inch.



Dalin Hand-feed Milling Machine.

NEW DESIGN OF THE LO-SWING LATHE.

The accompanying half-tones illustrate changes recently made in the design of the well-known "Lo-Swing" lathe, built by the Fitchburg Machine Works, Fitchburg, Mass. The improvements relate principally to the design of the carriage and tool-holders. The whole machine was described in the November, 1905, issue of MACHINERY. The changes are best seen by referring to Fig. 3, which shows a view of the lathe from above, with the tools operating on a piece of work. Two rigid and compact carriages have been provided, retaining the useful features of the feed mechanism of the previous machines. These carriages are provided with longitudinal ways at the top, on which the tool-holders may be mounted in any position. Two or more of these, if desired, may be used on each carriage, spaced apart by a suitable distance to give the shoulders required on the work. The provision made

for supplying oil to the point of the tool is unique. Oil is conducted to a passage in each carriage by a flexible piping system from the circulating pump. From this passage in the carriage, short sections of flexible tubing are used to supply the lubricant to each individual tool-holder. Plug valves are provided for each outlet. This arrangement is entirely out of the way, and very convenient.

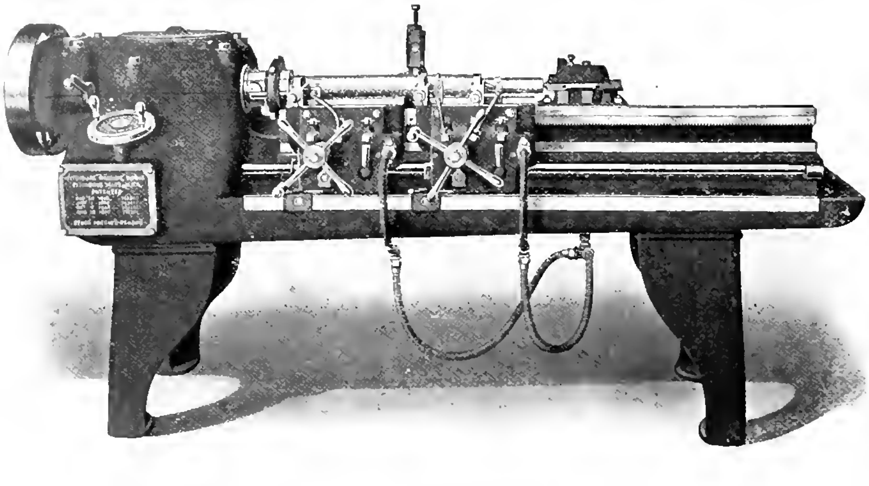


Fig. 1. New Design of Lo-swing Lathe.

A new attachment used with this machine provides for the turning of tapers. This is shown in Fig. 2. It consists of a tool-holder with a slide at right angles to the axis of the work, actuated by means of a flat tapered bar or templet, placed directly back of the tool, but fastened to the bed of the lathe so as to always hold the same relation to the work. This templet is planed to half the included angle of the taper desired, and is arranged to be swung out of the way when other cuts are being taken. The taper tool is fitted to receive the follow rest, which on long work precedes the cutting tool, bearing on a previously turned straight furnace. The tool-holder and its guiding frame are easily attached to either carriage, and since it is only $\frac{3}{4}$ inch wide, ample room is left for several other tools if necessary.

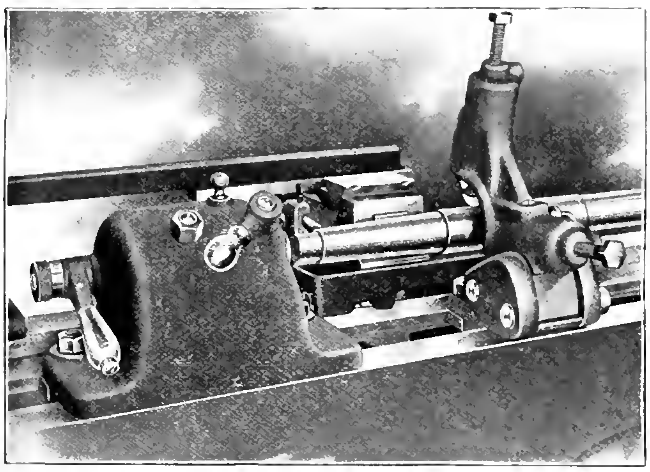

Fig. 2. Taper Turning Attachment for Lo-swing Lathe.

The general plan on which the "Lo-Swing" lathe is designed has been before described, but it may be worth while in this connection to explain it again in a few words. It is built for specialized turning of shafts, pins, studs, forgings, etc., not over $3\frac{1}{2}$ inches in diameter, and with any number of diameters and shoulders. It is designed to do this work with the greatest accuracy obtainable in lathe work. As the work turns on centers, it is readily transferred; so it is used, not only for straight turning, but for any piece on which there is straight or taper turning to do in combination with other special operations, such as threading, chucking, etc. Its advantages for this work are: the fact that several tools may be used at once, provision being made for this by the use of the specially adjustable tool-holders just described; the fact that there is a minimum number of joints between the tool and the bed which supports it, giving the cutting point a very rigid support; and, finally, the machine is designed to furnish convenient means for making rapidly all the changes required, such as altering the adjustment of the tools, changing the feeds, etc.

The decrease in the number of joints and sliding surfaces between the point of the tool and the bed of the machine is especially noticeable. Another point is the fact that the bearing has been brought well under the cutting edge; this could be done on account of the small swing to which the lathe has been restricted. Even when cutting clear down to the center, the overhang of the tool is inappreciable. In the case of an 18 or 20-inch lathe of the usual design, especially if it is furnished with a compound rest, the point of the tool may be anywhere from 8 to 15 inches from the guiding surface of the Vs. There is thus seen to be a great difference between the degree of rigidity obtained in standard lathe design, and in this specialized form for small diameters.

FOSDICK BORING, DRILLING AND MILLING MACHINE.

The machine herewith illustrated is designed for boring, drilling, milling, or tapping, at any angle. It is called by its builders, the Fosdick Machine Tool Co. of Cincinnati, Ohio, their style D horizontal boring, drilling, and milling machine. The machine has a bed plate, tongued and bolted to a main bed, on whose wide upper surface is carried the column, which has a horizontal travel on the ways shown. This column carries the saddle, which is counterbalanced, and can be adjusted by the pilot wheel, or raised and lowered by power. Suitable feeds in either direction are provided for the spindle. These feeds can be used not only for the horizontal travel of the spindle, however, but for the vertical travel of the head on the column, and the horizontal movement of the column on the bed. All these movements can be instantly reversed. The pilot wheel shown can also be used for operating any of these adjustments by hand. These various movements make it possible to provide power feed for milling in any direction, as well as for drilling and boring. For heavy milling, the column can be fed backward and forward on the bed. This places the strain of the cut on a screw of suitable diameter and

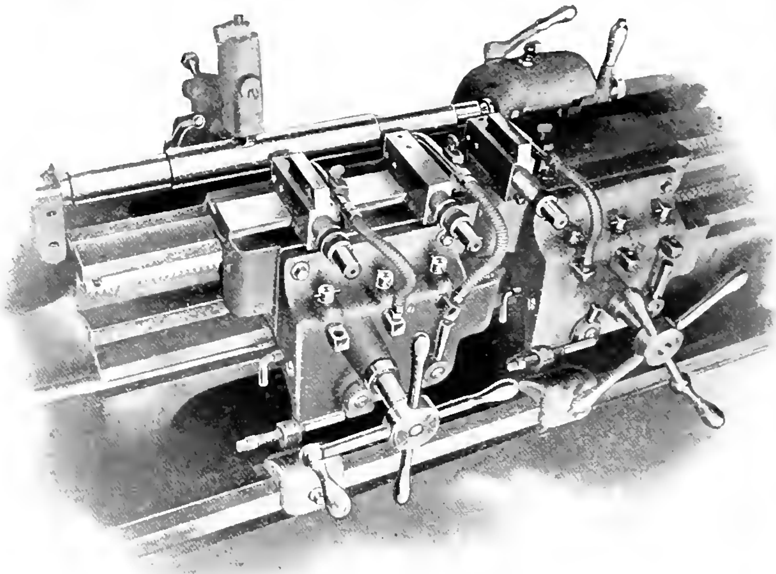

Fig. 3. View showing Carriages and Tool Blocks.

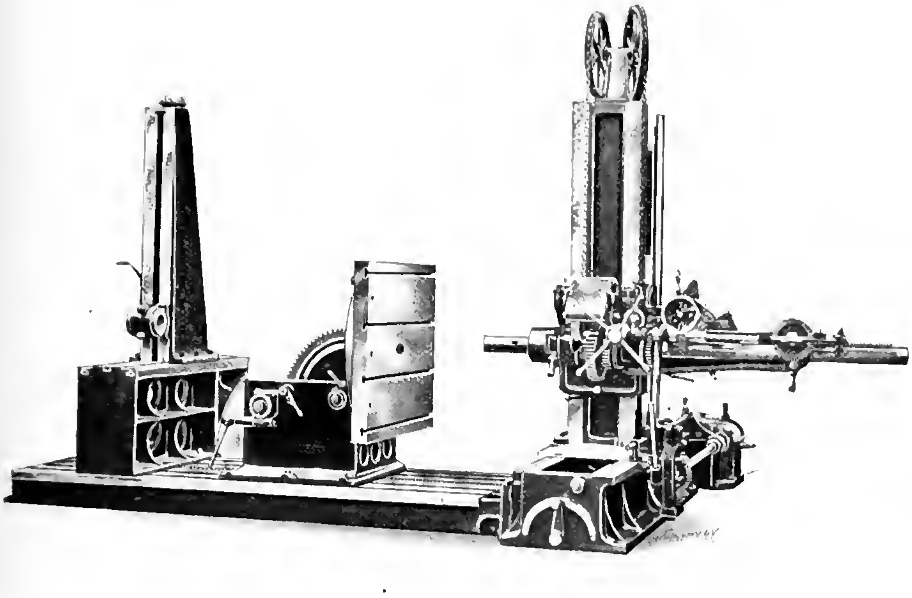
lead, having ball thrust bearings. This feed can be controlled by the lever shown on a semi-circular guide on the front of the machine.

The spindle is connected to a constant speed drive, which can be driven either by a belt or may be geared direct to a constant speed motor. A speed box with positive changes is used, which gives six variations; these may be easily and noiselessly obtained while the spindle is running. This, in combination with the two changes in the head, gives 12 changes of spindle speed of from 4 to 260 revolutions per minute. A friction clutch placed between the back gear and the speed changing device provides for starting, stopping and reversing the movements of the whole machine. This clutch has a toggle friction motion, and is powerful enough to carry the greatest loads it will be called on to sustain. The spindle bearings are of large diameter and length, and are fitted into adjustable taper bronze bushings with provision for taking up wear. The spindle sleeve has a threaded collar of large diameter so arranged that it may be used for securely tightening the spindle bar centrally in any desired position.



Boring, Drilling and Milling Machine with Universal Table.

The bed plate carries a universal table, which may be swung to present the work at any angle. An outboard bearing is also provided for boring bars. The universal table or the outboard bearing may be moved toward or away from the spindle by a rack and pinion movement, operated by a ratchet. A horizontal movement in the other direction is provided for the outboard bearing through a rack and pinion, while the vertical movement is controlled by a crank and screw. All the various movements of the column, spindle, head, outboard bearing, etc., are provided with scales to facilitate setting.

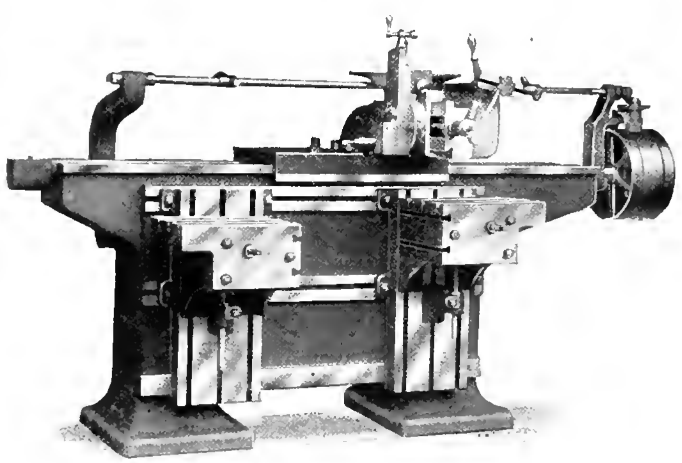
This machine is built regularly in two sizes, of practically the same construction, but with different work holding capacity and traverse of the feeds. The No. 2 machine has a spindle with a No. 6 Morse taper socket and a traverse of 30 inches. The vertical adjustment of the head and column is 54 inches; the horizontal adjustment of the column and the bed is 62 inches. The center of the spindle can be raised to a distance of 72 inches above the base, or lowered to within 22 inches of it. The base is 42 inches wide by 127 inches long, and the universal table has a clamping surface 40 x 46 inches. The total height of the No. 2 machine is 9 feet 6 inches, and the net weight is 20,000 pounds.

CINCINNATI OPEN SIDE SHAPER.

This machine, shown in the accompanying half-tone, is one of a line of which the smallest size was illustrated in the January, 1907, issue of MACHINERY. As there described, these machines are especially adapted to certain classes of work which cannot be easily handled on the ordinary shaper. For instance, there is practically no limit to the diameter of shaft which can be key seated. The usefulness of the ordinary shaper in this direction is limited by the size of the opening through the column under the ram. Again, it has the advantage of having a uniform deflection for the tool throughout the length of the stroke, the amount of over-hang being constant during that time. In the regular shaper the tool and arm spring upward, and the work deflects downward more at the end of the stroke than it does at the beginning, giving the well-known "fan-tail" cut, which is one of the objections to the shaper for accurate work. The range of the machine is also considerably increased. Castings of great size can be brought up to it and worked on by it without interfering with any portion of the machine.

The size shown in the cut planes 15 inches wide by 60 inches long. The maximum distance from the head to the table is 23¼ inches. There are two tables, each 15¾ inches wide with a vertical adjustment of 19 inches. They are 15 inches deep and rigidly constructed. The use of two of them, independently adjustable, makes it easy to hold irregular work that would otherwise have to be supported on blocking at one end.

The head is traversed by the method adopted by the builders is their previous machine, a bronze nut and steel screw being used, directly keyed to the driving pulleys without the intervention of gears. The reversing action depends on the turning of the shifting rod. This is accomplished by cams on the saddle, coming in contact with dogs, which may be adjusted to any position of the rod; or the rod may be turned by hand from the saddle if desired. This shifting rod is supported on ball bearings, as are also the elevating screws for the table. This machine is built by the Cincinnati Shaper Co., Cincinnati, Ohio.

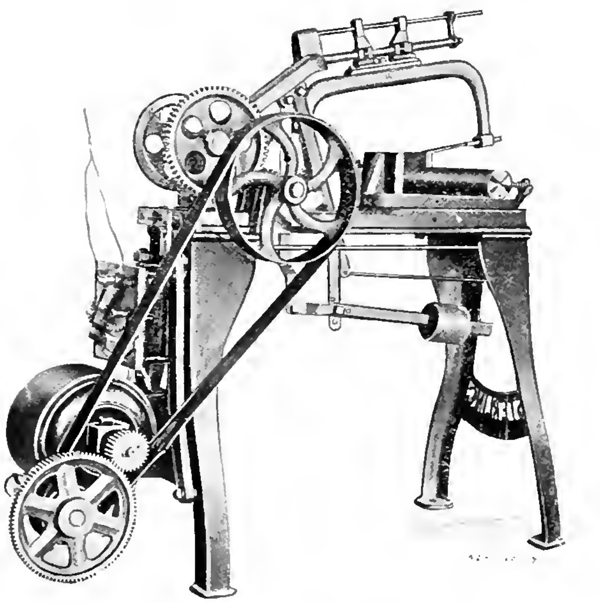


Richards, or Open Side Shaper.

STERLING MOTOR DRIVEN HACK-SAW MACHINE.

The hack-saw shown in the cut is built by the Diamond Saw and Stamping Works, Buffalo, N. Y. As shown, arranged for motor drive, it is especially useful in stock rooms and tool and machinery warehouses, where there is no line shaft power available; it is useful also where electrical drive is used for other purposes in the plant. The motor is mounted as a unit with the speed regulating rheostat, on a special base secured to the rear legs of the machine. Either a direct current or an alternating current motor will be supplied. The direct current motor will be wound for 110 or 220 volts, and under special conditions for 500 volts. The type used provides for slow speed, rigid construction, and a considerable overload capacity. It is entirely dust and moisture proof, and has large oil wells with ring oilers. It is provided with a fiber

pinion and is noiseless in operation. The rheostat provided permits of a regulation of the stroke from 45 per minute for tool steel up to 55, the latter being used for machinery steel and cold rolled shafting. The alternating current motors are supplies for circuits of 110 or 115 volts, with 25, 60, or 133 cycles. They are constant speed self-oiling induction motors,



Sterling Motor-driven Hack-saw.

without brushes or commutators. Although they are designed for single phase currents, they may be run between two branches of a three-phase installation.

These machines have a special attachment by which long bars of angle iron or other kinds of stock may be cut off at an angle of 45 degrees or more, if desired. These machines are built in lots of 200 each, so that the manufacturers are able to take advantage of improved methods of producing them economically, giving the producer the advantage of a good machine at a comparatively low cost.

RADIUS MICROMETER.

The accompanying illustrations, Figs. 1 and 2, show two forms of a neat measuring instrument devised by Mr. W. A. Farrar, Whitman, Mass., which he names "radius micrometer." The tool shown in Fig. 1 consists of two micrometer heads mounted in a bar, which is provided with carefully reamed centers at the ends. The micrometer heads are so mounted that the ends of the spindles just coincide with the axial

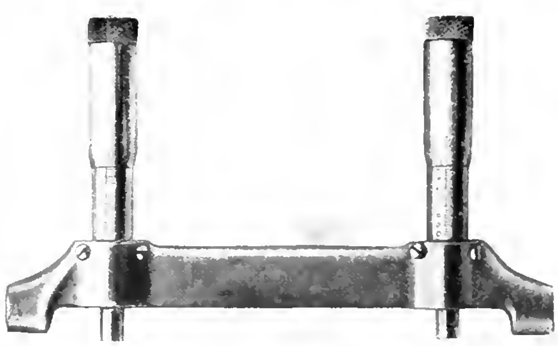


Fig. 1. Radius Micrometer for use on Centers.

line joining the centers, when the barrels register zero. The construction shown in Fig. 2 is on the same principle, the taper shank being substituted for the centered bar. This shank is offset in the part supporting the micrometer, so that the measuring point coincides with the center line when the barrel stands at zero, the same as in the double-head tool. Figs. 3, 4 and 5 show two forms of the tool in use on the lathe.

Within its range, the radius micrometer enables a turning or boring tool to be set precisely to turn or bore any required diameter. The tool also may be used to adjust the cutters held in a boring bar, and it may be used for a wide variety

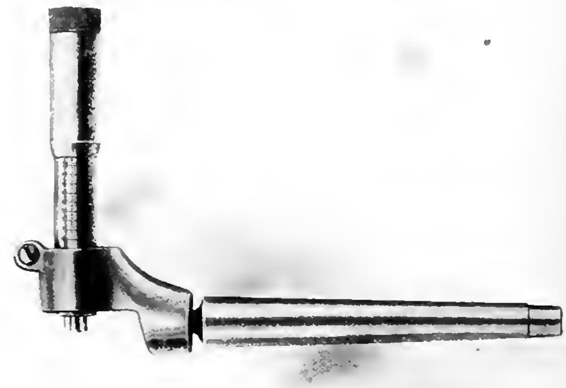

Fig. 2. Radius Micrometer, with Taper Shank.

of general work, as, for example, turning cams. The height of the cam may be measured when ordinary calipers are useless, because of the absence of metal at a point opposite the throw. The tool may also be used to measure the variation of lathes in relation to the ways, etc.

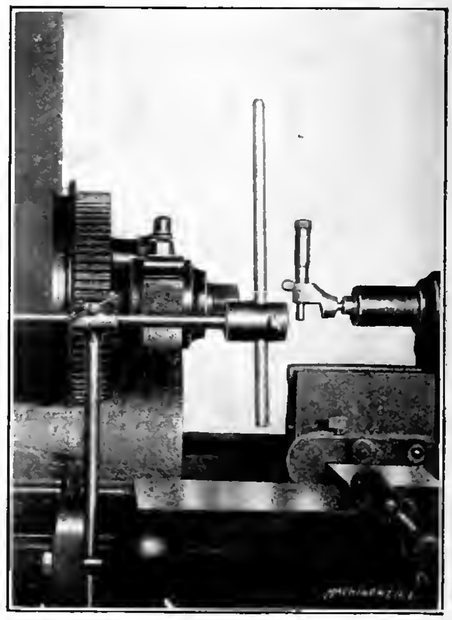

Fig 3. Setting a Boring Tool to the Correct Diameter.

Fig. 3 illustrates the method of setting a boring tool, using the form of radius micrometer shown in Fig. 2. The micrometer is mounted in the tail spindle and adjusted to read the required radius of the hole or one-half its diameter. An auxiliary attachment is required, shown at the left, this being in the form of a standard clamped to the ways and having an adjustable rod. In this view both the pointer and the micrometer are shown in a vertical position, both being turned upright so as to show clearly. The adjustable rod, shown

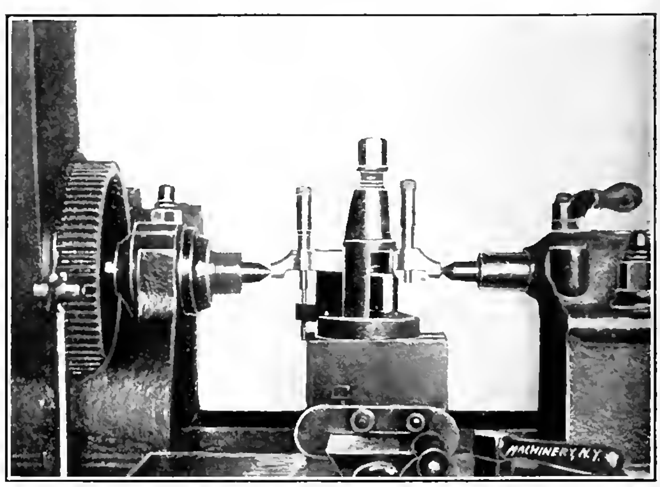

Fig. 4. Measuring the Vertical Alignment of Lathe Centers.

standing in a vertical position, is set so as to just touch the end of the micrometer spindle. After adjusting the point of the adjustable rod to touch the end of the micrometer spindle,

the tail-stock is moved back on the ways and the boring tool is put in place in the tool-post. When it is adjusted so that the cutting edge touches the end of the measuring rod, it is set to bore the radius indicated by the radius micrometer. If several cuts are required to bore the hole to size, the ordinary stop used in screw cutting may be adjusted to regulate the final cut.

Fig. 4 shows the method of using the double radius micrometer illustrated in Fig. 1 to measure the height of the lathe

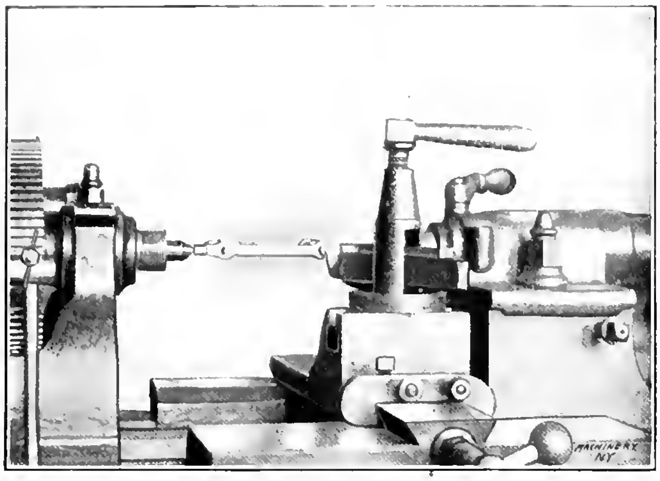

Fig. 5. Setting a Tool to Diameter, or Aligning Centers Laterally.

centers. A holder carrying a steel point is held in the tool-post, and the carriage is moved from one micrometer spindle to the other to ascertain the condition of alignment. When both micrometer barrels read the same, then the centers are in vertical alignment.

Fig. 5 shows the method of using the same instrument to set a tool to turn a desired diameter, or to secure lateral alignment of the centers. It is obvious, of course, that the tool is convenient for setting the tail-stock so as to turn tapers. Mr. Farrar states that there are many other uses of the tool which will suggest themselves to users.

COMMUTATOR TRUING DEVICE.

The Patterson Tool and Supply Co., Dayton, Ohio, is placing on the market the useful device shown herewith. It consists of a pedestal with ways formed on its top surface to carry a tool slide. The manner in which this device is used is obvious. It is blocked up beside the commutator to be trued, on the floor

Portable Tool Post for Truing Commutators.

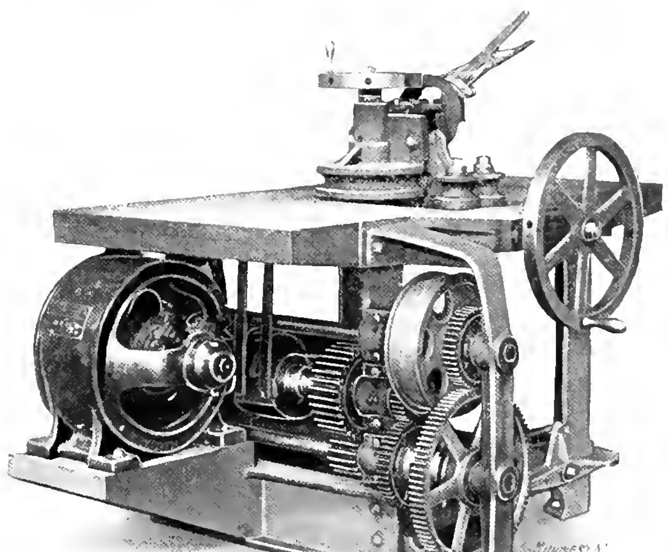
or on the base plate of the dynamo or motor, and is then clamped in position. The slide being lined up with the armature shaft, the tool is placed in the tool post, which is fed into a depth sufficient to just finish out the inequalities of the commutator. The tool is then fed steadily by hand, by operating the longitudinal feed screw of the machine. This longitudinal feed is 15 inches in length. The cross adjustment is 5 inches, and the vertical adjustment for bringing the tool to the center line 6 inches; the tool post is for tools with shanks $\frac{3}{4}$ x $\frac{3}{4}$ inch section. The weight of the device is about 75 pounds.

STOEVER AUTOMATIC PIPE BENDING MACHINE.

This machine, built by the Stoever Foundry and Mfg. Co., of Myerstown, Pa., is designed to bend pipe of from 1 inch to 2 inches in diameter, with a radius of bend varying between the limits of $2\frac{1}{2}$ inches as a minimum for the 1-inch size, to a maximum of 12 inches.

The pipe is bent by carrying it around a circular former of the proper radius, fixed to a spindle on top of the table, as shown in the half-tone. This former or roll is made in two pieces, the joint being at the center of the groove in the roll. The lower half is fastened firmly to the spindle; the upper half is keyed to the spindle, but can be raised or lowered by means of the hand wheel shown at the top of the spindle. This dividing of the main forming roll is necessary to release the bend after it has been formed, particularly in the case of 180 degrees or "return" bends, when made cold.

The lever shown operates a vise, which can be attached to whatever former is in place on the machine at the time. This vise has jaws equipped with interchangeable steel grips or bushings, to fit various sizes of pipe. The large hand



Stoever Automatic Pipe Bending Machine.

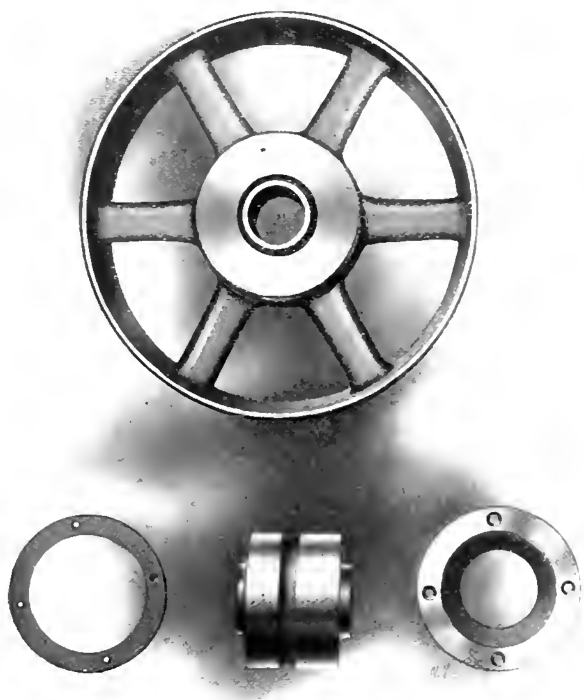
wheel shown at the front side of the table operates a slide, which may be adjusted toward or away from the central former. This slide holds two rollers, one directly in line with the main forming roll and serving to press or force the pipe onto it, while the other acts simply as a guide roller for holding the unbent portion of the pipe in the proper position. The operation of bending is, then, to introduce the pipe between the two rollers on the slide until it lies in the groove of the main former; here it is grasped at the proper point by the vise, after which the vertical spindle is started, being rotated the number of degrees required to give the bend desired.

The spindle is driven by power. The machine shown is motor driven, although the belt pulley is also in place in the foreground of the cut. The belt driven machine has but one speed. With the motor drive a variable speed motor is usually used, so that a variety of speeds can be obtained to suit the work in hand. A reversing mechanism is interposed between the motive power and the spindle, operated by a treadle within convenient reach of the operator. This serves to control the machine, and permits the spindle to be returned to the starting position rapidly, by power, after a bend has been made. Adjustable dogs are provided on the vertical spindle for stopping automatically the movement of the spindle in either direction at predetermined points, to give the degree of bend required.

In using this machine no filling of the pipe is necessary. It is placed in the machine in its normal condition, and the normal section is retained in the completed bend. Sixteen complete bends have been made in ten minutes with this apparatus. In daily runs, 300 bends have been made in 9 hours a number of times. In the work referred to, the bends were made in 2-inch pipe to a 4-inch radius, 180 degree curvature, the length of the legs being 5 or 6 feet. It will be noted from the cut and the description given, that the machine is intended for manufacturing service particularly. It is a special machine, like some forms of turret lathes and engine lathes, and when set for a single piece of work should be used on that work for some time.

JOHNSON & BASSETT SELF-OILING LOOSE PULLEY.

The subject of loose pulleys has always been a sore one. Much thought has been given to remedying the difficulties and annoyances consequent on the use of those of the common



The Johnson & Bassett Self-oiling Loose Pulley.

type. Of the various designs resulting from this extended thought, that shown in the accompanying half-tone and line cut is perhaps as promising as anything we remember to have seen. The arrangement provides for a loose pulley, having a reservoir of oil which is automatically, and yet by simple means, conducted to the bearing surface, whence it is returned

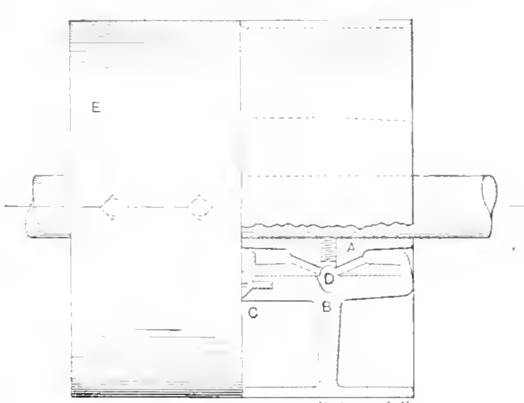


Fig. 2. Section of Pulley, showing Oil Ducts and Reservoir.

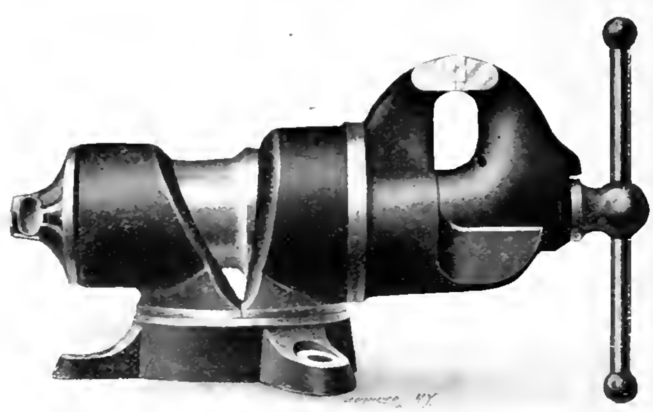
to the reservoir as fast as it escapes at the end of the bearing. The way in which this is done will be understood by referring to the cuts and the accompanying description.

The pulley does not run directly on the shaft, but on a bearing of its own secured to the shaft by set screws. This is shown at *A* in Fig. 2, and directly under the assembled pulley in Fig. 1. When the pulley *B* is slipped over this bearing, it bottoms against an internal shoulder at one end of the hub of the pulley, while endwise movement is prevented at the other end by a washer or collar *C*, which is screwed to the hub of the pulley. A channel is turned in the inner periphery of the hub and on the opposite side of the bearing, as may be seen at *D*. This furnishes the oil reservoir referred to. Deep grooves in the sides of the bearing *A* are connected with this channel by the slanting oil ducts shown. The effect of this arrangement is plainly evident with a little consideration. As the oil contained in the reservoir escapes through the bearing surface, it gradually oozes out into the side channels in the bearing, whence it is returned to the central reservoir, by centrifugal force if the shaft is running, and by gravity through whichever of the oil ducts may happen to be downward at the time, if the shaft is standing. From the reservoir, the oil repeats the cycle.

No collar is necessary to position this pulley on the shaft, since it is held by its own hub. Running as it does, on its own bearing, it can be applied to worn shafts, damaged by running with ordinary loose pulleys. The bearing is of large diameter and the surface is sufficient to hold the oil either running or standing, so that tight belts do not squeeze the oil out. The higher the speed the better the lubrication, owing to the part centrifugal force plays in distributing the oil where it is needed. The pulley is neat in appearance, and is in no sense an experimental device, having been thoroughly tested under severe conditions for the past two years. It is regularly made in various diameters of from 6 to 14 inches, with larger sizes to order. Johnson & Bassett of Worcester, Mass., are the manufacturers.

PITTSBURG VISE OF UNUSUAL SIZE.

The Pittsburg Automatic Vise and Tool Co., of Pittsburg, Pa., has built what it believes to be the largest vise ever constructed. This tool weighs 695 pounds, is 36 inches long, 18



A 695-pound Vise.

inches high, and has a jaw opening of 15 inches. It is so constructed as to secure the greatest possible strength; for instance, the jaws at the neck are over 4½ inches thick, while the slide bar is 7 inches in diameter.

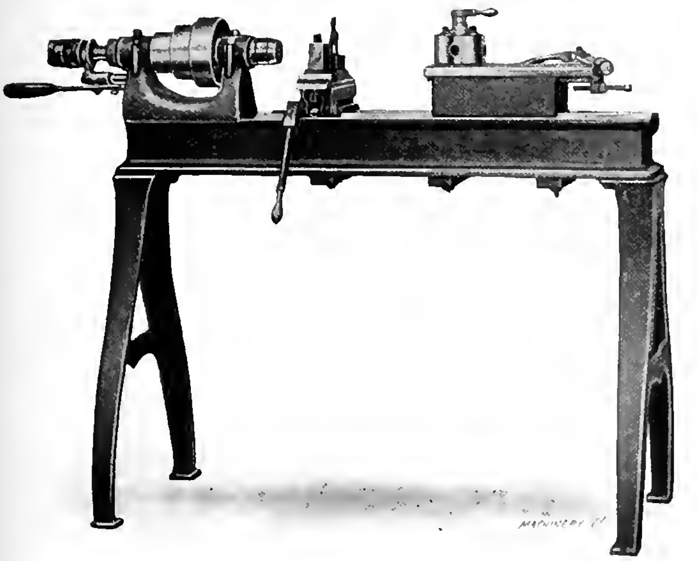
This tool is of the same design as the regular line of double swivel vises made by its builders. The whole vise may be swung in its base about a vertical axis, and the jaws may be set at any angle in the axis of the tightening screw. The setting up of the jaws on the work clamps the whole structure immovably, without requiring any special movements for this purpose. Careful fitting and smooth finish make it possible with even the large vise shown to swing the jaws around, or shift the angle of the vise itself, without requiring the workman to exert himself in the least. This tool fills the needs of shipbuilding yards, railroad and forge shops, and other works where parts of great size are handled, and for holding which provision has to be made. As an instance of the way in which it may be used, work too heavy to be lifted into a vise can be readily stood on one end on the floor and be grasped by the jaws of the chuck, which are turned at right angles for the purpose, thus getting a grip the full length of

the jaws. The heaviest work can then be performed without loosening the grip.

As a contrast to this heavy tool, mention might be made of another vise of the same design which this firm has recently added to its line. This has jaws 1¾ inch long, opening 3 inches and weighing about 3½ pounds. This is intended particularly for emergency work on motor boats and automobiles. The base in which it is set may be permanently fixed to the deck, floor, running board or seat of the machine, where its small size renders it unobjectionable. When a breakdown occurs and it is desired to use the vise, it is simply set into this base, and the tightening of the work clamps the whole structure. The parts are so designed as not to be affected by an accumulation of mud, dirt or water. By the use of extra bases, the vise can be utilized anywhere—in the work-shop, store or home. It will be seen that there is a ratio of about 200 to 1 in the weights of these two tools.

WELLS TURRET LATHE.

The F. E. Wells & Son Co., of Greenfield, Mass., are placing on the market the new lathe for manufacturing use shown in the accompanying half-tone. It is designed to meet the need for a reasonably priced tool for rapid and accurate work in the manufacture of small parts. The general design follows the lines of the other lathes built by the same makers, a noticeable point being the fact that the head-stock is cast solid with the bed. The spindle is supplied with an automatic chuck operated by a lever, so that it can be opened and closed while running at full speed. This allows small pieces to be handled rapidly. The nose of the spindle is threaded, so that geared or scroll chucks up to 8 inches in diameter can be used for handling larger pieces, such as castings, etc. When the split chucks are being used, this thread is covered by a cap. When required, a wire feed can be supplied. The turret slide is operated by a lever. The turret may have four or six holes as desired. The cut-off slide has a tool on each side of the machine, is of new and substantial design, and has tool-posts for properly carrying either straight shank tools or circular forming tools. These lathes swing 11 inches, and are made with 3, 3½, and 4-foot beds.



Turret Lathe for General Manufacturing.

WELLS BROS. STANDARD AND LIMIT GAGES.

In Fig. 1 are shown standard internal and external gages for testing Briggs pipe threads on pipes, fittings, etc. They are designed particularly for reference, and are to be used by the users of pipe and fittings. Some way of testing is necessary in all material threaded with the Briggs standard, since the pipe and the fittings are seldom made by the same firms, and it is often necessary to know whether the parts supplied come to the standard size without testing them in the parts they are to go in. These gages are intended for this use. They have a uniform taper of ¾ inch to the foot to agree with the standard to which they are made. The ring gage has a thickness equal to the length of the threaded end of the pipe, and is used to test pipe ends by being screwed on as far as possible by hand, when the end of the pipe should be exactly flush with the small end of the ring. The plug gage is made three threads longer than the ring gage, with the large end the same size as the large end of the ring. When used to test pipe fittings, it is screwed in as far as possible, when the large end should come flush with the outside of the fitting. It will be seen that in this way the fitting is tested three threads deeper than the pipe end, so plenty of margin is allowed for forcibly screwing-in with the pipe wrench to make a tight joint. The plug and ring screw together until their large ends are flush. They are made with cuts milled through to clean out the chips from the thread being tested. Since they are tapered, it would be impossible to screw them to a bearing without this provision.

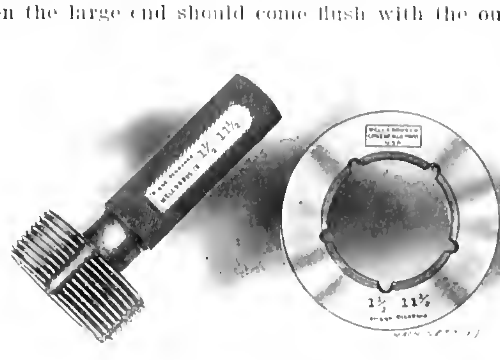


Fig. 1. Plug and Ring Gages for Testing Pipe Threads.

Fig. 2. Solid Limit Gages for Threaded and Cylindrical Work.

In Figs. 2 and 3 are shown limit gages for small and large work respectively. Those at the right of the cut in each case are for threaded work, while the other is for plain cylindrical work. In the thread gages the points are off-set half the pitch of the thread to allow the work to enter with the center lines square with the gage. The gage points provided are set on the common plan of having the outer pair for a "must-go-through" maximum limit, and the inner pair for a "must-not-go-through" minimum limit. Ordinarily, on work of medium size, the working points are set so there is a difference of about 0.002 inch in diameter between the two limits, the first one being 0.001 inch over size, and the second 0.001 inch smaller than standard. The only difference between the limit gages for screw threads and those for cylindrical work is in the working surface, the former having points for measuring on the angle of the screw thread, while the latter has flat working surfaces. These gage points can be removed at any time, and reground if worn. They may then be read-

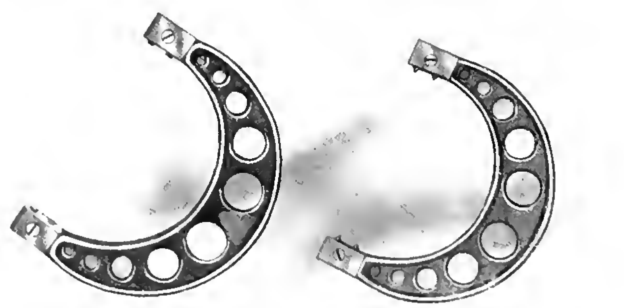

Fig. 3. Calliper Limit Gages for Large Diameters.

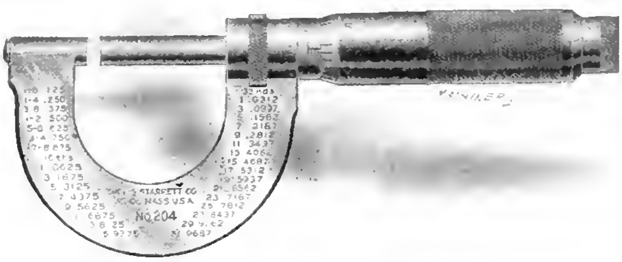
justed to size by comparing them with the setting disks furnished for each pair of working points; these are provided for both the threaded and the cylindrical form. These gages are made in all sizes from $\frac{1}{4}$ inch to 10 inches inclusive, the style of Fig. 2 being used up to $2\frac{1}{2}$ inches in diameter, and that of Fig. 3 for larger sizes. Wells Bros. Co., Greenfield, Mass., is the maker.

THE STARRETT QUICK ADJUSTING MICROMETER.

The new micrometer shown in the cut was recently brought out by the L. S. Starrett Co., Athol, Mass. It has the interesting feature of quick adjustment. By pressing the finger on a plunger in the end of the thimble, a split nut on the micrometer screw is opened, permitting the thimble and spindle to be instantly adjusted to any required point within the capacity of the instrument; then the removal of the pressure on the plunger closes the nut and permits the exact adjustment to be made in the usual manner. Inasmuch as 40 turns

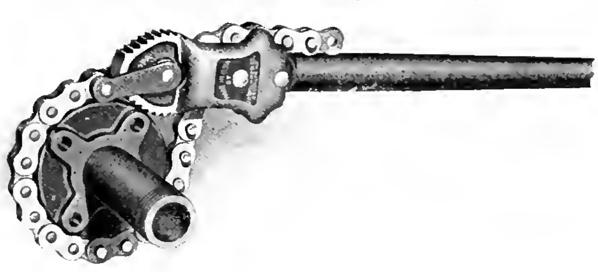


Starrett Quick Adjusting Micrometer.

of the thimble are required to move the spindle of the ordinary micrometer 1 inch, it is estimated that the quick adjustment feature saves at least 20 seconds on each extreme movement of the spindle. The micrometer has the ratchet stop, lock nut and patented sleeve by which adjustment for wear is readily made.

"AGRIPPA" PIPE AND FITTINGS WRENCH.

J. H. Williams & Co., of Brooklyn, N. Y., have made for several years the well-known Vulcan pipe wrench. They have recently placed on the market a tool operating on the same principle, for use where limited space will not permit employing the wider, or double jaw wrench. They call this a fittings wrench, since it is especially adapted for use on narrow flanges, short nipples and other parts with contracted surfaces. The tool is made throughout of wrought steel, and has a drop-forged, saw tempered jaw, permanently fastened in

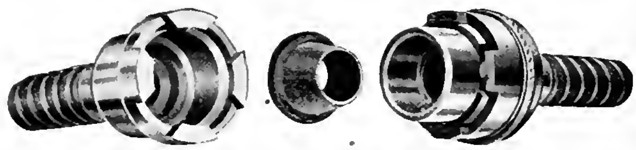


The Agrippa Pipe and Fittings Wrench.

a milled seat in the handle. The chain is longer than in similar wrenches for pipe work only, and is hand made. It swings from the center of the jaw and can be used on either side. All parts are interchangeable. While this tool is only recently offered for sale, it has been thoroughly tested in some years of use. It is made in seven sizes, with a capacity for pipe and fittings from the $\frac{1}{8}$-inch to the 12-inch size, inclusive.

DALLETT AUTOMATIC HOSE COUPLING.

This coupling is the result of a continuous series of experiments and tests, extending over a period of four years, made by the Thos. H. Dallett Co., of 23d and York streets, Philadelphia, Pa. The makers believe that the coupling resulting from these tests and experiments is as superior to that in present use as are the pneumatic tools of the present day to those of ten years ago. The cut shows the two halves of a Dallett coupling, and the gasket used between them. To connect this coupling, the parts are pressed together and given one-eighth of a turn; the locking ring springs into place of itself. It is then impossible to pull the coupling apart, or disconnect it accidentally. When the connection is to be broken, the locking ring is pressed back and the coupling



Dallett Automatic Coupling, Taken Apart.

turned back. In making the connection, the tapering end of the gasket enters the conical opening in the male part, being a loose fit therein; when the pressure comes on the coupling, this tapered end of the gasket is expanded against the wall of this opening, making a joint which increased pressure will only make the tighter. As soon, however, as the pressure is released, the gasket is again loose, so no matter how long a coupling is connected, it will not adhere when the joint is again separated. This gasket is made of a rubber composition which will not be affected by oil or gasoline. It is held in the female half by a flange around the larger end, which fits into a recess. It is thus impossible for it to fall out or be lost, though when necessary a new one can be inserted in a few seconds. As will be noted, the two members are provided with locking lugs equally spaced around the circumference, and when they are snapped together, these lugs insure their being held squarely, thus obviating the tendency to leak, as is common in other couplings of this class, especially those provided with only two lugs. This coupling is made in various sizes to fit hose and threaded ends of from $\frac{3}{8}$ to $1\frac{1}{4}$ inch in diameter.

* * *

NEW APPLICATION OF COMPRESSED AIR.

One of the most remarkable applications of compressed air has recently been made by Mr. Phillip Brasher, Brooklyn, N. Y. He has found that the discharge of air into water below the surface breaks up the wave action of the water and leaves a practically smooth surface. In emergency cases he expects, says *Compressed Air*, that this principle may be applied to prevent the injurious action of waves on objects exposed to them. He expects that a disabled ship, drifting toward shore, by throwing out an anchor to which is fastened a distributing pipe for compressed air, and held far enough from the ship by means of a secondary anchor, could lie in perfectly smooth water until repairs were made, or the sea subsided. In the same way stranded vessels could be protected from the pounding of the waves until floated. Light ships could be surrounded by a circular pipe line and lie in the center of an absolutely calm surface. Some of the expectations, as for instance, that in the not distant future there will be harbors constructed in the middle of the ocean, in vicinities of more than ordinary roughness, by means of pipes suspended from a series of floats so placed that both floats and compressor plant will be protected from any danger of wave action, seem to be rather daring dreams of the enthusiastic inventor.

* * *

Fixing up a thing to be as good as it was before it was broken is merely setting up again the trap in which you have once been caught.

The answer to the question, "What caused it?" must be pursued with relentless energy. In the full and complete answer to this lies the way to success.

The utter absence of the need for hurry is measurably preferable to the most brilliant exhibition of it. The man who skips over an accident with the remark, "Oh, that is nothing; little things like that happen every day. We can't help it," is a dangerous man to have around.

Complaining about the stupidity of your help but proclaims your own.—*Paul Lüpke, in an address before the National Electric Light Association Convention.*

INDUSTRIAL NOTES FROM EUROPE.

BRITISH TRADE TOPICS.

Commercial conditions remain much the same as for some time past, but a continuance of the general pressure is not over-confidently looked forward to. Productive plants of all kinds have so greatly increased their efficiency that to keep them simply running necessitates a much larger volume of work than formerly. In labor matters, the trend indicated by the general results of strikes in the engineering trade during the last few years is unfavorable to this method of attempting to improve working conditions. This, notwithstanding an apparently successful outcome of a strike at the works of Vickers, Sons & Maxim, Ltd., Erith, against the continuance of the premium bonus system, and also directed towards the curtailment of the functions of "speed-and-feed" men. The energies of trades unions appear likely to be increasingly directed into political channels with a view to the economizing of union funds, the more effective presentation of the labor point of view in legislative discussions, and the urging forward of industrial reforms. "Collective" bargaining respecting disputes or changes in trade customs is being almost forced into general recognition, the unwisdom of avoidable stoppages in large industries being more clearly seen than formerly.

Shipbuilding Records.

Though the shipbuilding returns of the first half of the present year do not compare so favorably as was anticipated with the same period of last year, individual concerns have made some remarkable records. John Brown & Co., Ltd., of Sheffield and Clydebank, recently launched the armored cruiser *Inflexible*, the completed cost of which will be about $8,650,000, and also delivered the Cunard liner *Lusitania* for her preliminary trials. The concern also has other large orders on its books. It has practically completed the purchase of a valuable ironstone field at Frodingham, and has also strengthened its shipbuilding connection by the acquisition of an interest in the firm of Harland & Wolff, Ltd., Belfast, which will necessitate the creation of about $7,500,000 additional capital. The latter firm is to build nine steamers for the Morgan combine at a cost of about $20,000,000. About $250,000 are being expended on immediate extensions. The combined firms will employ about 30,000 men, and will be able to turn out battleships complete with guns, mountings, and armor plate, in addition, of course, to the most modern types of commercial vessels. Harland & Wolff are also building large repair shops at Southampton.

Legislation Against Trusts.

Efforts are being made to legally restrict the monopolistic conditions laid down by certain machinery trusts, of which the shoe machine trust is typical. Clauses are being introduced into the new patent laws by which conditions of sale or lease which call for the user of a patented machine to use other articles or inventions, or to prohibit him from using any other than those dictated by the patentee, will be void. It is also intended to empower the Board of Trade to appoint an arbitrator in connection with the termination of existing contracts of the kind, to assess the compensation to be paid for the determination of the agreements in question. The Australian Commonwealth government also propose to put in force the extreme powers of their customs regulations in case more equitable terms are not speedily granted.

"Stringer-type" Composing Machine.

An interesting machine is being brought to the notice of the printing trade over here, in the shape of the "Stringer-type" matrix composing and casting machine. The machine is named after the inventor, Mr. H. J. S. Gilbert-Stringer, and its special feature is the ability to produce movable type ready for machinery purposes at the rate of 9,000 to 10,000 per hour by one operator. Certain of the linotype features are embodied as regards the keyboard and the arrangement of matrices, together with advantages associated with machines of the perforated ribbon or monotype variety. The characters are on the flat face of the matrices and not on the edge, hair lines practically being eliminated. The temperature of the metal is automatically adjusted, and the variation of the spacing between the words is similarly attended to. Safety stops are provided in the case of a matrix being incorrectly placed on its way from the magazine, or if too much is endeavored to be set in one line. The bottom end of each type has the fin caused by casting so automatically knocked off that the bearing surfaces left allow the length of the type to be kept within extremely fine limits. The frame of the mold is cooled by water circulation so that the type may easily be handled when cast at the highest speeds. Quite a number of other points appealing to the printer are claimed, but, apart from the good quality of work apparently obtained from it, the point most likely to attract favorable attention is the fact of one man performing the whole of the operations.

Trade Conditions and the Tariff.

Little has been heard of late in the way of holding up the principal industrial nations as models or warnings to the others. It is increasingly evident that much is to be learned from the practice evolved by force of circumstances in each country, and that a deficiency in one respect is often fully counterbalanced by special efficiency in another direction. What lecturing is taking place would appear mainly devoted to pointing out to American manufacturers directions in which their typical mass production methods fail to compete favorably with the productions of countries less favorably placed as regards supplies of raw materials, but in which latter countries artistic bent or technical skill adds considerably to the value of the finished product. Great Britain received a considerable amount of well-meant advice until fairly recently, the United States being prominently placed as the exemplar, but most of the admonitory statements now current are concerned with the presentation of the theory that unless a move is made in the direction of protective tariffs, Continental competitors, owing to their home market being largely preserved for them, have inducements to carry out an aggressive foreign trade policy, whereas the British manufacturer, through his Free Trade environment, is practically precluded from such a stimulus It may be more or less so, such statements are hard to prove or disprove.

Dr. Nicolson on Rational Machine Design.

Dr. Nicolson of the Manchester School of Technology has for some years been working with a view to the designing of machine tools being conducted on "rational" lines as distinct from the more generally followed plan of advancing tentatively from designs which, notwithstanding certain deficiencies, gave good service under working conditions. Some deductions from experiments made by him, and mentioned in a paper recently discussed by the Institute of Civil Engineers, appear to suggest that lathes should be capable of taking a cut equal to one-fortieth the height of centers, with a feed one-fourth of this. The ratio between the highest and lowest speeds on lathes designed to use carbon steel tools is indicated as 50 to 1 on 12-inch swing lathes, to 180 to 1 on 120-inch swing lathes. When employing high-speed steels the ratios are 10 to 1 on 12-inch swing lathes, to 120 to 1 on 120-inch swing lathes. He considers that the power available in high-speed lathes should be from three to seven times that required for lathes using tools of carbon steel. Dr. Nicolson also advocates front bearings of smaller diameter than often used on British high-speed lathes, a view dissented from by a number of makers, who draw attention to the weight of face-plates and heavy jobs often suspended from them. Another suggested innovation is the use of solid bush bearings without means of adjustment, but with arrangements for forced lubrication, to prevent metal and metal contact at the lower speeds, the spindles, as before mentioned, being of smaller diameter than now usual, and the front bearings only about half the present length. The form of bed strongly recommended for adoption is of circular or box form in place of the double H section with cross girts, commonly employed. Many practical objections may be urged against such a departure, but the author of the paper considers that such difficulties may be satisfactorily overcome, when toolmakers are

disposed to give such a form of bed a thorough trial, its bending and torsion resisting qualities being such as to justify reasonable expenditure in its development. In any case, Dr. Nicolson's ventilation on the subject is likely to lead to its more consistent treatment by designers and builders.

Commercial and Technical Education.

Commercial and industrial or technical education obtains fairly constant attention even though it be of a critical rather than constructional character. The Birmingham University authorities are forming an advisory board of engineering business men to assist in the inauguration of a scheme of training in the commercial side of engineering. At Oxford University it is proposed to found a chair of engineering. No attempt at practical training is proposed at present. In Lancashire some difficulty exists as regards placing students in positions after attending technical schools. Manufacturers have not yet become accustomed to the idea of frankly assimilating in their works organization technical school graduates, and consequently disappointment is expressed both by students and those responsible for the general oversight and administration of educational matters in the county. In a recent report of the Lancashire County Education Committee it was stated that the work sent in by students in the textile branches—who submit samples of work designed and actually woven by them—was considerably superior to all previous efforts, there being an entire absence of unworthy material. The weakest feature of the work was the coloring, which was crude in several instances. On the results of these competitions scholarships tenable for three years at the Manchester School of Technology are awarded, and also various prizes. Every effort is being made to train students to be of service to employers, but as previously mentioned, a mutual understanding is not as yet arrived at as to what is required from students after completing their courses.

JAMES VOSE.

Manchester, Eng., August 1, 1907.

MISCELLANEOUS FOREIGN NOTES.

GERMAN SHIP BUILDING INDUSTRY.—Like all other industries, the ship-building yards in Germany increased their business materially during 1906. The tonnage of new merchant vessels constructed was 387,820 tons, as compared with 277,731 tons in 1905. This represents an increase of 32.4 per cent. At the close of 1906 there were under construction in various German ship-building yards merchant vessels with an aggregate tonnage of 323,000 tons.

RŒCHLING IRON AND STEEL WORKS, Voelklingen, Germany, has put into operation a new Kjellin induction steel furnace, having a capacity of 24 tons. About 15 tons are poured at the end of each run, 9 tons being left for the beginning of the next run. The power consumption is 736 kilowatts per hour. There are two smaller induction furnaces in operation at these works and a fourth in construction, having a capacity of 150 tons. A high production economy is claimed for the new plant.

BRITISH AUTOMOBILE INDUSTRY.—According to the London *Times* the motor car industry in Great Britain is still in a state of remarkable progress. The business of 1906 doubled that of 1905, while in 1907 every indication points to a demand far exceeding anything yet experienced. The home product has succeeded in competing with the foreign vehicle. Not so long ago it was almost impossible to find a British car outside the boundaries of the United Kingdom, except those owned by British tourists. Now there is a distinct and growing demand for them in the British colonies, in America, and on the Continent. The exports for the first four months this year amounted to $1,243,525 in finished cars, and $796,940 in automobile parts. This is more than double the exports for the same period in 1906.

INDUSTRIAL CONDITIONS IN SWEDEN.—The industrial development of Sweden depends largely upon the development of the country's resources of power, obtainable from the waterfalls, and convertible into electrical energy. The value of these resources is becoming more appreciated than ever, and electrical machine companies are prospering. The largest of these is reported to have delivered, in 1906, 3,319 electrical machines, with a total of 87,720 H.P., and to have orders on hand for machines of more than 200,000 H.P. The machine-tool industry is in a flourishing state, but the production of the country in this line falls by far short of the demand, and high class American machinery finds a ready sale at the present time.

STANDARDIZATION OF MOTOR PARTS IN GREAT BRITAIN.—It is reported that the British Institute of Automobile Engineers has appointed a committee for inquiring into the possibility of a standardization of motor parts. It is appreciated that those accessories and component parts used in engines of all types, as well as nuts, bolts, bolt heads, and wrenches, could be made the same on all kinds of modern automobiles, not only in the United Kingdom, but on the Continent as well. One difficulty in the standardization is the fact that Continental motor makers use the metric system, while manufacturers in Great Britain do not. The fact that this subject is receiving attention is an important one as the first step toward agreements which are likely to be beneficial to the motor manufacturers in all countries.

THE PROPOSED WORLD'S FAIR IN BERLIN.—Some time ago it was announced in the press that an initiative had been taken in leading industrial and political circles for the arranging for a world's fair in Berlin, Germany, 1913. The immediate cause for the selection of this year was the twenty-fifth year anniversary of the German Emperor's ascension to the throne of the empire. On account of this proposition the German Commercial Union sent out a circular letter to the German chambers of commerce in order to learn their views with reference to a world's exposition, to be held at Berlin in 1913 or other year of the coming decade. In answer to this the chamber of commerce at Mayence has recently adopted the following resolution, which seems to voice the opinion generally entertained in Germany concerning world's fairs: "The chamber of commerce has resolved to answer that it can not recognize the holding of a world's exposition at Berlin in the year 1913, or in some other year of the coming decade, as in the interest of Germany's industries and commerce; that it deems it more advisable, instead of general world's expositions, to organize for all products of human activity international expositions of a special industry, as such only can have the effect of fructifying and stimulating the industries and trades."

* * *

THE KRONPRINZESSIN CECILIE.

The latest addition to the passenger fleet of the North German Lloyd Steamship Company, the *Kronprinzessin Cecilie*, arrived in New York harbor August 14, 1907. This boat is another evidence of the faith in the commercial possibilities of the large size, high speed, luxuriously equipped vessel. The use of reciprocating engines has been continued, this being in line with German engineering practice, which is inclined to regard the steam turbine as not yet out of the experimental stage. The vessel is propelled by twin-screws, each driven by two quadruple expansion engines. The cylinder diameters are as follows: High pressure, 37⅜ inches in diameter; first intermediates 49¼ inches; second intermediates, 74⅞ inches; and low pressure, 112¼ inches; the common stroke is 6 feet. The horse-power is 45,000. The comparison of this figure with the 70,000 horse-power of the *Lusitania* gives some idea of the cost of raising the speed of two vessels of comparable size from 24 knots per hour to the 25½ knots which the new English vessel is expected to make. The most impressive thing to the visitor on the *Kronprinzessin Cecilie*, aside from the great size of the vessel, is the perfection of detail which has been observed throughout the boat in the matter of fittings, furnishings and decoration. There is something very fine in the design and workmanship of even the most inconspicuous details of the interior decoration, and this rises to a high pitch of beauty in the case of the dining room and saloons, and the more luxurious of the staterooms and suites.

OBITUARY.

Henry W. Clarke, senior member of Hill, Clarke & Co., Boston, Mass., died July 27 at his home in Watertown, near Boston. Mr. Clarke was born May 10, 1822. He began his business career in hardware, being first employed by George H. Gray & Danforth, of Boston. In 1866 he became connected with the firm of Horace McMurtrie & Co., who were engaged in engineering enterprises and in selling machinery. The firm was later reorganized as Hill, Clarke & Co. Mr. Clarke was actively connected with the company until about two years ago. His son, Charles A. Clarke, is the present president of the company.

* * *

PERSONAL.

T. B. Burnite of the engineering and sales department of The John A. Traylor Machinery Company, Denver, Colo., has been appointed superintendent.

E. B. Boye, until recently manager of the Cleveland office of Messrs. Manning, Maxwell & Moore, has accepted a position with the Warner & Swasey Co., Cleveland, O., as its Chicago representative.

J. Cecil Nuckols, for the past three years advertising manager of The S. Obermayer Co., Cincinnati, O., has recently received the additional appointment of advertising manager of the Cincinnati Electrical Tool Co.

George H. Hall, who for the past four years was connected with the sales department of the Crocker-Wheeler Co., Ampere, N. J., has accepted the position of manager of the Boston office of the Diehl Mfg. Co., Elizabethport, N. J. Mr. Hall was formerly associate editor of MACHINERY.

F. B. Maltby, who has been connected with the Panama Canal work as principal assistant engineer to Mr. J. F. Stevens, has resigned to go with Dodge & Day, Philadelphia, Pa., in the capacity of chief engineer. Mr. Maltby is a graduate of the University of Illinois, class of 1882, and has had a wide engineering experience.

* * *

NEW BOOKS AND PAMPHLETS.

A COURSE IN STRUCTURAL DRAFTING. 64 pages, 6 x 9 inches, with 48 cuts, numerous tables and diagrams, and 15 large folding plates. Published by the Industrial Magazine, Collinwood, Ohio.

This book is, so far as we know, the first one treating the subject of structural drafting from the drafting room standpoint. It deals with the conventions used in making drawings, discusses the technique of the business, and gives a very lucid introduction to the subject of structural design. The scope of the work can be gathered from the following chapter headings: General Remarks, Terms Used, etc.; Riveting, Spacing; Bolts, Pins and Eyebars; Connection Angles and Anchors; Copying; Strength of Materials; Beams, Girders; Column and Sole Plates; Truss Outlines; Title Page and Cover; Drafting Room Practice. It is a pity that a book as excellent as this appears to be should not have had more careful proofreading. Errors are noticeable on almost every page. We trust that its popularity will be sufficient to require a new edition in the near future, at which time these defects can be remedied.

CATALOGUES AND CIRCULARS.

THE CUSHMAN CHUCK CO., Hartford, Conn. 1907 catalogue and price list of chucks and face-plate jaws, describing the different types and discussing repair parts, outfits for lathes, etc.

THE ELECTRIC CONTROLLER & SUPPLY CO., Cleveland, O. Illustrated bulletin descriptive of universal insulator supports, touching upon application, construction, special work, cost, advantages, etc.

THE PITTSBURG AUTOMATIC VISE AND TOOL CO., Pittsburg, Pa., has issued a unique catalogue, in black and white, illustrating its special automobile and motor boat vise.

GOODELL-PRATT CO., Greenfield, Mass. Catalogue No. 8 for toolsmiths, illustrating and describing automatic drills, punches, hack saws, vises, etc. The company has added more than fifty new tools to its line since issuing its last catalogue.

LUCAS MACHINE TOOL CO., Cleveland, O. Pamphlet entitled "Pull," which states that the best way to get a "pull" is to push, and describes the four ways in which this company pushes its machines.

THE O. K. TOOL HOLDER CO., Shelton, Conn. Catalogue illustrating the lathe, shaper and planer tools, and drop forgings manufactured by this company. The various combinations of these tools and toolholders, their sizes and prices are included.

THE BURKE MACHINERY CO., Cleveland, O. Catalogue on machine tools, describing the various types of milling machines and attachments, drill presses, vises, tapping machines, etc., manufactured by this company. A price list is also issued with this catalogue.

J. T. SLOCOMB CO., Providence, R. I. Catalogue No. 11 illustrating and giving brief descriptions, with prices, of micrometer calipers and gages. The book also includes tables of decimal equivalents, drill list, and instructions how to read a micrometer.

INDEPENDENT PNEUMATIC TOOL CO., First National Bank Building, Chicago, Ill. Catalogue No. 8 illustrating and describing the complete line of Thor pneumatic tools and appliances. A number of interesting photographs show these tools at work under different conditions.

J. M. CARPENTER TAP AND DIE CO., Pawtucket, R. I., has compiled in convenient form the recently adopted standard of the American Society of Mechanical Engineers for machine screws and machine screw taps and dies. A copy will be sent to all users of machine screws, who apply.

J. L. OSGOOD, Buffalo, N. Y. Card illustrating and describing the Osgood "indestructible" file and tool handles. These are made with a thin steel tube forced into the handle and interlocked with the ferrule. The construction is such that the file tang is held in a wood seating the same as in usual construction, but the tube restrains the handle from splitting.

WESTINGHOUSE MACHINE CO., Pittsburg, Pa. Catalogue descriptive of the Westinghouse storage battery for stationary use. The company has spent many years in studying the various types of storage batteries, and has made many exhaustive tests, the result of its work being embodied in the type S storage battery here completely described and illustrated.

THE PITTSBURG AUTOMATIC TOOL & VISE CO., Pittsburg, Pa., has published a book in two colors describing and illustrating the Pittsburg two-way vise. It deals particularly with "high-speed" bench vises. The cover of the book is an attractive design in color showing a Pittsburg mill scene. Copies may be obtained by applying to any of the agents of the company or to the general office at Pittsburg.

THE L. S. STARRETT CO., Athol, Mass. Catalogue No. 18 containing 232 pages description of fine mechanical tools and illustrated with over 300 engravings. Many new and unique tools are shown and some additions to the sizes of former tools have been made. A number of improvements in design have been incorporated in certain tools and a few changes in prices. The new catalogue has been carefully revised and every tool is indexed both by name and number.

CHICAGO PNEUMATIC TOOL CO., Fisher Building, Chicago, Ill. Catalogues No. 23 and 24. Catalogue No. 23 contains more than 100 pages and is devoted exclusively to Franklin air compressors, containing descriptive matter and information. Catalogue No. 24 also contains more than 100 pages and is devoted to the company's line of pneumatic tools and appliances, including "Boyer" and "Keller" hammers, "Little Giant" drills, sand rammers and hoists.

GOLDSCHMIDT THERMIT CO., 90 West St., New York City, has recently issued pamphlets entitled "Butt-Welding Wrought Iron and Steel Pipes and Rods by the Thermit Process" and "Metals Free from Carbon Produced by Aluminothermic Method." The former contains a description of the process of butt-welding and equipment to be used. The latter is a reprint from *Electrochemical Industry* and *Electrochemical and Metallurgical Industry*.

AMERICAN LOCOMOTIVE CO., 111 Broadway, New York, has just issued the ninth of its series of pamphlets covering the standard types of locomotives. As the title indicates, this number of the series is devoted to six-wheel switching locomotives, and contains half-tone illustrations and the principal dimensions of twenty-six different designs of this type. The designs illustrated range in weights from 102,000 to 176,500 pounds, and are adapted to a variety of service conditions.

THE NEWALL ENGINEERING CO., LTD., Warrington, England. Catalogue of gages and measuring machines. This pamphlet, which contains about 70 pages, describes and lists one of the most complete and interesting line of gages that has ever come to our notice. The completeness of the line may be judged from the following list, giving some of the tools manufactured: Internal limit gages; fixed point external limit gages; adjustable external limit gages; double end external limit gages; limit reference bars; standard reference bars; internal micrometers; external micrometers; standard cylindrical gages; standard end measuring rods; standard snap gages; length micrometers; length gages; end measuring blocks; spherical end measuring blocks; standard screw gages; pipe thread screw gages; hardened screw gages; taper gages; surface plates; straight edges; and measuring machines. These are made in both English and metric sizes.

MANUFACTURERS' NOTES.

THE SCHWERDTLE STAMP CO., Bridgeport, Conn., in order to accommodate its growing business, is building a three-story addition to its plant, which will be ready for occupancy about October 1.

NORTHERN ENGINEERING WORKS, 26 Chene St., Detroit, Mich., has installed power station cranes, one of 20 tons capacity, for the Toledo Gas and Electric Co., and two of 20 tons capacity in the Murphy power plant at Detroit, Mich.

THE DAYTON PNEUMATIC TOOL CO., Dayton, O., owing to its increased business in the Buffalo district, has established an agency with Root, Neal & Co., 178-180 Main St., Buffalo. This concern will carry in stock a complete line of Dayton and Green pneumatic hammers, as well as repair parts and accessories.

THE PITTSBURG AUTOMATIC VISE AND TOOL CO., Pittsburg, Pa., has recently replaced the entire vise equipment of several of the larger plants of the U. S. Steel Corporation with the high speed Pittsburg vise. The company reports a very large volume of business from their exhibit at the Jamestown Exposition.

THE S. OBERMAYER CO., Cincinnati, O., has just completed a factory for the exclusive manufacture of Kantbebeat dry core compound. This factory has a capacity of 25 tons per day, and the company expects, from present indications, that the sales of this commodity will increase to a great extent.

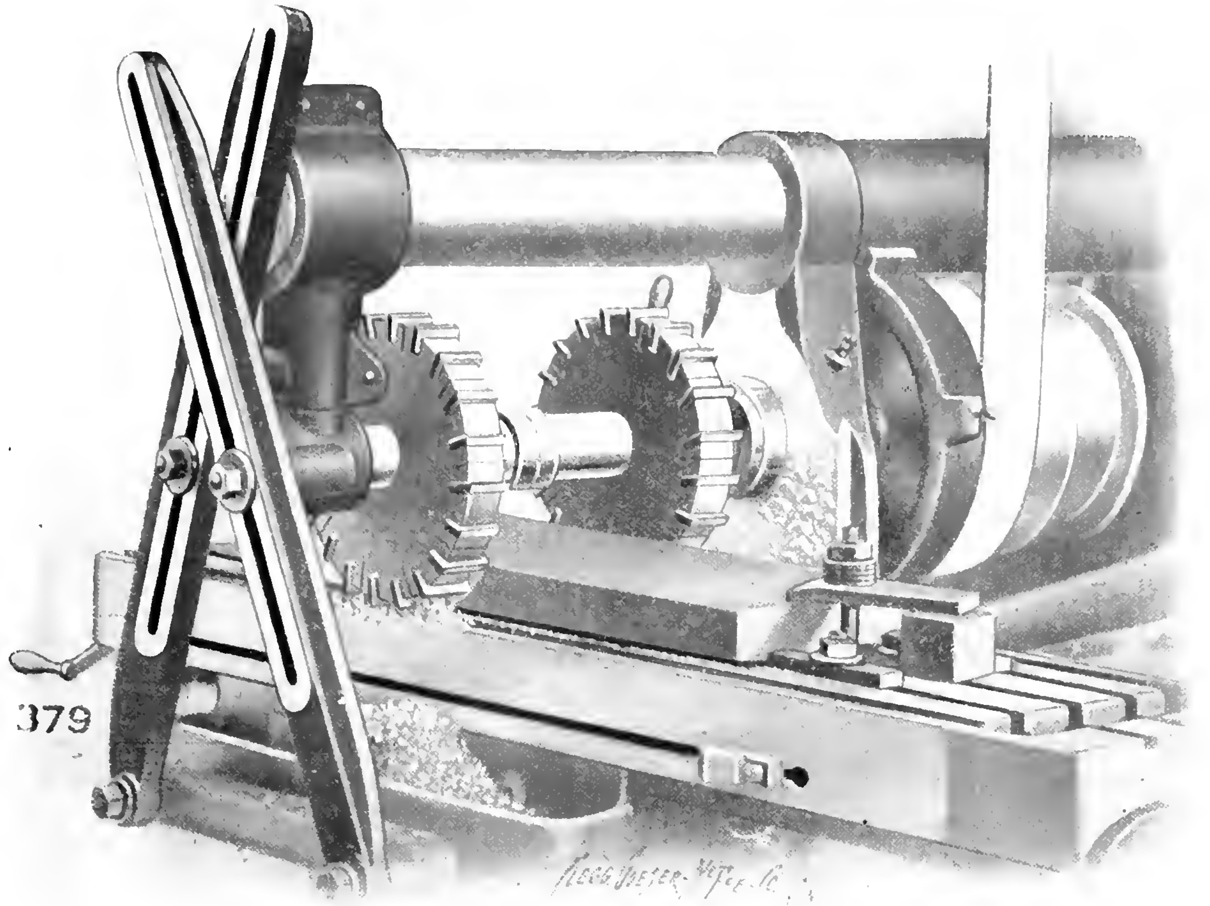
THE CARNEGIE LIBRARY (Technology Department), Pittsburg, Pa., is making an extensive collection of trade catalogues, and will be glad to receive catalogues from MACHINERY'S advertisers. These catalogues will be given a prominent place on the shelves, carefully indexed under both firm name and subject, and made accessible to the public. Catalogues should be addressed care of H. W. Craver, Technology Department, Carnegie Library, Pittsburg, Pa.

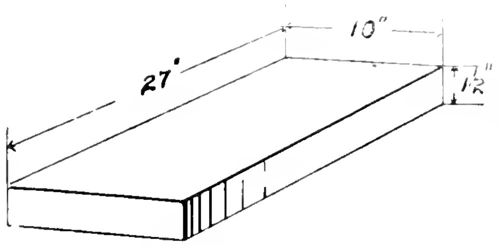
AMERICAN LOCOMOTIVE CO., 111 Broadway, New York City, has recently received an order for 101 four-wheel motor trucks for the Brooklyn Rapid Transit Co. The trucks will be built entirely to designs prepared by the builder, following closely the M. C. B. standards, and will embody as far as possible the practices of locomotive construction, thereby insuring strength combined with easy riding qualities, the two essential characteristics of the motor truck of the present day.

THE HOGGSON & PETTIS MFG. CO., New Haven, Conn., reports that a fire broke out in its japanning room on August 6. The damage, however, was confined to this department and interfered in no way with the manufacture of the Sweetland chuck. Although very busy in the chuck department, the company, having lately considerably increased its capacity, is able to make prompt deliveries. Important improvements are being made, which will appear from time to time.

ARMSTRONG BROS. TOOL CO., 113 N. Francisco Ave., Chicago, Ill., owing to the rapid increase of its business, has been compelled to make further additions to the large modern plant which it erected about two years ago. These consist of two buildings of steel and brick construction, one 50 ft. x 105 ft., the other 40 ft. x 105 ft., with brick smoke stack, 60 inches diameter, 115 feet high. In these buildings the company is now installing a modern power plant of 300 H. P., consisting of two 150 H. P. water tube boilers equipped with automatic stokers, direct-connected engine and generator, etc., and an up-to-date drop forge department of large capacity with steam drop hammers of the latest improved design and other high grade equipment, including a complete die shop with machine tools, especially adapted to that important work. The machinery is now being set in position and will be in operation about October 1.

Fast Feeds with Large Cutters





These grey iron castings are 1½" thick. The two edges are finished at one cut on a **No. 3 Plain Double Back Geared "Cincinnati" Miller.** Depth of cut is ¼" on each side; cutters 11½" diameter; 16 r.p.m.; feed .252" per turn—a table travel of 4" per turn.

On such work the outer arbor bearing carries the same load as the main bearing. Note how we support it by rigid bracing from the box section knee and the large diameter overhanging arm. The double back gears and large driving cone give the machine its great spindle power.

Do you use "Cincinnati" Millers?

CONTENTS FOR SEPTEMBER.

The Turner Brass Works, formerly of Chicago, Ill., has completed its new factory at Sycamore, Ill., and is now occupying it. The main factory building has a floor space of 40,000 square feet, with power and heating plants additional. Improved machinery has been installed, the facilities being enlarged and greatly improved. The factory is located on the main line of the Chicago & Great Western Railway and the Galena Division of the Chicago & Northwestern Railway, both roads having side tracks to the factory. As soon as completely settled, all orders will be shipped promptly. All correspondence and orders should be sent to the main office, 50 Park Ave., Sycamore, Ill.

American Locomotive Co., 111 Broadway, New York, has received a number of large orders during the past few months for foreign shipments, especially for the far East, aggregating in all 251 locomotives. One order of 183 locomotives is said to be the largest ever received by a locomotive-building concern in this country for foreign shipment. These locomotives are for the South Manchuria Railroad Company. One of the most interesting facts in connection with this order is that all of the locomotives are of American design throughout. The Pacific, consolidation and ten-wheel engines are the heaviest locomotives of their class ever built for foreign shipment. Another order received by this company is three Mallet compound type locomotives for the Central Railroad of Brazil, weighing, locomotive and tender complete, 303,000 pounds. These engines are the only ones of their type built in this country for foreign shipment, and it is a noteworthy fact that the company who introduced this type into America is now building it for foreign countries.

MISCELLANEOUS.

Advertisements in this column, 25 cents a line, ten words to a line. The money should be sent with the order. Answers addressed to our care will be forwarded. Original letters of recommendation should not be enclosed to unknown correspondents.

240 Discs Cut from $2\frac{5}{8}$" Bar

WITH A "VICTOR"

THE BLADE THAT DID THE WORK

That's the record of a Victor Hack Saw in a recent test. A bar of machinery steel $2\frac{5}{8}$" in diameter was cut through 240 times, making 240 thin discs, before the saw broke by the carelessness of the operator in starting 241st cut. Both the discs and the saw that did the work are shown here. The performance was made possible

BY USING OIL ON THE BLADE

for the first 150 cuts, making saw cut a trifle slower but preserving the teeth so well that 90 more were taken, and a still higher record would have resulted except that the saw broke.

Do you know of any other hack saw made, that can equal this "Victor" performance?

The "Victor" is proving every day that its special steel, correct temper and hooked teeth make it 15% to 400% more efficient than any other hack saw in existence.

You can prove it to your own satisfaction by asking us for free sample blades and testing them in your shop. You might as well let the "Victor" make a few records for you. Write us to-day.

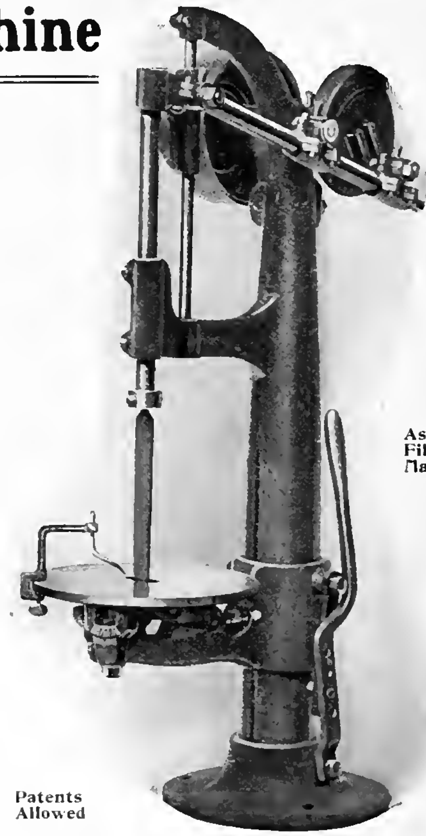
Don't Start up the Milling Machine

For that piece of work—the SIMPLEX FILING MACHINE will do it just as well, do it quicker and at a much lower cost.

There are a great many dfferent kinds of work that can be done on this BENCH FILER instead of the Miller—if you will take the trouble to fix up a few jigs and fixtures to hold your special line of work in position on the FILING MACHINE the same as in the Miller.

A lot of people are doing this every day, as well as utilizing the machine for Die Making and other work.

Glad to send a machine on 30 days trial.
Write for a list of firms who have "discovered" the Simplex Combination Bench Filer and Hack Saw.



The Simplex Mfg. Co., 90 West St., New York

Our Five Thousandth Shaper Has Just Been Shipped

There is a world of meaning behind that statement. It means 5,000 satisfied Shaper owners and operators. Five thousand pieces of satisfaction scattered all over the world, in the best manufacturing establishments, U. S. and Foreign Government Navy Yards and Arsenals, Railroad Shops, etc., is a pretty good advertisement in itself. The "Boss" likes our Eberhardts' Patent "High Duty" Shaper because it does more and better work (reduces cost); and the operator because it is easier to handle.

Five Thousand Shapers

EBERHARDTS G & E

If you want to meet a satisfied Shaper user, look up a man who has one of ours. We'll be glad to give you a list of users in your vicinity. We've been making High Class Machine Tools for over sixty years (Established 1840) and during that time our machines have been recognized as the standard for Shaper Excellence. Shaper satisfaction means G. & E.

Our New "High Duty" Shaper Catalog is now ready for distribution.

GOULD & EBERHARDT, Newark, N. J., U.S.A.

"CHAMPION"
14-inch Engine Lathe

An up-to-date machine, new design, extra large ground spindle, wide face gearing, T-slots in carriage, rapid feed changes, wide belt. It is provided with an Index Dial for catching threads quickly, has automatic stop in either direction, and cuts threads from 2 to 96.

For other special features see our circular.

Champion Tool Works Co.

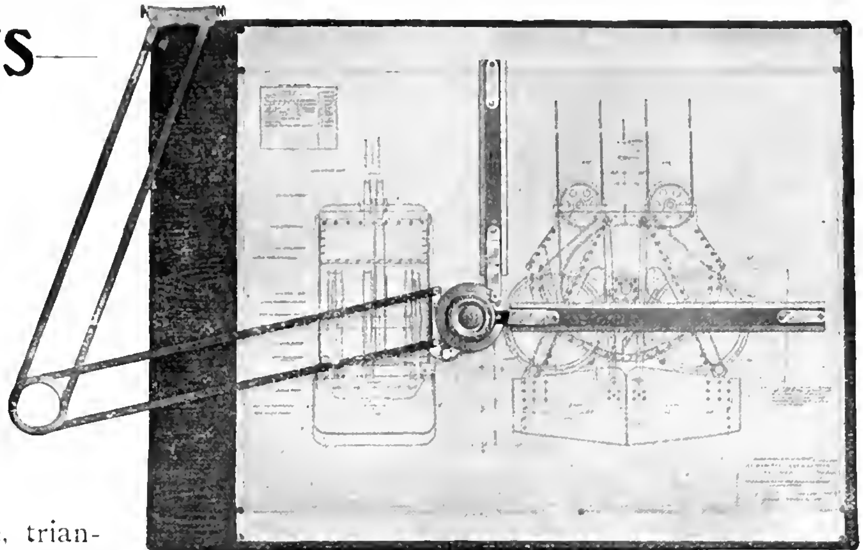
IN OLD DAYS—WITH OLD WAYS

Tee-square, triangle and scale it required **twelve** operations to draw two measured lines at right angles—

IN THESE DAYS—

With the UNIVERSAL DRAFTING MACHINE



It requires but **two** operations to do the same work.

The "Universal" is tee-square, triangle and scale in one, saves all the time and bother of changing from one tool to the other, leaves your draftsman's mind free to work out his plan or design, is virtually an insurance against error and will save fully 25% in time on your drafting work.

If this device is not already a part of your drafting room equipment—write for catalog and full description today.

Universal Drafting Machine Co., Cleveland, Ohio

The Akron Friction Clutch

Compact—Simple—Powerful—Adapted for High Speeds

The construction of this clutch is of the highest grade, making it particularly suitable for driving machine tools or for similar service. It requires no attention—just oil it, that's all—the Clutch will take care of itself, stand rough usage and when necessary will slip under full load without damage. The compact form is another advantage, as it takes up little room on the shaft. It is easily and quickly adjusted, does not require a special pulley, is positive and noiseless in operation, and on very high or very low speed shafts succeeds where other clutches fail. All working parts protected from dust and grit.

If you are in need of a powerful and satisfactory clutch write for our booklet

We make a full line of light drills—single and multiple spindle, bench, electric drive, flexible spindle, adjustable heads, etc.

DWIGHT SLATE MACHINE CO.

1 SPRUCE STREET, HARTFORD, CONN.

TEMPER

in a Twist Drill is a good deal like temper in a man. If it is not even the drill will not stand up to the work it is called upon to do; it soon goes to pieces. But when the temper is just right the best results are obtained from either man or drill. In making "Diamond" Twist Drills special attention is given this essential feature with the result that they wear longer, do more work with less grinding and show less breakage than any other **Twist Drills.** Selected stock, proper milling, correct clearance and grinding, also help to make "Diamond" Twist Drills the best on the market.

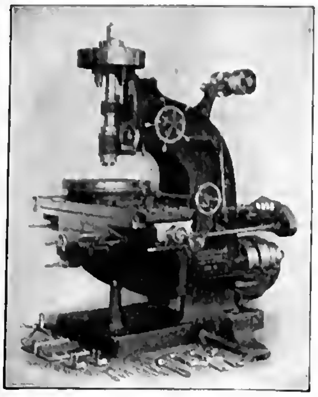
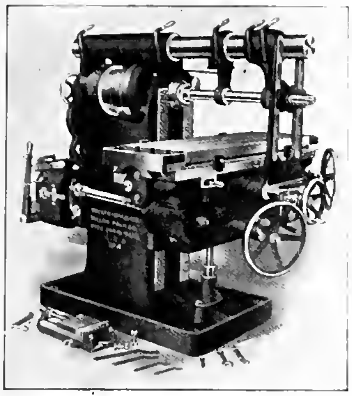
BECKER-BRAINARD

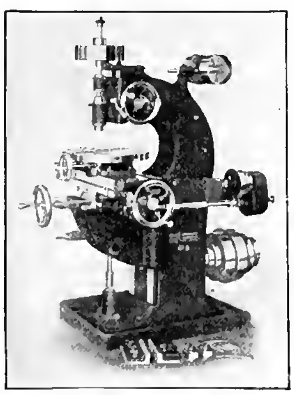
Milling Machines

AND

Milling Cutters







The Highest Efficiency of Production

is secured when the size and design of the machine is exactly suited to the work. We build two distinct types of Milling Machines—

The Horizontal and the Vertical

—and are therefore in a position to furnish whichever is best adapted to the work. We have reason to believe that our own experience will be of material assistance to the purchaser in selecting the machine best suited to meet his requirements. To this end we are always pleased to study specific cases, offer suggestions for improvement, determine the most desirable sizes of machines and design, and make special cutters to accomplish the desired result.

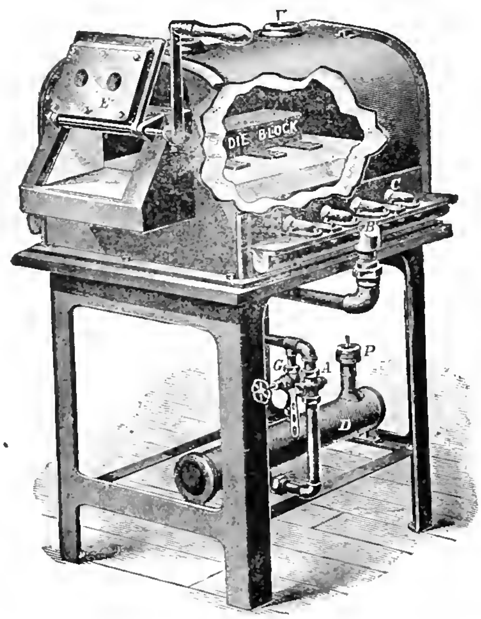
OVEN FURNACES

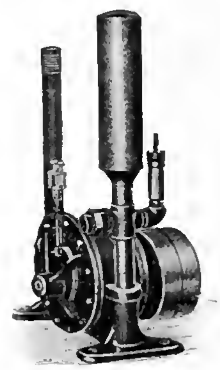
For Hardening and Annealing Metal Work



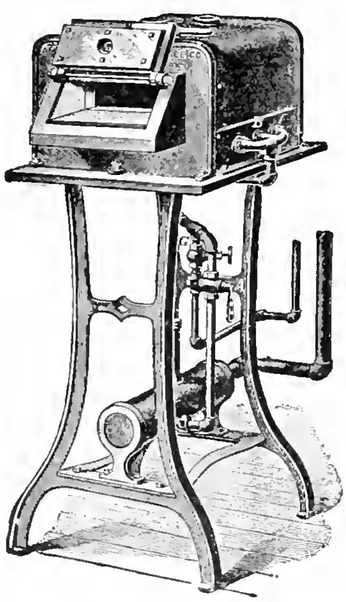
Oven Furnace No. 1

These furnaces are made in a wide range of sizes; are designed to heat square or oblong space of any desired dimensions to the required temperature and maintain a uniform heat under all conditions. The Oven Furnace is generally more satisfactory than a muffle furnace because there is a complete absence of oxidization. The No. 1 Furnace as shown, is adapted for general hardening and annealing—the No. 16-a smaller size, is much used in tool rooms for heating cutters, dies, lathe and planer tools and like work.

Air Blast under pressure of one pound to the square inch indispensable.



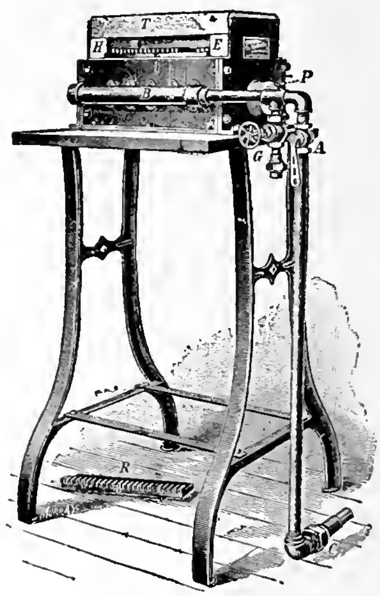
Positive Pressure Blower



Oven Furnace No. 16

"American" Gas Blast Forges

For the machine shop and tool room will heat the work quickly and uniformly, with little or no scale, and danger of overheating stock is practically eliminated. They are ready at all times, develop the required amount of heat in a few minutes and are both convenient and economical.



Gas Forge No. 7
For Cutlery, etc.

We shall be glad to forward Catalogue showing full line of Furnaces.

DISC GRINDERS

Charles H. Besly & Co.

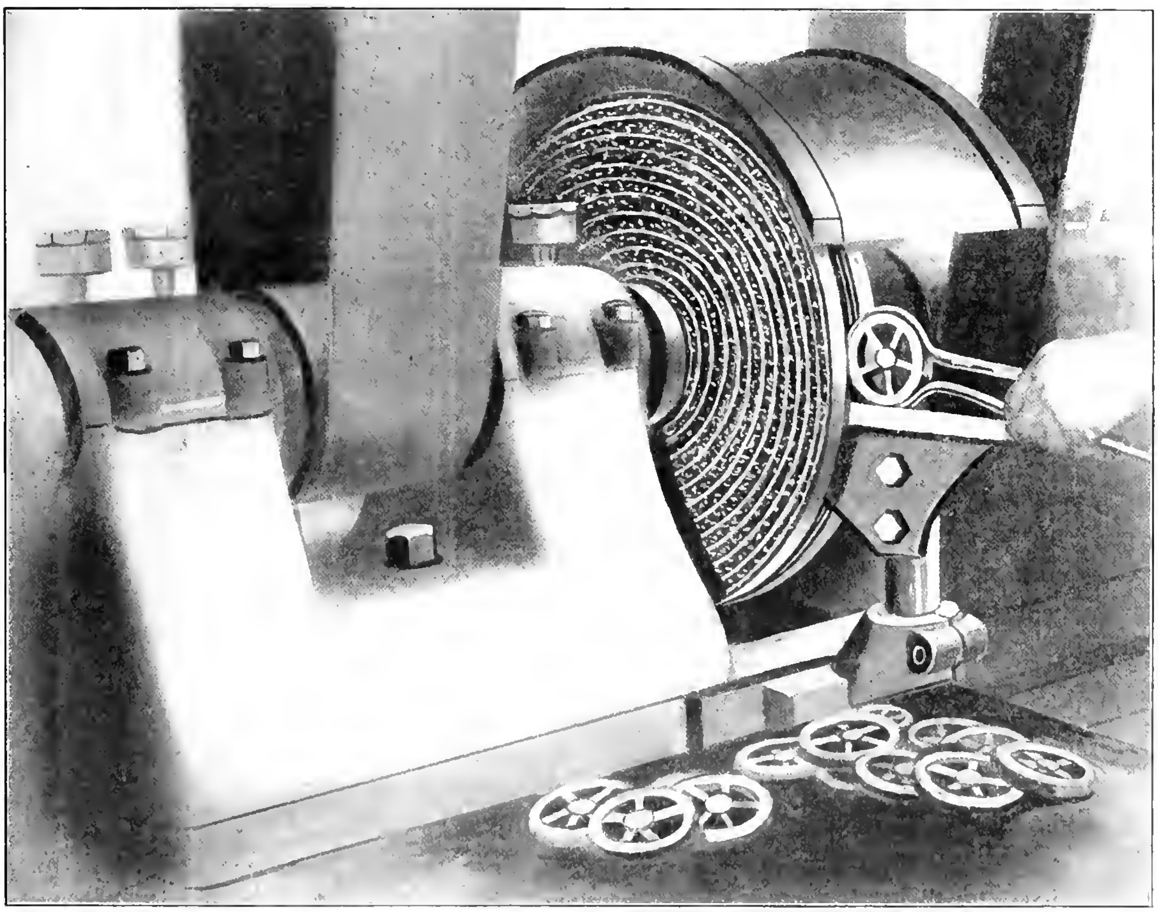
SPIRAL GROOVED DISCS
SPIRAL CIRCLES

HELMET TAPS ARE THE STANDARD

ORIGINATORS OF DISC GRINDERS

Economy and Accuracy go Hand in Hand

when your grinding is done on a Besly Spiral Grooved Disc Grinder. The advantages offered by this machine for flat surface grinding of all kinds—all materials—are unequaled and will save fully 50 per cent. over other methods, besides permitting the closest measurements.



The illustration shows a No. 6 Besly Grinder with double discs at work on 3-inch brass Magneto Gear Blanks for telephones. These blanks were ground at the rate of 250 pieces—500 surfaces—per hour; the circles used being No. 2350 Helmet Spiral Circles, grain 60, removing $\frac{1}{32}$-inch stock. As an example of accuracy these blanks were finished parallel throughout, within .0005 inch. The cost of circles did not exceed two cents per hundred surfaces ground.

It is quite possible we could handle your work with an equal or perhaps greater economy. Send us a sample and we will grind and return it free of charge, marking full data as to time, machine, circles, etc.

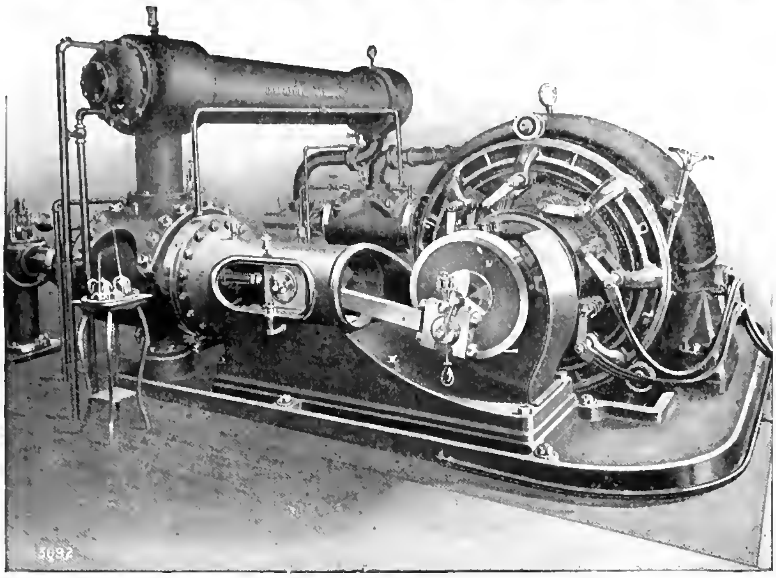
ELECTRIC DRIVEN
COMPRESSORS



One of the Ingersoll-Rand Direct Connected Electrical Compressors in the Gould Coupler Co.'s Shops, Depew, N. Y.

The advent of cheap electric power where fuel is costly and water scarce has developed the electrical compressor. In many instances its adoption has marked the line between unprofitable and profitable operation.

Ingersoll-Rand electrical compressors are the highest refinement of electrical and pneumatic practice. They embody the Company's experience of thirty-five years, covering the building of nearly a million compressor horse-power. More than 90 per cent. of the electrical compressors in use today are Ingersoll-Rand machines—a fact establishing them as the recognized standards of electrical compressor economy.

VIM IS STRONGEST

Strength of leather is in direct proportion to the length of its fibres.

The above illustration shows a piece of VIM and one of oak leather broken under the same conditions.

The superior length of the fibres of VIM gives some idea as to why

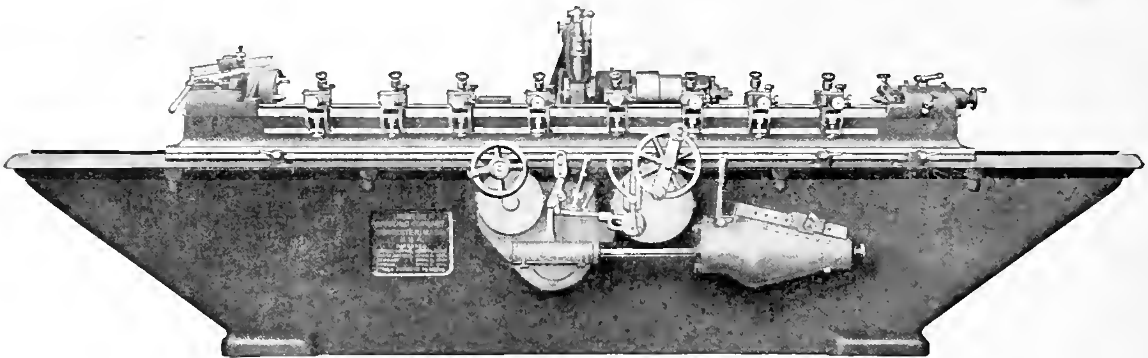
LEATHER
TRADE
VIM
MARK
PACKINGS

can be guaranteed to wear twice as long as oak.

But this is only one of the many reasons.

Get the others by sending for an illustrated catalog.

NORTON



About Speeds

An important feature of the **NORTON** Grinding Machine is the convenience of obtaining different speeds to suit the work.

Every speed of work, wheel and table can be changed at the machine without over-head cones.

All adjustments, operating levers and handles can be reached from one point in front of the machine.

All speed changes can be made without stopping either the work or the wheel.

The Grinding Wheel is always in plain view of the operator when he is in position to make all speed changes and adjustments.

For full details send for our latest Catalog—N 7, 1907.

CARBORUNDUM
NIAGARA FALLS

Carborundum will cut every other known abrasive—

No other known abrasive will cut carborundum—

This has been absolutely proved by tests made by some of the best known scientists of the world—

It simply emphasizes and confirms what we have been saying for years—

that

> Carborundum is the hardest abrasive in the world—
>
> Carborundum is the sharpest abrasive in the world—
>
> Carborundum is the longest lasting abrasive in the world—

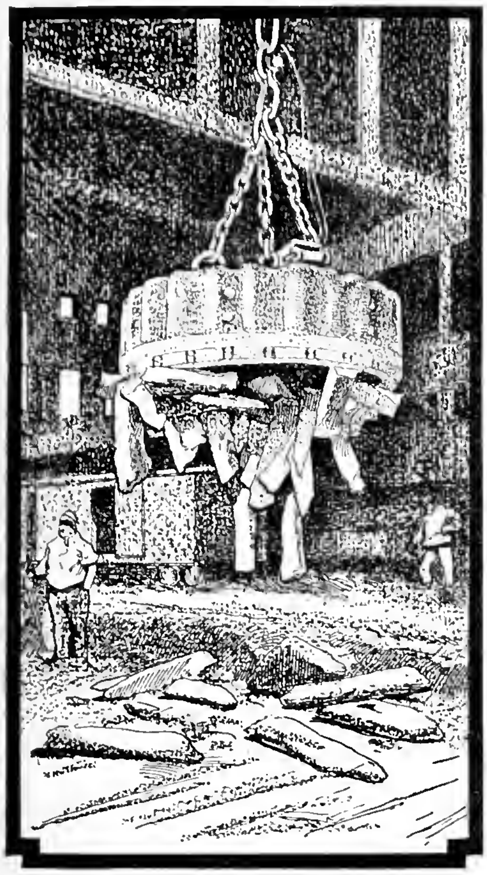
And all these things make Carborundum the most economical abrasive in the world.

There is a Carborundum grinding wheel for every possible grinding need—

Let our experts help you to get the right one for your purposes.

The Carborundum Company

Niagara Falls, N. Y.



LIFTING MAGNETS

After several years of quiet preparation we announce our readiness to fill orders for Lifting Magnets.

Cutler-Hammer Lifting Magnets are designed by engineers who for years have devoted themselves to problems involving electric and magnetic control. They possess **distinct advantages** not to be found in any other magnet now on the market.

Under rigid service tests the records established by these magnets have been so far in advance of anything previously accomplished that we are prepared to accept orders under the following:

"THREE-WAY" GUARANTEE.

1.—AS TO WEIGHT: The magnet we will build for you will be as light as is consistant with proper design and its weight will be guaranteed **not to exceed** that of any comparable magnet.

2.—AS TO EFFICIENCY: The lifting capacity of our magnet will be guaranteed to **exceed** that of any comparable magnet now in use.

3.—AS TO OPERATING COST: The operating cost per ton of material moved will be guaranteed to be **less** with our magnet than with any comparable magnet.

Send for illustrated booklet. When writing, state size of magnet desired and nature of material to be handled.

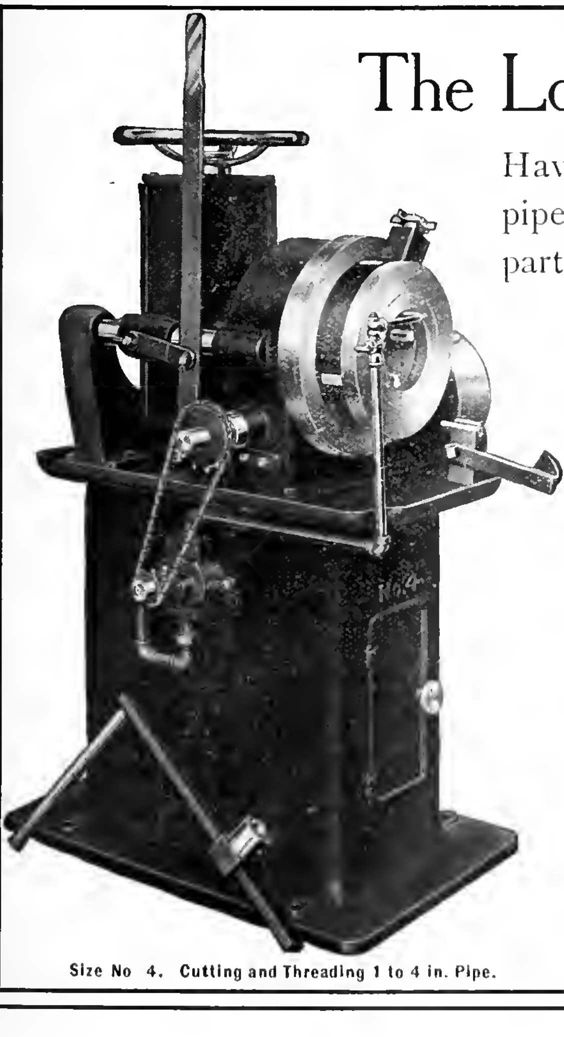
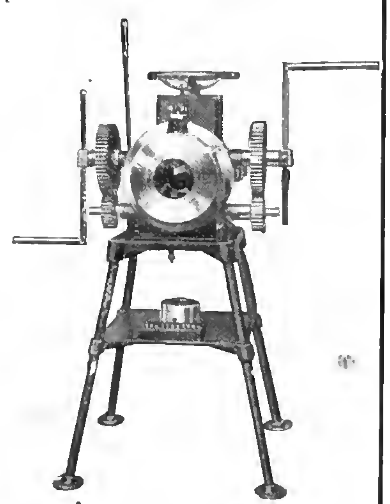
The Loew Victor Pipe Machines

Have advantages which put them in the lead for pipe work of all kinds. They are simple in design, particularly durable, and rapid, accurate workers.



Size No 4. Cutting and Threading 1 to 4 in. Pipe.

SPECIAL FEATURES ARE: The self-locking die head, the improved cut-off attachment, the absence of noisy gears, and the automatic device for releasing the dies and removing burrs from the thread.



Size .02 Hand Power Machine with Cut-off Attachment

Write for Catalog showing full line. The easiest hand operated Hand Power Pipe Machines on the market, and the best Pipe Machines for all classes pipe cutting and threading.

The Loew Mfg. Company, Cleveland, Ohio

Sterling Hack Saws

"BEST-BY-TEST"

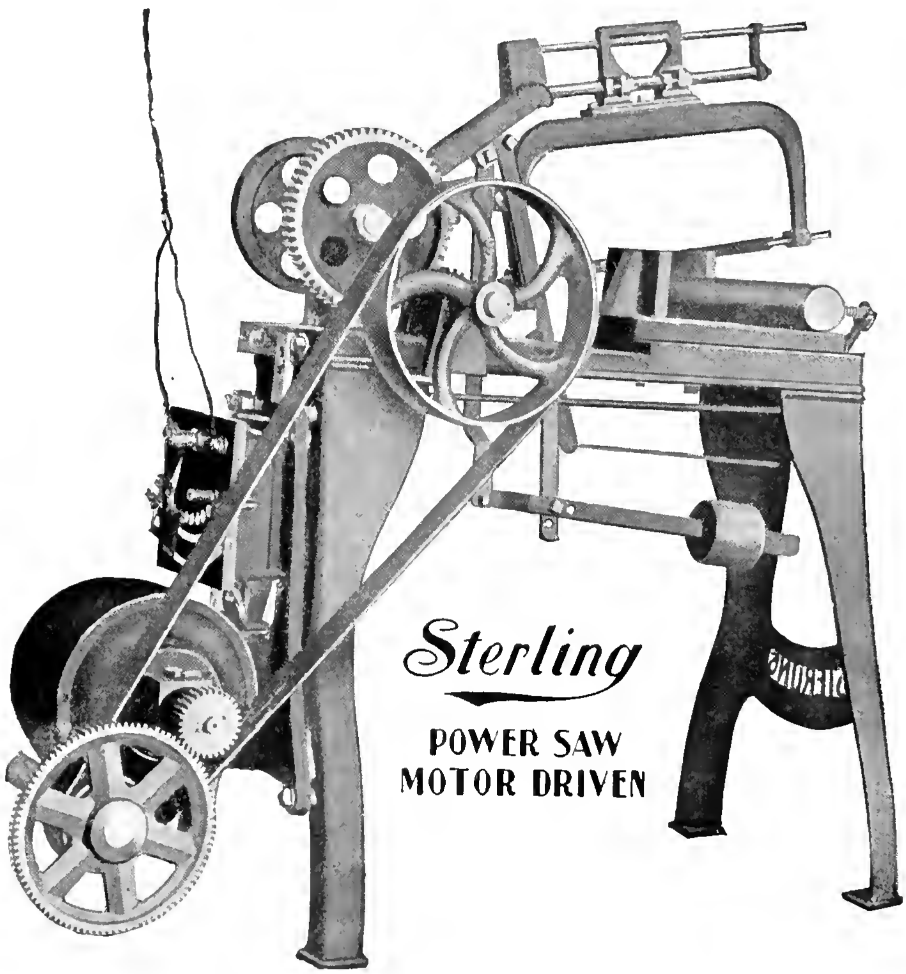
Hand Blades ½ in wide
Machine Blades ⅝-¾-1 in

Machine Features

1. Swivel Vise.
2. Tight and Loose Pulleys.
3. Driven by Milled Gears.
4. Gravity Feed.
5. Automatic Shut-off.
6. Attachment for cutting off long bars at 45° angle.

Motor Features

1. Armature speed 1150 R. P. M.
2. Starting Box—regulating speed from slow to fast.
3. Automatic Shut-off.
4. Fully enclosed—dirt-proof.
5. Location—Back of Machine away from saw cuttings.



Runs smoothly, noiselessly, continuously. Simply attach an electric wire. The saw does the rest.

The "Sterling" Power Hack Saw Machine

Is the latest development in Hack Saw perfection —soon pays for itself. Saves time, material and money.

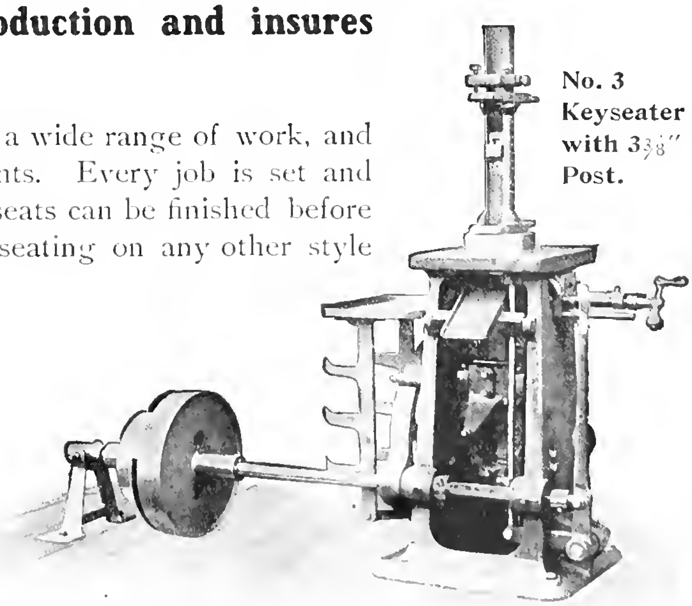
Mitts & Merrill's Giant Keyseater

Solves the time saving problem in keyseating, permits economy in production and insures accurate work.

The machine is built in six sizes covering a wide range of work, and is quickly adjusted to different requirements. Every job is set and fastened by its bore and two ordinary keyseats can be finished before one piece can be fastened ready for keyseating on any other style machine. Will cut perfectly true keyways whether the hole is straight or taper or whether the hub is faced true or left rough as it comes from the foundry. The support being absolutely solid, the tool cannot spring. Send for Keyseater book—mailed free.

These machines are in use in the leading shops of America and Europe.



No. 3 Keyseater with 3⅜" Post.

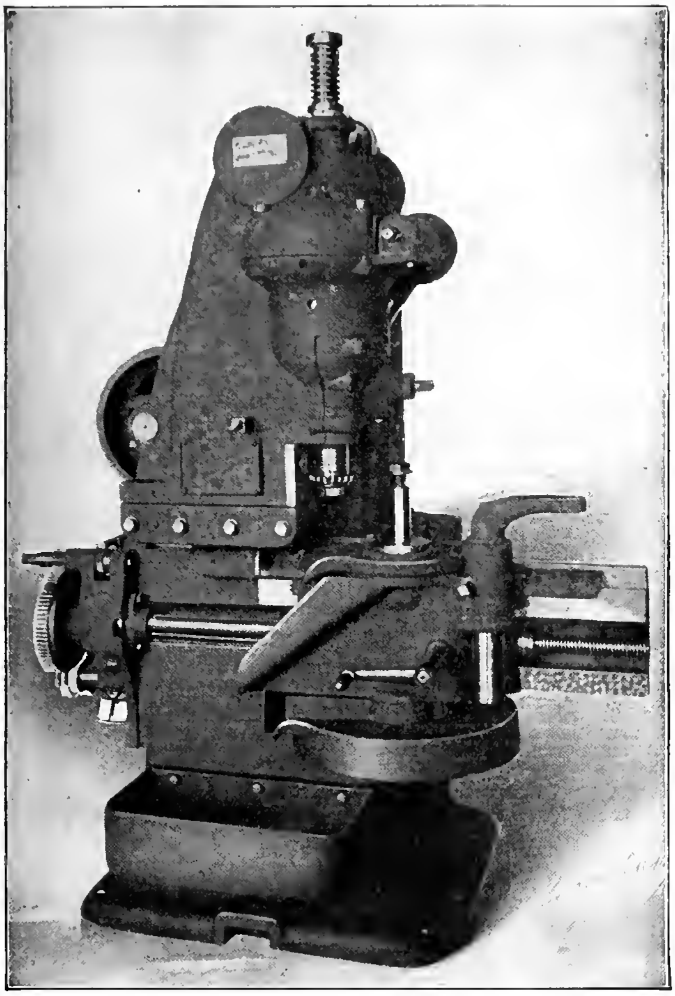
CHICAGO OFFICE, 453 ROOKERY

Better Gears at Less Cost.



Not better gearing at increased cost nor poorer gearing at less cost, but a combination of high quality and low cost is the result of using the Gear Shaper.

In no other part of a machine will inferior workmanship be detected so quickly as in the gears, because of the noise of inaccurate gearing. Therefore it is important that you use gearing that is the nearest approach to absolute accuracy of any obtainable, and that without extra cost. Such is the product of the Gear Shaper.

WHY?

1st. The cutter is theoretically correct; it is a generating tool.

2d. The cutter is correct in practice; after being hardened it is ground to the theoretical involute curve.

3d. The cutter has several teeth in operation at once; it travels practically the face of the blank only; the speed steel cutter is practicable even on the finest quality of work, because as stated above, it is ground after it is hardened; the machine is stiff enough in every detail to carry this cutter at speeds and feeds limited only by the endurance of the best speed steels. The above are some reasons why.

4th. Two Gear Shapers will do the work of three rotary type machines, which means a large saving in capital invested, floor space and operators.

In addition to the above, on account of the planing cutter the Gear Shaper will cut a large variety of work impracticable by any other method.

We would cut your gears until the Gear Shaper reached you.

"OUR GUARANTEE"

The Ney Disk Grinder is the equal of any made, in Cutting Speed. We do not "guarantee" this only, but we *state* it and it's *a fact.*

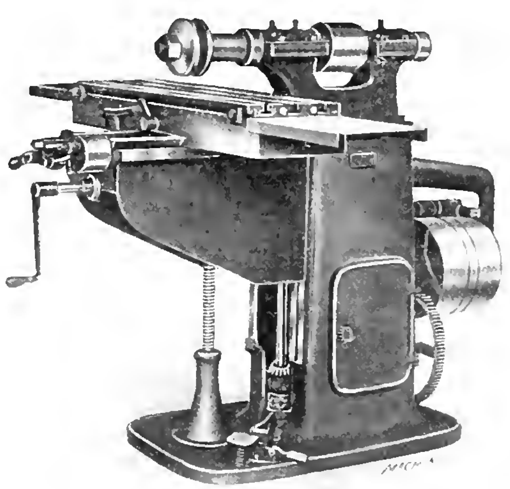
The *ordinary* loose guarantee simply means that if a machine doesn't fulfill the maker's claims you can return it — and try someone else. Now, where do you come in on that?

"OUR" guarantee means that if our machines are not as represented we will send you one that *is* right. Our first complaint is yet to arrive.

PRECISION DISK GRINDERS

ROSCOE W. NEY, Kingston, N.Y.

The Saxon Surface Grinder



When a machine, at a reasonable price and with more than the ordinary capacity, is wanted for finishing flat work accurately and rapidly, this one meets every requirement. It is making an enviable reputation in both manufacturing department and tool room. If it saves money for others isn't it worth your investigation? The price is not its least attractive feature. Why not get it?

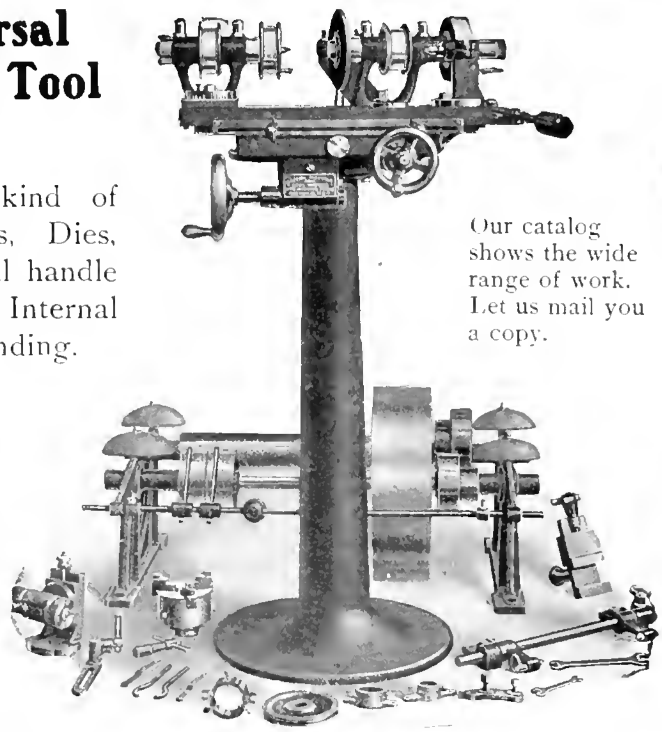
FAST GRINDING WHEELS

The Universal Cutter and Tool Grinder

Grinds every kind of Cutter, Reamers, Dies, Chasers, and will handle a wide range of Internal and Surface Grinding.



Our catalog shows the wide range of work. Let us mail you a copy.

A special advantage of this machine is the accuracy of work turned out, and the ease with which adjustments can be made. Rigidity is another strong point. All working parts are protected from dust and dirt.

DAYTON MACHINE & TOOL WORKS, DAYTON, O.

THE BLACKSMITH'S GUIDE

By J. F. SALLOWS

Over One Hundred and Fifty Illustrations

Price, $1.50

A Book that Tells How by a Man Who Knows How

Tells how to do machine forging; weld iron and steel; weld a ring true to size; forge, harden and temper lathe, planer and hand tools; harden cutters, taps, dies, punches, broaches, etc.; treat high-speed steel; anneal steel; case-harden; pack-harden; mottle and color steel; braze; bend pipe; straighten sheet steel; and do general blacksmithing.

Contains full directions for making an oven for hardening and tempering; for making a brazing furnace; and a special forge for high-speed steel. Complete working drawings for a furnace that can be built at small expense for case-hardening and coloring metals; two color charts as guides in hardening and tempering; and a colored plate showing the beautiful results in coloring obtained by Mr. Sallows by methods explained in his book.

If YOU want to know how, get this latest handbook on the treatment of steel.

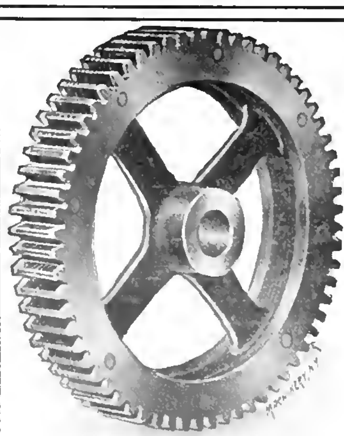
SYRACUSE, N. Y.



Peerless Raw Hide Pinions

Adapted for the Severest Service--Noiseless--Satisfactory on every score

We'd be glad to tell you just how great the advantages of Raw Hide Pinions are—if you will send us your address.

We are also equipped for Gear Cutting in all its branches —Cut Gears, Planed Bevel Gears. Estimates furnished.

THE HORSBURGH & SCOTT CO., Cleveland, Ohio

How do you clamp the work on your Planer, Miller or Boring Mill? Still using Bolts and wasting precious time?

Drop Forged Steel Case Hardened

Lang's T Bolt Heads

Take the place of weak headed bolts for this work and save enough time on the day's work to almost pay an extra man. It's a simple matter to keep a good supply of studs of various lengths on hand, and with them and the T heads you are always ready. No need to stop to clean out the slots when a job comes off either—put the new piece on and set the T Head Bolts where needed **after** the work is in place. Strong, will not break or injure the slots of the table. If you want to save time, increase your output and keep your men contented, you want to get posted on our T Bolt Heads.

TOLEDO TESTED TOOLS

are designed and built by the world's largest EXCLUSIVE manufacturers of

Sheet and Bar Metal Working Machinery

Don't Experiment We will give you the benefit of our years of experience and diagnose your press needs so carefully that a machine SPECIALLY SUITED to the work required will result as a matter of course. No skill and no material too good for Toledo Tools.

Our 72 inch No. 94 F, Special Double Pitman Geared Power Press, with openings through the two housings right to left, is particularly adapted to blanking, perforating and forming strip metal and can be made to perform the work on strips 8, 10 and 12 feet long, and longer if necessary, by feeding through the housing finishing the entire strip in several operations.

This type of press is particularly serviceable in shops where machines wide enough to accommodate full width of strip cannot conveniently be accommodated.

Built in various capacities and widths. We make a specialty of crucible cast steel and other forgings for dies, shafts and machine parts. Toledo Dies for long life and accurate results.

The Jacobs
Improved
Drill Chuck
No. 4, cut
full size.

Patented
Sept. 16, 1902

The Five Sizes Jacobs Drill Chuck

Now on the market cover all requirements between very fine, small work, for which the No. 1 Chuck is designed, and work that requires a chuck with capacity up to one inch—

Get the One You Need

The "Jacobs" meets the demand for a chuck which is at once strong, accurate, effective and convenient to operate.

The toothed sleeve and key—its distinguishing feature—saves time, patience, tools. Any one can adjust it—there is no twisting of the spindle when tightening the tool, no slipping when the tool is in place—and no need for a man to have *three* hands to do the trick.

Write for our book—tells all about it.

The Jacobs Manufacturing Co.

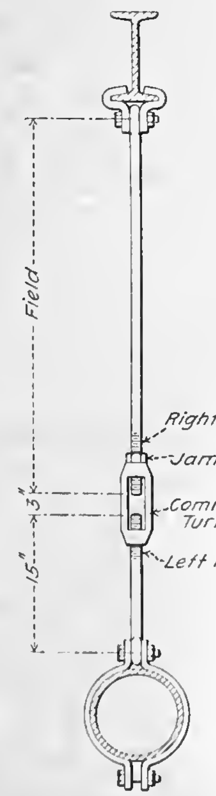
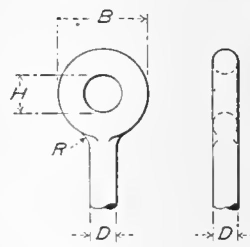
PIPE CLAMPS AND HANGERS.—IV.

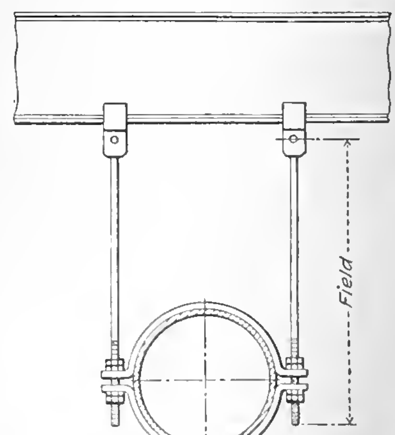


Vertical Type



Detail of Eye Bolt End

Size of Rod (D)	B	H	R
3/4	2 1/2	1	1
7/8	2 7/8	1 1/8	1 1/8
1	3 1/4	1 1/4	1 1/4



Horizontal Type

All dimensions in inches

The size of the rod is determined by the size of the pipe. See tables II and III.
The size of the beam clamp is determined by the size of the beam and the size of the rod. See table I.
For the vertical type make the lower rod 15 inches long with left hand thread. These can be made up in lots and be carried in stock.
Upper rod to have right hand thread and one jam nut. Determine length of rod in field.
Use commercial turnbuckles.
Figure clearance between upper and lower rods as about 3 inches.
Rods are not upset at ends. Make threads 6 inches long. Horizontal type rods to have 4 nuts each, right hand thread. Determine length of rod in field.

VANADIUM STEEL.*

THE CHARACTERISTICS OF A NEW STEEL FOR MACHINE CONSTRUCTION.

E. F. LAKE.†

Among the many new alloy steels which have been brought out in the last few years, the vanadium steels are probably the latest addition which steel makers have adopted, and this has been done after many experiments had been made. This steel, in many different percentages of alloy, has been given numerous tests of many different characters in order to determine the qualities of the steel and its action when submitted to the various strains and stresses it is liable to meet when put into actual use. These tests would seem to place it in the front rank of high-grade alloy steels, although it will be, after all, the actual use of it for the moving parts of machinery and other purposes that will demonstrate to a certainty its wearing qualities, as well as its ability to withstand strains and stresses.

strains applied in a totally different manner to that under which it was tested by simply pulling a bar until it broke.

In machine construction, those parts which are liable to failure while in use require high dynamic qualities, that is, resistance to repeated stresses, alternating stresses, simple repeated, or alternating impacts, and fatigue, the latter being the outward and visible sign of the inter-molecular vibratory deterioration.

Thus a new field is being opened out, and while vanadium affects steel in a manner that tends to increase the static strengths of other alloys, it also raises the dynamic properties to an extent that is not thought of in other alloys. It is here that vanadium gives an added value to the high grade alloy steels.

As manufacturers are beginning to use this steel for different purposes, the positive proof will be forthcoming in the very near future, if it has not already been obtained by those who are using it.

The mechanical engineers of the present day have been forced to become better metallurgists than they ever were in the past, in order to intelligently design high-grade machinery, as the, so-called, mysterious failures of steels are becoming more numerous and more pronounced every day.

These, so-called, mysterious failures of steel, which occur in high-grade alloys the same as in the Bessemer steel rails, although not as frequently, have proven to the engineers of to-day that the old custom of judging a steel by its resistance to static load, and the amount it would stretch under that load, is not always to be depended on.

The uses to which steel is put call upon it to resist

Some recent tests of armor plate, made by the United States Government, give an illustration of this. In the past it has been the custom to make armor plate as hard as possible, and at the same time retain a high degree of strength. For this reason chromium was used as the principal alloy, and in many cases the only alloy, as it gave steel a hardness that is not obtainable with any other. In the recent test spoken of, a vanadium-chrome steel was used with a hard outer shell and a very soft core, similar to the condition obtained by carbonizing. The result was that it withstood a much higher test of the impact blows delivered by the shots from a gun than the formerly used hard steels.

Vanadium acts as a physic on the other elements and is a very powerful medicine, as very small percentages give the desired results; but if used in too large a percentage it will dynamically poison the metal. Sometimes the vanadium will perform its mission properly and physic through the metal, leaving but a trace to show on analyzing the steel, but in the majority of instances it stays in the metal. Vanadium

* For additional information regarding the manufacture and characteristics of this and kindred steels, see the article in the September, 1907, issue of MACHINERY: Nickel Steel, and previous articles referred to in the same issue.

† Address: 111 Crane St., Detroit, Mich.

steel is the most difficult of all the alloy steels for the chemist to get a correct analysis of.

Vanadium has the property of elusiveness to a very marked degree, and must be handled by the steel maker very carefully in order to get the necessary results. It is, therefore, marketed in the form of ferro-vanadium in the proportions of about two parts of iron to one part vanadium. For machinery purposes it is generally alloyed with steel in percentages of from 0.10 to 0.30 per cent, but it has been tried as a tool steel with as high as 3 per cent, and when this was compared with a 3 per cent tungsten tool steel by cutting

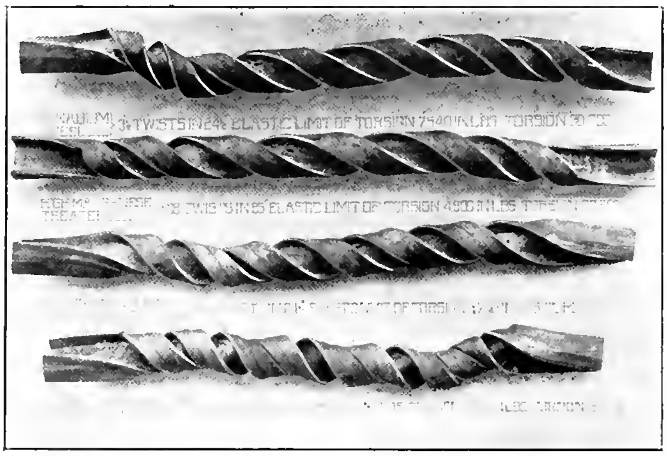

Fig. 9. Axle Steel Samples showing Difference in Physical Qualities Length, 52 inches; Depth, 2 inches; Width, 1 1-2 inch; Thickness of Flanges, 3-16 inch at Edge, 3-8 inch at Web; Thickness of Web, 3-16 inch.

a chilled white iron plate, and then collecting and weighing the cuttings, the vanadium tool steel was found to excel the tungsten tool steel by 25 per cent. It is used in manufacturing a tool steel by one steel maker, in this country, who uses vanadium in a small percentage, tungsten in a large percentage, chromium in a small percentage, and a few other ingredients in small percentages, and the tests given this steel show that it excels other tool steels by from 10 to 20 per cent in their cutting qualities.

Vanadium is not like nickel, chromium, manganese and other mineral elements used in high-grade steel making, as it contains within itself no virtues but in its action as a physic

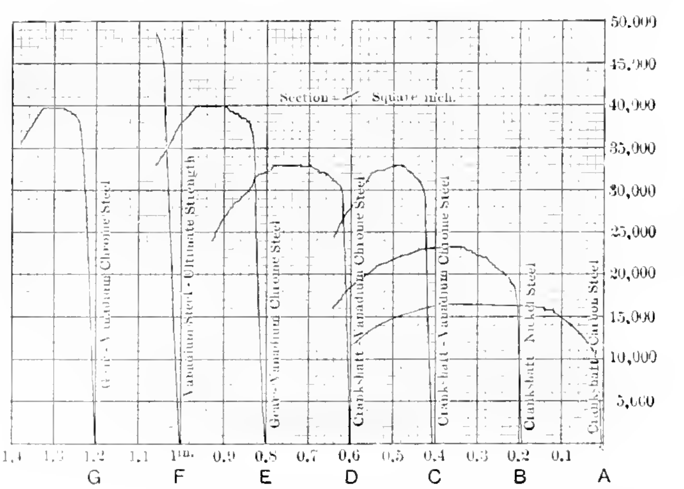

Fig 10. Chart taken on Olsen Testing Machine. Test Bar, 1-5 square inch Section. Figures should be multiplied by 5.

on the other elements. It imparts some very desirable properties, hence its most successful application lies in the direction of the quaternary steels such as chrome-vanadium or nickel-vanadium. In a technical sense it retards the segregation of the carbides, thereby producing in steel a high degree of homogeneity and a grain of great uniformity and fine texture. This is best shown by the series of microphotographs Figs. 1 to 8, which are magnified 350 diameters. One of these shows the ordinary carbon steel, another nickel steel axle stock, and the others vanadium-chrome steel under different degrees of heat treatment.

These photographs were furnished the writer by the Ford Motor Co., Detroit, Mich., from a special heat of 50 tons which it had rolled for its own use. This steel is being used on all the automobiles built by the company.

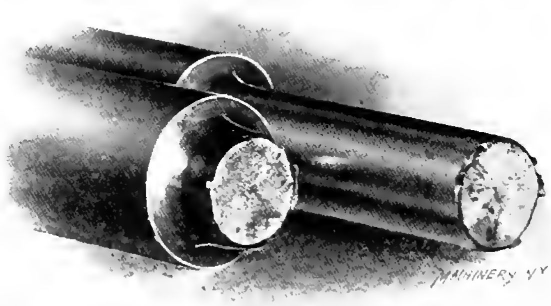

Fig. 11. Test Bar, 1-2 inch Diameter. Heat Treated for Mesh-gears. Star Fracture.

In retarding the segregation of the carbides, vanadium renders steel susceptible to great improvements by heat treatment or tempering, and in this manner the steel can be prepared to resist wear and erosion. It also renders possible the natural formation of the "sorbitic" structure which is necessary in metals which have to withstand wear and erosion.

Vanadium steel also has self-lubricating properties to a greater extent than other high-grade steels, hence it is more

Fig. 12. Test Bar, 1-2 inch Diameter Vanadium Axle Steel. Star Fracture.

valuable for shafts running in parallel bearings and for gears. It also produces soundness mechanically as well as chemically and toughens the steel, thus conferring great powers of resistance to torsional rupture.

Chromium gives to steel a brittle hardness which makes it very difficult to forge, machine or work, but vanadium, when added to chrome-steel, reduces this brittle hardness to such an extent that it can be machined as readily as a 0.40 per cent carbon steel, and it forges so much more easily that the Ford front axle—shown twisted in Fig. 9—which is 52

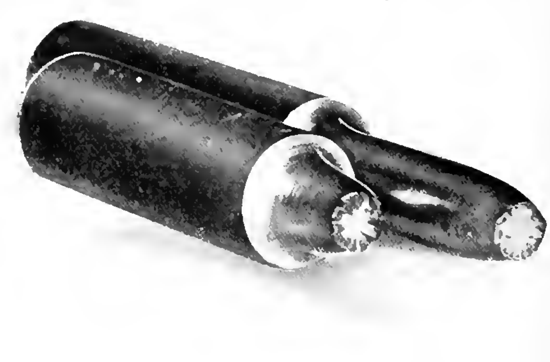

Fig. 13. Test Bar, 1-2 inch Diameter, Vanadium Crank-shaft Steel. Star Fracture.

inches long, 2 inches deep, of I-beam section, with the web only 3/16 inch thick, is being forged in three heats. The first heat is used to forge the straight I-beam part; the second heat is used to forge the arm for the steering-rod connection and the projections for the steering pivot, on one

end, while the third heat is required to forge the same on the other end of the axle. Automobile axles of similar design, when forged out of chrome-nickel steel, require from 15 to 20 heats to give them the proper shape, and even then the dies give a great deal of trouble.

For these reasons the nickel or chrome-nickel axles are usually forged in two halves, and welded together in the center by the electric welding process.

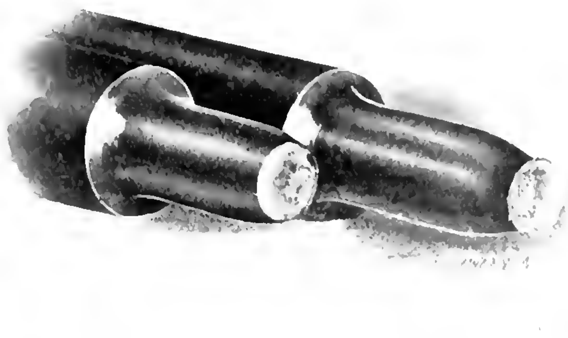

Fig. 14. Test Bar, 1-2 inch Diameter, Vanadium Crank-shaft Steel. Cup Fracture.

Vanadium, by reducing the brittle hardness of chromium and rendering steel very homogeneous, makes it capable of being machined as easily as ordinary carbon steel, that is, running at the same speed and using high-speed tools. The Ford Motor Co. says: "Thus we find in actual practice that vanadium steel costs no more than ordinary carbon steel and vastly less than nickel, because of the saving in machining, forging and tempering, and the greater accuracy we are able to obtain, owing to uniformity of metal and the lighter weight of metal we are capable of using, owing to its great strength."

TABLE I.

Specimen.	Tensile Strength in pounds per square inch.	Elastic Limit in pounds per square inch.	Elongation in 2 inches, per cent.	Reduction of Area, per cent.
A	82,500	50,000	30	66
B	116,000	90,000	21	71
C	165,000	147,000	11	61
D	165,000	147,000	16	59
E	200,000	185,000	11	56
F	228,375	228,375	..	..
G	198,750	190,000	9	34

TABLE II.

Specimen.	Tensile Strength in pounds per square inch.	Elastic Limit in pounds per square inch.	Elongation in 2 inches, per cent.	Reduction of Area, per cent.
1	88,000	64,500	29	59
2	98,750	67,500	25	77
3	127,500	110,000	14	59
4	147,000	140,750	17	57
5	165,000	155,000	16	55
6	176,500	175,000	7	27

Fig. 9 shows the comparative amounts of torsion which vanadium and some other steels will stand by twisting. Fig. 10 shows the comparative strengths of carbon, nickel and vanadium-chrome steels. The figures for this chart read as in Table I.

A is a 0.06 per cent carbon steel, heat treated. *B* is a 0.07 per cent nickel steel, heat treated. The others are all taken from the same bar of vanadium steel and subjected to different degrees of heat treatment. *F* merely shows the ultimate strength.

Vanadium steel can also be given a wide range of strengths together with hardness or softness by properly heat treating. This is best shown by the accompanying Table II, of test bars which were pulled on an Olsen testing machine by the Ford Motor Co. especially for the writer. The test bars were all made out of one bar of steel.

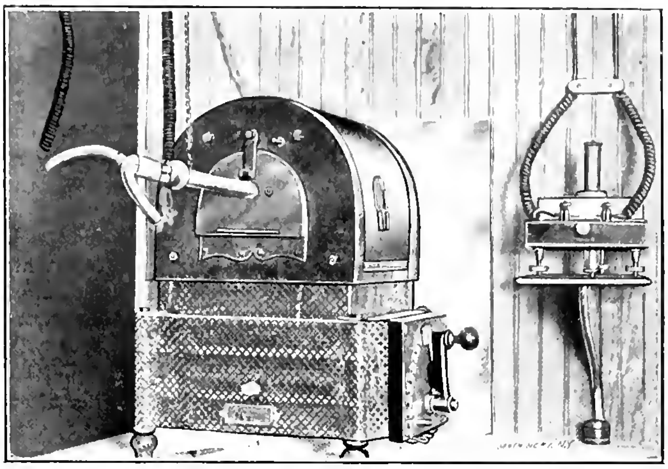

Fig. 15. Heat Treatment Furnace, electrically heated.

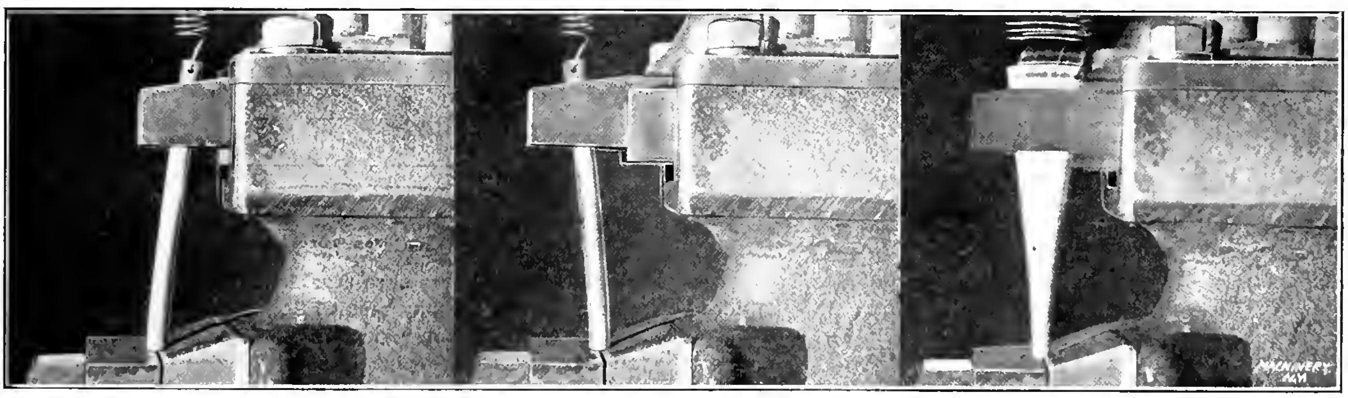
Specimens 1 and 2 are in their softest condition; specimen 3 is in the condition of an axle; specimens 4 and 5 are in the crank-shaft condition; and specimen 6 is in a mesh gear condition.

Other tests have shown much higher strengths, but the remarkable features of these tests are the way the elastic limit has been brought up nearly to the tensile strength, and the high reduction of area.



Figs. 16, 17 and 18. Alternating Impact Machine.

Figs. 11, 12, 13, and 14, which are photographs of four of these bars, will more clearly show the reduction as well as the almost perfect breaks.

TABLE III.

Kind of Steel.	Pendulum Impact, Foot-pounds.	Alternating Impact, Number of Stresses.	Falling Weight on Notched Bar, Number of Blows.	Rotary Vibrations, Number of Revolutions.
Carbon axle stock ..	12.3	960	25	6,200
Nickel axle stock..	11.0	800	35	10,000
Vanadium axle stock..........	16.5	2700	69	67,500
Vanadium crank shaft stock.....	12.0	1850	76	......
Vanadium mesh gear stock........	6.0	800	..	......

Fig. 15 shows the furnace which was used in treating the steels in Table II. To it was attached a pyrometer, which was

fastened to the wall above, and therefore does not show in the cut, but the wire at the back leads to it. With this it was possible to regulate the heat to the exact degree required for obtaining the heat treatment wanted for each specimen.

While the static strengths before stated are and can be made the equal of almost any alloy steel, it is in the dynamics that vanadium steel excels all others, and these are becoming more and more the real tests of steel for use in moving machinery or where strains other than a direct pull are put upon it.

The dynamics of vanadium steel as compared with carbon and nickel steel are shown by the tests given in the accompanying Table III. These tests were made with a bar ½ inch in diameter.

These tests have given the present day engineer something tangible on which to base the size, shape and strength in designing parts for machinery which has to withstand great strains. In the past the engineer was contented if he knew the static strengths were high, but these, in reality, were but about 15 per cent of his requirements, and having made sure of these, he hoped that in some way he had acquired the other 85 per cent.

At the present time, however, by submitting his steels to the dynamic tests, he no longer hopes, but knows, what his steel will stand under all kinds of conditions and strains, and is therefore enabled to do his designing with much more assurance and knowledge of what the different parts will require.

Figs. 16, 17 and 18 show the machine on which the alternating impact tests were made, the first two showing it in its extreme position at each end, and the third showing it while in motion.

* * *

EFFECT OF MOISTURE ON WOOD.

The Forest Service of the U. S. Department of Agriculture has just issued a publication entitled "The Strength of Wood as Influenced by Moisture," in which is shown the strength of representative woods in all the degrees of moisture, from the green state to absolute dryness, and the effects of resoaking. By different methods of seasoning, two pieces of the same stick may be given very different degrees of strength.

Wood, in its green state, contains moisture in the pores of the cells, like honey in a comb, and also in the substance of the cell walls. As seasoning begins, the moisture in the pores is first evaporated. This lessens the weight of the wood, but does not affect its strength. It is not until the moisture in the substance of the cell walls is drawn upon, that the strength of the wood begins to increase. Scientifically, this point is known as the "fiber-saturation point." From this condition to that of absolute dryness the gain in the strength of wood is somewhat remarkable. In the case of spruce, the strength is multiplied four times; indeed, spruce, in small sizes, thoroughly dried in an oven, is as strong, weight for weight, as steel. Even after the reabsorption of moisture, when the wood is again exposed to the air, the strength of the sticks is still from 50 to 150 per cent greater than when it was green. When, in drying, the fiber-saturation point is passed, the strength of wood increases as drying progresses, in accordance with a definite law, and this law can be used to calculate, from the strength of a stick at one degree of moisture, what its strength will be at any other degree.

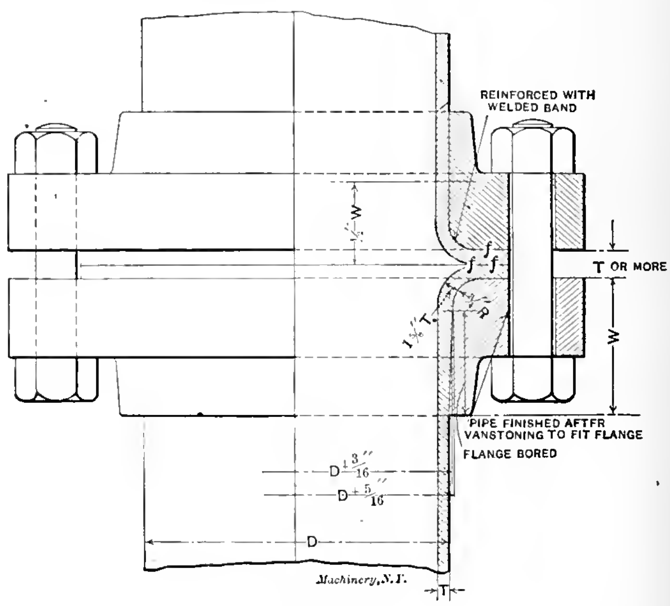
Manufacturers, engineers, and builders need to know not only the strength, but the weakness, of the materials they use, and for this reason they are quite as much interested in knowing how timbers are weakened by knots, checks, cross-grain, and other defects, as they are in knowing how they are affected by moisture. It is obvious that where timbers are certain to be weakened by excessive moisture they will have to be used in larger sizes, for safety. So far, engineers of timber tests, while showing that small pieces gain greatly in strength, do not advise counting on the same results in the seasoning of large timbers, owing to the fact that the large timbers usually found in the market have defects which are sure to counterbalance the gain from seasoning.

MATERIALS FOR CONTROL OF SUPERHEATED STEAM.*

Since the introduction of superheated steam as a large factor in economy in stationary power plant use, the question of what type of material is best for the proper controlling of the resulting high temperatures has caused a great deal of investigation and interest. This article treats particularly of what might be called in a general way piping systems, which systems are made up of pipe, fittings, valves, and the necessary details connected therewith, such as joints, gaskets, etc., and are taken up separately.

Pipe.

There can be little question as to the matter of pipe except quality. Of course, welded wrought iron or steel pipe is successful, but the difference in the quality of pipe is very material. As in nearly all instances in a superheated steam station the old fashioned screwed joint is not satisfactory, it is necessary to do what is termed "work" the pipe—that is, weld, van Stone, etc.—to make either a welded, van Stone, or other joint of the same general description. In the cut is shown what is known as a van Stone joint. For this work the pipe made from open hearth steel is by far the best for manufacturing reasons, because it can be properly "worked," there being less carbon, and the quality is much more uniform. Bessemer steel pipe will very often act in a satisfactory manner, but one is never sure that Bessemer will run even, and, therefore, troubles may result. It is practically impossible to "work" wrought iron pipe. In making what is known as a van Stone joint, the pipe is nearly sure to split very badly, not only at the weld, but all around its outer circumference.



Van Stone Joint.

Nearly opposite qualities from those used for getting good results from "working" pipe are required for threading. A good quality of wrought iron will cut and thread more easily with standard pipe machines and standard dies than a steel pipe, and a Bessemer steel pipe will thread much more easily with standard dies than open hearth. A great many manufacturers have difficulties in threading open hearth steel pipe, for the reason that they set the dies exactly the same as if they were cutting other qualities. This causes ripping of threads, etc. The die in a pipe machine should be set at a greater angle with the radius of the pipe, passing through the point of contact of the die, for soft steel than it would be for other kinds, and this in itself will very often eliminate great troubles in this line.

The ordinary commercial pipe will stand more pressure than the average person believes. A standard 1-inch piece of welded pipe will usually not break under 1,600 pounds per square inch hydraulic pressure. Full weight pipe is suitable for any temperature and any working pressure up to 225 or 250

* Paper by M. W. Kellogg, read before the American Society of Mechanical Engineers, May Meeting, 1907.

pounds, as long as it is not thinned at any point by cutting and threading.

Fittings.

The designs of fittings as generally manufactured for different purposes are, in a general way, satisfactory, with the one exception that very few manufacturers on their standard articles include what is known as the "long fillet" between the body of the fitting and the flange. This is a very desirable point, due to the fact that at this place there is the greatest strain from shrinkage in the molds, which also tends to develop porous spots. Most large users of this type of material have learned this thoroughly, and design their fittings accordingly. The quality of the material in fittings, however, is a very important thing in connection with superheated steam.

The latest practice is to do away with fittings entirely on high pressure steam lines, and put what are known as "nozzles" on the piping itself. This is accomplished by welding wrought steel pipe on the side of another section, so as to accomplish the same result as a fitting. In this way rolled or cast steel flanges and a van Stone or welded joint can be used. This method has three distinct advantages, to wit:

a. The quality of the metal used, for reasons explained hereafter, when the subject of the effect of heat on metals is taken up.
b. The lightening of the entire work.
c. The doing away with a great many joints.

As a general average, at least 50 per cent of the joints can be left out, and sometimes this proportion runs up as high as 60 or 70 per cent, according to the layout of the system. If this method is employed, substantial welds must be made, not only to stand the pressure required, but also the strain.

Valves.

It is important to have a good design of valve. In general, nearly any of the designs made by the best manufacturers are entirely suitable; such as a broken or solid wedge valve of the ordinary type, under the condition that all machine work is done thoroughly and the quality of metal used is of high grade, is satisfactory for the purpose intended.

Metals.

As a rule, different authorities vary slightly in their statements as to what temperatures different metals will stand with good results. German authorities state that cast iron should not be used above 480 degrees F. Other authorities allow us to go as high as 575 degrees F. Above these temperatures, in cast iron, the limit of elasticity is reached with a pressure varying from 140 to 175 pounds. Under such conditions the material is strained and does not resume its former shape, and eventually shows surface cracks, which continue to grow. These temperatures and pressures also lead in time to a shrinkage of all parts, and to a structural alteration of the metal, which results in leakages in valves at the seatings. Therefore, it would seem that iron castings are not suitable for either fittings or valves to be used in any superheated steam work.

The only adaptable metal is cast steel. Results of tests on this metal for the effect of temperature are such that at 572 degrees F., the reduction in breaking strength only amounts to about 1.1 per cent, and at 752 degrees F. to about 7.8 per cent. Therefore, it seems that this metal is practically capable of withstanding all pressures and temperatures up to at least 800 degrees F., without showing any appreciable weakness.

The influence of high temperatures on bronze, etc., is very material. At ordinary temperatures this metal has a breaking strength of about 34,100 pounds per square inch and an elongation of 36 per cent. At 572 degrees F. the breaking strength falls to about 19,500 pounds per square inch and the elongation to 11.5 per cent. At 662 degrees F., which is quite a common temperature, as the steam leaves the superheaters, the breaking strength of bronze only amounts to 12,200 pounds per square inch and the elongation at the breaking point is only approximately 1¾ per cent. This seems to eliminate entirely brass or bronze of ordinary composition for use with highly superheated steam.

The effect of temperature on nickel is very similar to that on cast steel, and in consequence this material is very suitable for use in connection with highly superheated steam. Even neglecting the special quality of nickel seatings, on account of the great toughness of this metal and the methods which can be used for securing rings of this substance to the valves and conical surfaces, it has the special advantage of having the coefficient of contraction and expansion with temperature almost exactly the same as that of cast steel, so that no slackness of the rings occurs and the valves remain absolutely steam tight. There are instances in which valves constructed with nickel seating have been satisfactorily used with steam temperatures up as high as 932 degrees F. Seats, disks, and bushings made of brass or plain bronze do not retain their shape.

For spindles on superheated steam works nickel steel is recommended. Seatings in valves should not only be screwed in, but also pinned in addition, using a fine thread which is very long, to give a tight joint. Seats should also have a flange on the top that makes a joint with the body when screwed down, which prevents the tendency to leak through.

Joints.

It is generally acknowledged that the old-fashioned screwed joint, no matter how well made, would not be suitable for superheated steam work. This leaves for discussion two general types, *viz.*, welded joints and what are generally known as van Stone or climax joints, that is, any joint where the pipe is turned over the face of the flanges. In welding a flange on a piece of pipe, great care must be taken to see that the weld is perfect, because of the unequal thicknesses of the metals to be so welded. If the weld is thoroughly made, this type of joint is very good, although for erection purposes, due to the fact that the flanges cannot swivel, it does not equal the turned-over joint as mentioned above. The manufacturing expenses in making a welded joint are also much more for the same type of work accomplished, on account of the necessity of doing all finishing work after all rough work, such as welding and bending, has been completed.

In regard to the turned over or van Stone joint, the quality of its manufacture seems to be the most important feature. This joint can be made in a careless way where the pipe is in no way thickened up and only faced on the front. A joint of this latter kind does not give good results, principally for two reasons:

a. The thinness of the metal on the turned-over portion; and
b. On account of the recesses left between the back of the pipe on the turned over portion and the flange, due to the pipe not being finished at this point.

The writer believes, however, if this joint is properly made, it is equal to the welded joint as a manufactured article, and superior to the welded joint as an article for erection.

To have this type well made, the pipe on the end should be thickened up an amount sufficient so that after the joint is turned over there will be enough metal left to face the turned over portion on the front, on the outer edge, and on the back. We, of course, take for granted that the flanges are finished on the front. After the work above mentioned is done, the pipe should be as thick on the turned over portion as the original thickness, or very close to it. The point made of facing the turned over portion of the pipe on the back is an exceedingly important one, much more so than most people seem to realize. In reference to making up a joint, it is certain that the face of all flanges or pipe where a joint should be made ought to be given a fine tool finish and have the face level, and then a gasket of some description used.

Gaskets.

There are large numbers of gaskets manufactured of all types and descriptions. It is very hard to take up this subject and be fair to each of the manufacturers, for the reason that practically no one has ever had experience with every type made, to judge for himself, and hearsay would lead us to suppose that all of them are at one time perfect and at other times useless. The writer has used many different types of gaskets, however, and has obtained the best results with a corrugated soft Swedish steel gasket with "Smooth-on" applied, and with the McKim gasket, which is of copper or bronze surrounding asbestos. The ordinary corrugated copper gasket is a very popular make and has been used a great deal. On superheated steam, usually sad results follow. There seems to be some peculiar action that causes this, as on super-

heated steam lines a corrugated copper gasket will in time pit out in some part of the flange nearly through the entire gasket.

The wear of a gasket depends largely on the method of pulling up bolts on flanges. If joints are pulled up entirely on one side and left loose on the other, and then taken up on that side, trouble with the gasket is almost certain. The bolts should be taken up gradually all around the flange. The experience of the erecting crews on high class superheated steam lines is an exceedingly important thing. The average steam fitter is not suited to this type of work. Most troubles can be eliminated by using only steam fitters experienced in the type of work under consideration.

* * *

PHOTOGRAPHING DRAWINGS.

Photographing drawings to a greatly reduced scale, for the purpose of record, or even for use in the shop, is coming to be quite common practice in the larger manufacturing plants. The Schenectady works of the American Locomotive Company follows this practice extensively for card records, and has a room in the engineering building specially fitted for the purpose. The standard size tracings of locomotive erecting "cards" are about 25 x 66 inches, and these are reduced to 8¼ inches length, a 6½ x 8½-inch plate camera being used. One plate is large enough for the reductions of two tracings, so, for example, the side elevation and cross-sections, or any other combination of two tracings desired, may be photographed on the same plate.

The tracings are photographed by transmitted light, as experience has demonstrated that the results are more uniform and generally satisfactory than when photographed by reflected light. North light is used, a large "window" facing the north having been provided. The window is double, there being two frames, each carrying a pane about 4 x 11 feet. The frame carrying the inner pane is swung on hinges at one end, and a circular track and trolley supports the opposite end, this being necessary because of the great weight and length of the frame and pane. Both panes are mounted flush in their frames, facing each other, so that when the swinging frame is closed upon the stationary frame, the panes are closely pressed together.

The tracings are mounted on the outer pane by stickers at the corners, and then the inner frame is closed upon it, thereby pressing the tracing down flat, holding it firmly and without wrinkles. The large size of the "window" permits four standard tracings to be mounted at once. These may be the locomotive side elevation, and cross-sections, and the boiler side elevation, and cross-sections, thus compressing on two comparatively small plates all the general data of a locomotive not carried on the specification card.

* * *

A good illustration of the cost of selling goods and the apparently extravagant prices that must be charged for small articles that can be cheaply made, is the safety razor. One of these useful tools of a certain make is sold for, say $5, including one dozen blades. Extra blades are sold for 50 cents a dozen. Now, of course, the principal part of any razor is the blade, but here we have a dozen blades sold for one-ninth the price charged for the handle and its case. Now, while the handle is nicely made, no doubt it and its case could be produced with some profit for 50 cents. This leaves $4 for profit and selling costs, which seems like a most exorbitant figure. No doubt it does represent a handsome profit, but not as much as is derived from the sale of the blades, notwithstanding their low price. The reason is simply that when a razor has been sold, there is no further selling cost of consequence. Every user is a customer for blades without solicitation.

GENERATING A LARGE WORM-WHEEL.

In the December, 1904, issue of MACHINERY was described a machine built by the Eberhardt Bros. Machine Co. of Newark, N. J., for cutting the teeth of worm-wheels to the proper form without the use of a hob. This machine is in daily use in this plant, having been built for custom work. While the principle on which it works was described in the article referred to, it may be worth while to explain it again in a few words.

Fig. 1 is a partial view showing a worm, A, meshing with a worm-wheel, B. The shape of the tooth of the worm-wheel should be the same as would be given to it by the worm if the wheel were made of some plastic material, like clay or wax,

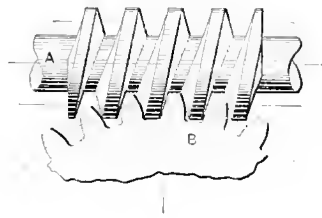


Fig. 1. Section of Worm-wheel Meshing with Worm.

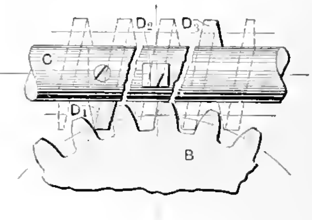

Machinery N. Y.

Fig. 2. Helical Path of Fly-tool for Cutting Worm-wheel shown in Fig 1.

and it were revolved with the worm at the proper rate. In usual practice this form is obtained by replacing the worm with a hob, having cutting teeth of the same shape as the worm threads, the hob being fed into the work with work and hob revolving at the proper speed. This hob has to have a multiplicity of teeth to give the same effect as that produced by the theoretical solid worm on the clay or wax wheel. The way in which this same correct shape can be formed with a single tool will be evident from Fig. 2. Here the worm of Fig. 1 shows in the dotted lines. D_1 is a tool held in boring bar C, with an outline exactly coinciding with the thread of the imaginary worm at the point where it is located. If the wheel B and boring bar C are revolved together continuously

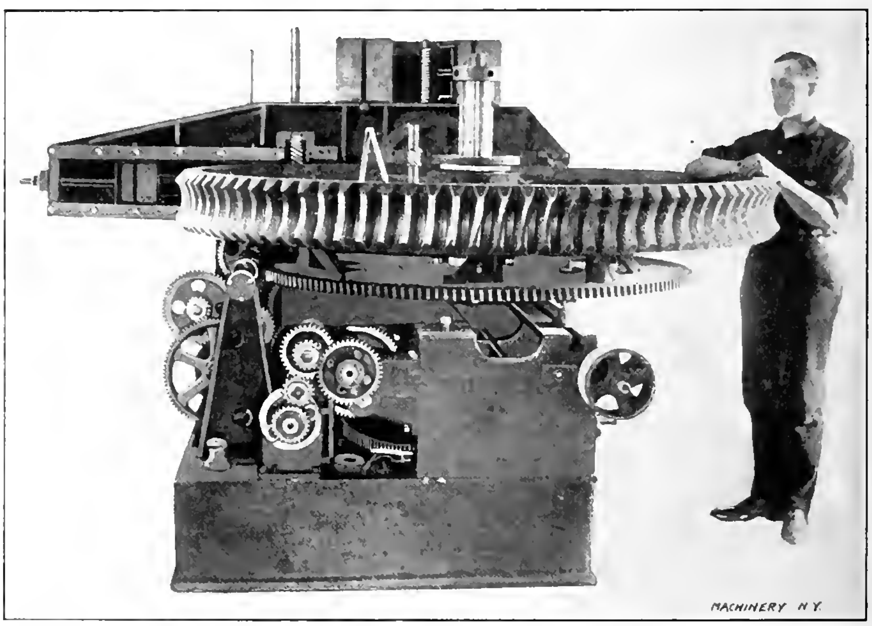

Fig. 3. Eberhardt Bros. Worm-gear Generating Machine, Involving the Principle shown in Fig. 2.

at the proper rate, with the tool in position D_1, it is evident that it will cut out in the wheel a suitable form for that portion of the worm with which it coincides. If the tool blade be shifted to D_2, and be rotated with the wheel as before, it will evidently at this point further shape the wheel to agree with the portion of the work with which it now coincides. The same may be said when the tool is shifted to D_3 or any other location in which it coincides with the thread of the worm. Evidently, in order to make the teeth which this tool cuts absolutely match the worm, it is only necessary to have it revolve with the work at the proper rate and be advanced meanwhile helically on the thread of the imaginary worm from one end of it to the other, so that it successively

coincides with every portion of the thread surface of the worm.

This is what is done in the machine shown in Fig. 3. The cross rail in the rear of the machine carries a boring bar with a single-bladed tool in it, shaped to match the outline of the worm which is to be used with the wheel. This spindle and the blank are revolved together. The tool meanwhile, starting to the left-hand end, is fed helically along in the direction of the thread of the worm which it represents. This movement is accomplished by a train of differential gears which shift the spindle endwise and give it at the same time a forward rotary motion, independently of the train of gearing connecting the spindle with the work arbor. For details as to this the reader should refer to the article previously mentioned.

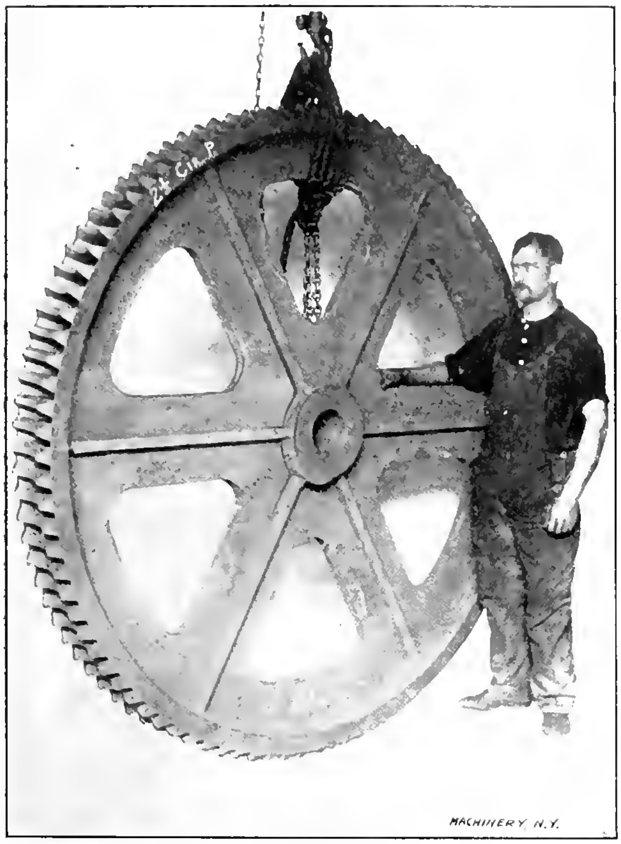

Fig. 4. The Completed Worm-gear.

The wheel shown in place in the machine in Fig. 3 and completed in Fig. 4 is believed to be the largest one ever made by this process, in this country at least. It has a pitch diameter of about 78 inches, with 98 teeth of 2½-inch circular pitch. It has a face 7½ inches wide, for a worm 10¾ inches outside diameter. The wheel blank weighs 3,150 pounds. It was made for a Western contracting firm, and is intended for some form of machinery used in the beet sugar industry.

For this large wheel, the work spindle is not rotated by the usual means provided for smaller ones; instead a face-plate drive is used. As shown, this face-plate has worm teeth formed on its periphery, and through these the rotary motion is transmitted to the work. Although this job is a large one, it does not tax the machine to the utmost, either in dimensional capacity or in driving power. As the other extreme of its range, a small worm-wheel shown standing upright on the rim of the work in Fig. 3, is interesting. This "wheel" is of the kind sometimes used for spindle drives in gear-cutting machines, in which the worm is considerably larger than its mate. This accounts for its peculiar appearance. These two parts together indicate the great range of usefulness which this process of cutting possesses, owing to the fact that the question of hobs is not the determining factor.

* * *

The parting sand used by the molder to prevent the sand in the cope and nowel sticking together is simply the burned sand scraped from the surface of castings.

FAULTS OF IRON CASTINGS.—1.

POINTS FOR THE MACHINE DESIGNER.

FORREST E. CARDULLO *

Forrest E. Cardullo.†

The most useful and indispensable of all the materials with which the designer has to do, is cast iron. Of all the metals used in the construction of machinery, it is the cheapest. It is the one to which we can the most readily give the form and proportions which we desire. It is, of all the common materials, the most easy to machine. While it is lacking in strength and ductility, its cheapness makes it possible to use it in such ample quantity as to overcome these disadvantages, and in many constructions it may be so shaped and proportioned, or so reinforced by other materials, as to make this lack but a slight detriment. It is therefore a matter of interest to the designer to learn of the various faults to which this valuable material is subject, and the best ways in which they can be avoided or minimized.

Causes of Blow-holes.

Probably the one fault which spoils more castings than any other, is the result of an outrush of gas from the materials of the cores or the mold, into the molten iron, at the instant of solidification. If the solidification of the iron has proceeded so far that the outrushing gas or steam cannot bubble through it, and escape through the vents which should be provided for the purpose, it will be imprisoned in the substance of the casting, forming one or more holes, according to the special shape of the casting, and the quantity of the escaping gas. These holes, which are known as blow-holes, may not be apparent on the outside, and quite often occur in such a location that they do no particular harm, but it is more often the case that they occur at some point where they become apparent when the metal is being cleaned, or where their presence weakens the casting greatly.

Steam from Moisture in Sand.

The gases which cause blow-holes may come from three sources. They may be, and generally are, caused by the generation of quantities of steam from the moisture contained in the molding sand, by the heat of the iron. In the case of dry sand and loam castings, the quantity of steam so generated is so insignificant, if the molds have been properly heated, that it gives no trouble whatever. In the case of green sand castings, however, the moisture present, and therefore the steam generated, is quite large in amount, and special precautions have to be taken to prevent blow-holes.

When the molten iron pours into a green sand mold, all the moisture in the layer of sand immediately in contact with the iron will at once be transformed into steam. The depth of the sand layer so affected depends on the thickness and extent of the fiery mass to which it is adjacent. The steam so formed must either force its way through the molten iron in the form of a mass of bubbles, or else it must escape through the sand. To facilitate its escape, the mold is vented. That is, after the damp sand has been packed around the wooden pattern by ramming it closely into place, a wire is thrust repeatedly into the mold, making numerous passages for the escape of the steam and gas.

* Address: Syracuse University, Syracuse, N. Y.

† Forrest E. Cardullo was born in Buffalo, N. Y., 1879. After completing a high school course, he attended Cornell University, receiving the degree of M. E. in 1901. He then served an apprenticeship with the Titusville Iron Co., and has since been employed by the Osborn Engineering Co., Cleveland; The Engineer Publishing Co., Chicago; the Holly Mfg. Co., Buffalo; and the Snow Steam Pump Works, also of Buffalo. His positions have been those of machinist, draftsman and designer, and he is at present instructor in machine design at Syracuse University, Syracuse, N. Y. His specialty is high power steam and gas engines and heavy machine tools. Mr Cardullo has been a frequent contributor to the technical press.

It is obviously impossible that one of these vent-holes should extend to every point in the layer of sand adjacent to the casting, so it is necessary that the most of the steam and gas should force its way for some small distance through the sand, before it can reach a vent-hole. This it can only do when the sand is somewhat porous. If the sand is too tightly rammed, it will lack the necessary porosity, and even though it be unusually dry, and the venting carefully done, the casting will be full of blow-holes. I have known of cases where molds have been rammed so hard that the castings were nothing better than shells, the whole interior being a mass of blow-holes.

Decomposition of Binder in Cores and Entrapping of Air.

The second cause of blow-holes in iron castings is the decomposition of the material, generally flour or molasses, used as a binder in preparing the cores, and its escape in the form of gas, into the iron, at the instant of pouring. It is impossible to prepare and bake a core in such a way that it will not give off large quantities of gas when the iron is poured, and so means must be provided for the escape of this gas. In order to do this, the cores are prepared with wax strips running through them. When the core is baked, the wax melts, leaving passages for the escape of these gases, known as core vents. If the core is of such form, and so set in the mold, that the gases can escape from these vents in an upward or sidewise direction, and leave the mold without forcing their way through the molten iron, no blow-holes will result.

A third source of blow-holes is the entrapping of air in certain parts of the mold, and its mixing, on expansion, with the iron. This trouble is due to insufficient venting of the mold, and is not a fault to which the designer need pay any particular attention.

Dry Sand or Loam Advisable for Large Complicated Castings.

In the case of large and complicated castings, it is generally advisable to make dry sand or loam castings, in order to avoid, as far as possible, the chance of blow-holes. When the mold is very large, it is difficult to vent it thoroughly, and when the work on it extends over a period of three or four weeks, it is impossible to keep the vents from filling up; hence the general use of dry sand work for large castings. Often, however, for the sake of economy, fairly large and complicated pieces must be undertaken in green sand, and it becomes a matter of importance that they be so designed that the molder will not be compelled to invite disaster by keeping his sand too wet, or ramming it too hard, and that there is no part of the mold which may not be thoroughly vented.

Elements of Green Sand Molding.

In order that we may understand thoroughly the effect of the design of a casting on the probability of blow-holes, it is necessary that we review in a brief way, the elements of green sand molding. The sand is sprinkled with water, and thoroughly mixed and sifted, preparatory to packing, or "ramming" it around the pattern. The object of wetting the sand is of course to cause it to stick together when it is packed. Up to a certain point, the wetter it is, the better it will stick, but the molder should not wet it any more than is necessary. In the same way, the more tightly the sand is rammed, the better its particles will cohere, and the more easily will the mold be handled, and the pattern drawn. However, tight ramming and wet sand, while they make a solid and easily handled mold, invariably produce blow-holes, and are therefore to be avoided.

It will be apparent then, that if a pattern be of complicated form, or hard to draw, or if when it is drawn it leaves the sand in such a form that the mold will easily fall together at a little jarring, the molder will be compelled to wet the sand more, and to ram it harder than usual. Small deep openings, sharp fillets, and thin walls and partitions of sand, are especially troublesome. Not only do they make it difficult to draw the pattern, and handle the mold, and so make excessive wetting, and hard ramming imperative, but they make spots in the mold which the venting wire is unlikely to reach. For these reasons, they are to be avoided when possible, in any class of molding, whether it be green sand, dry sand, or loam work, and on no account should such work be permitted in the case of large green sand castings.

When designing a casting to be made in green sand, the designer ought to know the position which it will occupy in the mold, when it is poured. In general, the parts of a casting which lie in the bottom of the mold will be the soundest, and those parts which must be machined, or which require the greatest strength, should therefore occupy the bottom of the mold, if possible, when the casting is poured. Having decided which side will be down, the designer needs generally to pay no particular attention to the configuration of the lower part of the mold, provided only that all of the pattern can be drawn, and that there are no sand partitions which overhang, or whose extent is large in proportion to their thickness. To insure a sound casting, the sand in the lower parts of the mold must be comparatively dry, and loosely rammed. This condition of affairs is not generally hard to attain, since all the work on the sand is done with the pattern in place, and that part of the mold is not generally moved or handled after the support of the pattern has been withdrawn. In the lower part of the mold, the sand is generally supported at all points in a very thorough manner by the sand lying under it, and so hard ramming or wet sand is unnecessary. If, however, the pattern must be made with loose pieces, or with sharp fillets, or must leave thin walls or tongues of sand when it is withdrawn, the case is changed. Then hard ramming and wet sand are almost compulsory, and the molder is not to be blamed if he does not produce sound green sand castings. The fault is with the designer.

The upper part of the mold must of necessity be rammed harder than the lower part, since the sand is not supported from beneath, but hangs from above. This is not as great a disadvantage as it might seem to be at first sight, since the escaping gases do not have to make their way through the iron, as they would if they were given off by the sand in the lower part of the mold. The venting, however, must be just as thorough, and it is desirable that the sand should be as dry as possible. The whole arrangement of the upper part of the casting should be such that the sand may be well supported from above. Generously rounded fillets and corners, simple surfaces, plenty of "draft," and an absence of depending walls and masses of sand, make the mold easy to handle, and therefore promote freedom from blow-holes.

When Green Sand and Dry Sand Both may be Used.

It often occurs that the larger part of a casting is of simple form, and easy to mold. A certain part of it, however, may be of a form exceedingly difficult to mold, and therefore likely to give a good deal of trouble. It is not necessary that the whole casting should be made in a dry sand mold, but a core-box may be made to take care of the difficult part of the work, even though the work would ordinarily be done without a core. It is just as easy, and often just as desirable to cast the external face of a casting against a core, as the internal face. While it may not pay to do this if only one casting is wanted, if a great many are wanted, it is often the cheapest possible way of making them, and reduces to a minimum both the work of the molder and the chance of a spoiled casting. Often forms may be cast in this way which could not be attempted in any other. If it is desirable to use this method of working, the designer has it in his power to make the construction of the core-box much simpler and cheaper than it might otherwise be, by giving the matter a little thought.

Support of Cores.

In arranging the coring of a mold, it is always better, if possible, to support the cores at the top. The gases formed in the core, being light, tend to rise, and if the core is supported at the bottom only, they tend to escape into the iron, and to bubble through it. If they can escape at the top, they will pass off without coming in contact with the iron. When it is impossible to support the cores at the top, they should be so arranged that the gases can pass off at the sides, and escape from the mold without coming in contact with the iron.

CUTTING BEVEL GEARS WITH A ROTARY CUTTER.*

H. P. FAIRFIELD.†

Pictures are a great help in understanding a machine shop operation. It is often possible, with a few half tones, to convey ideas that would require many pages of written matter to express them. In the following article advantage has been taken of this facility of the photograph to express ideas, so that a long story has been told in comparatively few words.

While the process of forming the teeth of a bevel gear by milling them with a rotary cutter, is not easy to describe without telling how to make a drawing of the blank, it seems best to leave the designing and drawing for another article. The average apprentice approaches the problems of the machine shop with hardly enough knowledge of the art of making drawings to enable him to read them, to say nothing of making them. It is to be hoped that the day will come when a boy may be given an opportunity to master some things of both sides of his life work.

The Drawing.

Fig. 5 represents the drawing of a bevel gear and its pinion, as it is given to the workman. It is to be noted that draftsmen are not all bound by the same conventions, but this drawing is as it would be made by at least one large firm who cuts many bevel gears. All dimensions other than those necessary to our description have been omitted to avoid confusion. The description will, therefore, be confined to those operations bearing upon the subject at hand, and will show what, in the writer's estimation, should be the best order of operation to insure accuracy, convenience, and speed. In machining the blank to the required angles and dimensions, use is made of an engine lathe fitted with a compound toolslide, and the tooth cutting operations are made in a milling machine fitted with a universal index head, with graduated dials on its feed screws.

In the drawing Fig. 5 are figured the angles needed to shape up the blank, and those needed when cutting the teeth. Those angles which are to be worked out in the lathe, using the compound slide, are figured from the line normal to, or at right angles to, the center line of the blank. Figured in this way, they conform to the graduations on the compound slide of the lathe, and all calculations by the workman in the shop are avoided. The cutting angle is figured from the center line to conform with the graduations upon the milling machine. The diameter of the gear, as drawn, is 6.18 inches, and operation No. 1 is to size the blank to this diameter. While some draftsmen in bevel gear work give the outside diameter to thousandths of an inch, the nearest hundredth is sufficiently accurate.

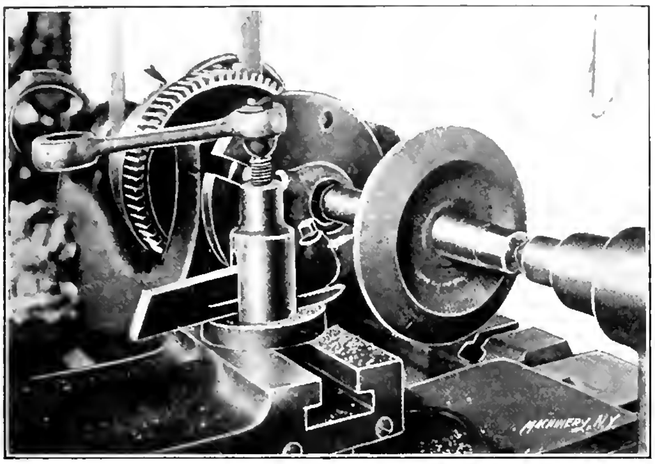

Fig. 1. Sizing the Outside Diameter of the Blank.

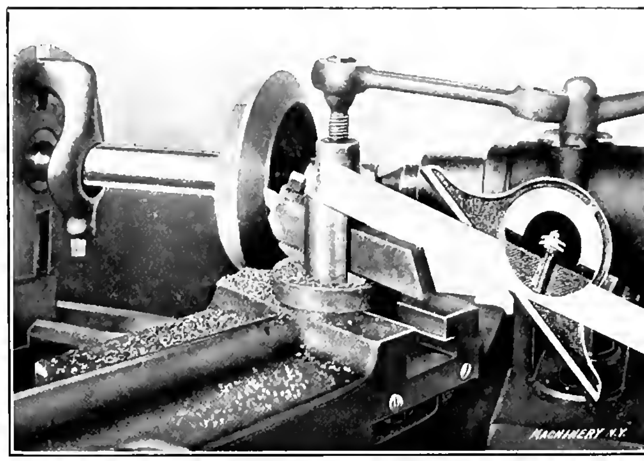

Fig. 2. Turning the Face.

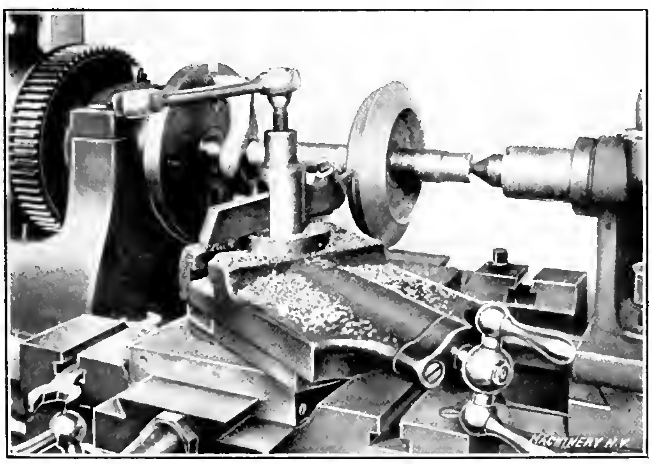

Fig. 3. Turning the Outer Edge.

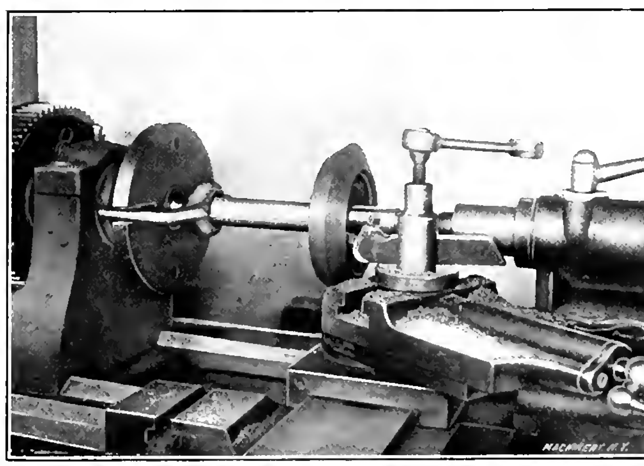

Fig. 4. Turning the Inner Edge of the Teeth.

Turning the Blank.

Fig. 1 shows operation No. 1, sizing the outside diameter, which leaves a flat surface easy to caliper.

Operation No. 2, shown in Fig. 2, is the turning of the face angle. As figured on the drawing, this angle is 31 degrees, and the compound slide, as shown in the cut, is set to conform to this. In setting the slide, the nearest quarter degree is all that is needed. A sufficient amount of stock is removed by this operation to leave a well finished surface for the tops of the teeth.

Fig. 3 shows operation No. 3, which is the forming of the back angle, or angle of edge. As figured, this is 56 degrees 20 minutes, and the compound rest is reset to read to the required angle. In this operation, sufficient stock is removed to bring this surface up to an edge with the one previously formed. Note that in all the operations the tool is adjusted normal to the surface operated on, to obtain the maximum cutting efficiency.

* The following articles relating to the calculation and cutting of bevel gears have been previously published in MACHINERY: Cutting Bevel Gears with Correct Teeth, and Cutting Bevel Gears, June, 1898; Gearing, March, 1902; Proportion of Gears, May, 1903, engineering edition; Use of Diagrams and Tables for the Solution of Problems in Gearing, March, 1904, engineering edition; An Automatic Gear Cutting Machine, July, 1905; Bevel Gear Chart, September, 1905; To Calculate the Center Angles of a Pair of Bevel Gears, having their axes at other than Right Angles, June, 1906; Bevel Gear Formulas, May, 1907, engineering edition.

† Instructor in machine construction and shop practice, Worcester Polytechnic Institute. Address: 25 John St., Worcester, Mass.

Fig. 4 shows operation No. 4, the finishing of the inner ends of the teeth. As these are parallel to the outer ends, the compound slide remains as set for operation No. 3. Sufficient stock is removed to make the teeth of the required length as figured (that is, 1¼ inch), and an ordinary steel rule obtains this measurement with sufficient accuracy. Filing or scraping the surfaces puts the blank in readiness, so far as the teeth are concerned, for the milling operations. If the performed operations have been done on a reliable lathe, and care has been taken in reading the figures on the drawing and the graduations on the compound slide, the blank must agree with the drawing. It is well, however, to check the angles with a protractor, and Fig. 6 shows this. While the blank and the tool would ordinarily be held in the hands when making this test, for convenience in photographing they are placed as shown.

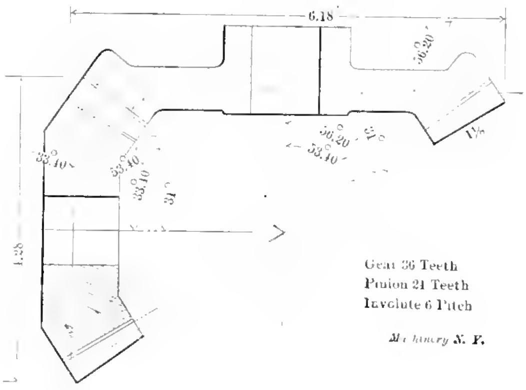

Fig. 5. Essential Dimensions of the Gear to be Cut.

With the drawing figured as shown, and the operations followed as numbered, it will be noted that so far the greatest simplicity has resulted in the setting of the machine and in the measurements made.

Selecting the Cuttter.

The tooth cutting operations are made in the milling machine, but the points to be brought out will apply to gear-cutting machines as well, with slight modifications due to the different mechanism. There are in use at least four different methods by which the machines may be used to form the teeth, and as all bevel gears cut with a rotary cutter must be in error, some latitude as to means can be allowed the workman. For the pair of gears shown, the diametral pitch at the large end of the tooth is 6, since the gear has 36 teeth or 6 teeth for each inch of the largest pitch diameter. At the inner end of the gear the pitch diameter is much less. The number of teeth is the same, however, and thus the pitch is finer; or, in other words, there are a greater number of teeth per inch of pitch diameter. Suppose, for example, that the pitch diameter at the inner end of the teeth is four inches, the number of teeth per inch would be nine, and the pitch is therefore nine, or, as it is commonly written, 9 P.

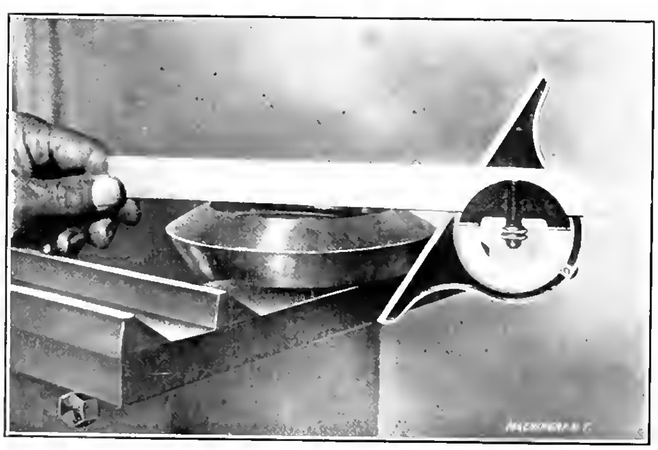

Fig. 6. Testing the Accuracy of the Angles.

In choosing a cutter with which to form the teeth, it will thus be seen that if it is the right pitch for one end of the teeth, it must be in error for the other, and it is for this reason that all bevel gear teeth cut by milling are at the best a compromise for the true shape. As noted above, there are four methods of compromising, but the one chosen for illustration is that usually termed the "rolling method," meaning that the gear is rolled to and fro for adjustment with the cutter.

To choose a cutter for spur gear cutting, the pitch and number of teeth being given, is a simple matter if Table I,

TABLE I. RANGE OF CUTTERS IN STANDARD INVOLUTE SERIES.

No. 1	will cut wheels from	135 teeth	to a rack.	
" 2	" "	55 "	134 teeth.	
" 3	" "	35 "	54 "	
" 4	" "	26 "	34 "	
" 5	" "	21 "	25 "	
" 6	" "	17 "	20 "	
" 7	" "	14 "	16 "	
" 8	" "	12 "	13 "	

taken from the catalogue of the Brown & Sharpe Mfg. Co., is used. To choose a cutter for milling bevel gears, however, the method given below, and illustrated in the diagram, Fig. 7, is used. Instead, then, of taking a cutter for the number of teeth which you wish to cut, it may have to be for a much larger number. While this rule is not universally followed and has its limitations, it covers most cases better than any other with which the writer is familiar, and a cutter chosen by this method is the correct curvature for the teeth at the extreme large end, though it cannot have the right curve, for the rest of the tooth. It must, also, be so

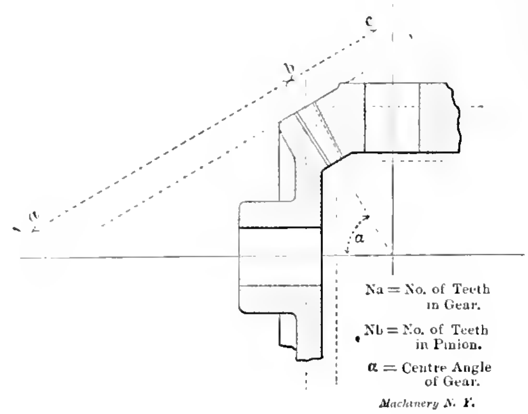

Fig. 7. Diagram showing Method of Selecting Cutters for Bevel Gears.

chosen as to be at least as thin as the width of space at the inner end of the teeth. This makes it necessary to use special cutters, somewhat thinner at the pitch line than those used for spur gears.

Measuring the dimension in the drawing, Fig. 5, which corresponds to the line *a b*, Fig. 7, and doubling it, gives a length of 10¾ inches, nearly. This dimension is not indicated in Fig. 5. Multiplying this by the pitch, makes the number of teeth for which the cutter must be chosen, sixty-four plus. In Table I, a No. 2 cutter is listed to cut from 55 to 134 teeth, and is the one selected. When it is inconvenient to measure the back cone radius, use is made of the following formulas, taken from Brown & Sharpe Mfg. Co.'s catalogue.

$$\text{Tan } a = \frac{N_a}{N_b} \qquad (1)$$

$$\text{No. of teeth to select cutter for gear} = \frac{N_a}{\cos a} \qquad (2)$$

$$\text{No. of teeth to select cutter for pinion} = \frac{N_b}{\sin a} \qquad (3)$$

If the gears are miters, or alike, only one cutter is needed. If one is larger than the other two cutters may be needed.

Setting Up the Work for Trial Cuts.

The cutting angle of the gear is 53 degrees 40 minutes, figured from the center line of the gear, which corresponds to the center line of the index centers. The center head is therefore swiveled in the vertical plane to the position shown in Fig. 8, or through an arc of 53 degrees 40 minutes by the graduations. The cutter is placed in cutting position upon

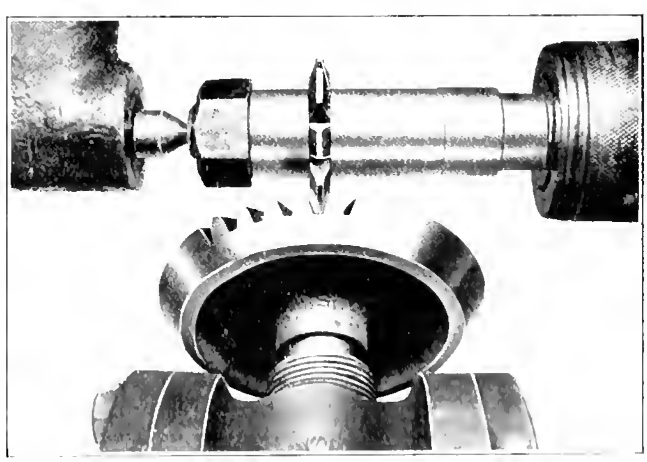

Fig 15. Cutter Completing the Tooth, showing Widened Tooth Space

the milling machine arbor, which must run true. Fig. 9 shows how the cutter and the index center are brought into alignment by adjusting the cross slide. Most makes of cutters have a center line scribed on the tops of the teeth, or on the back face, to set the center to in making this adjustment. Be sure that the center runs true. It is best to try it with a test indicator. The gear blank, as shown in Fig. 10, is mounted firmly on a special true-running arbor, with a taper shank to fit the index head.

Fig. 8 also shows the index pin and adjustable sector set for spacing thirty-six teeth on the blank. Although use can be made of the printed table which comes with the milling machine to learn the turns and parts of turns to make when

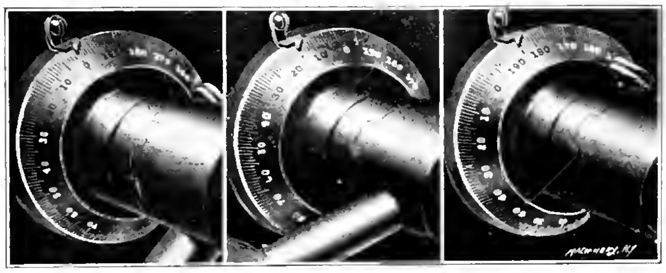

Fig. 16. Cross-feed Dial when Work Spindle is Set Central. Fig. 17. Cross-feed Dial Set for Cutting Outer Side of Tooth. Fig. 18. Cross-feed Dial Set for Cutting Inner Side of Tooth.

indexing, a very simple calculation gives it, when the number of revolutions which must be made with the index pin to give the work a complete turn is known. In most milling machine index heads, this number is 40, as they have a 40-toothed worm gear and a single-thread worm; 40, then, is the numerator of a fraction, the denominator of which is the required spacing; or, in other words, dividing forty by the number of spaces required gives the number of turns and parts of a turn of the index pin. In this case, $40/36 = 1\,4/36 = 1\,1/9$ revolutions, or one turn and one-ninth of a turn. Six holes in the 54-hole circle is taken to give the one-ninth of a turn required. Any circle of holes evenly divisible by nine, can, of course, be used.

With the blank set to the required cutting angle, the next step is to make a line on its back edge showing, as in Fig. 10, the depth of the teeth at this point. This is done with a "depth of gear tooth" gage of the proper pitch. Such gages may be bought in different sizes for different pitches. Be careful to hold it parallel to the back edge of the blank when scribing the line.

Fig. 11 shows the machine and work completely set up, and adjusted for the trial cut. This cut must not be so carelessly made as to be deeper than the tooth depth line marked out in Fig. 10, and several trial cuts, each deeper than the other, may well be made in getting the required depth for the first space.

Approximating the Correct Tooth-form by Rolling.

Fig. 12 shows the first space cut to depth. The work is then indexed for another cut. Fig. 13 shows the trial tooth left by the two trial or central cuts. It is noticeable that the tooth is much wider on the pitch line than it should be, at the outer end. This may also be true of the inner ends at the pitch lines, and is certain to be true of the inner ends above the pitch line when the gear is finished, unless this part of the tooth is afterward filed somewhat. The coarser the pitch and the longer the tooth face, the more this latter shows. The rolling method of approximating the true tooth shape starts by making several central cuts, such as shown in Fig. 14, giving teeth which may be used to test adjustments by as they are made. With the cross feed index set at zero, the table is moved off center *toward* the column of the machine a trial distance, and then clamped immovably. By means of the index pin, the work blank is rotated or "rolled" back toward the cutter again to just admit it to the space at the inner end of the teeth. Do not disturb the adjustable sector when doing this, but leave it to mark the hole which is correct for the central position.

Rolling the gear is equivalent to swivelling the tooth about the apex of the cone, and allows the cutter to take a heavier shaving or chip at the outer end of the tooth than it does at the inner end. The greater the adjustment off center and the more the blank is rolled, the greater this difference.

If, for example, the cutter leaves the trial teeth accurate in thickness at their inner ends, the blank would be rolled, when making adjustments, to allow the cutter to just enter the trial cut at that end without thinning the teeth. Exceptions to this will be noted further along.

After the trial cut has been taken upon one side of the tooth, the index pin and the cross slide should be returned to their original central position, and the blank indexed one tooth, to bring the cutter upon the side opposite to that already thinned off. Afterward set the cross slide off center *away* from the column and roll the blank toward the cutter again, the same amount as before, until the cutter just enters the space at the inner end. Thin off this side. If the larger end of the tooth is still too thick, it shows that the cross slide was not set off from its central position a great enough distance, and another trial cut must be made on each side of the tooth, carefully duplicating the operations just noted, but giving additional movement to the cross slide and the rolling of the blank, repeating this until the gage shows the right thickness at the outer end of the teeth as in Fig. 14. The gage shown is one of a form common in gear cutting practice. The notch in the end of it has a depth equal to the addendum, and a width equal to the tooth thickness, of the pitch for which it is intended—6 in this case.

As previously stated, all this has been done on the supposition that the thickness of the cut left the space and teeth at

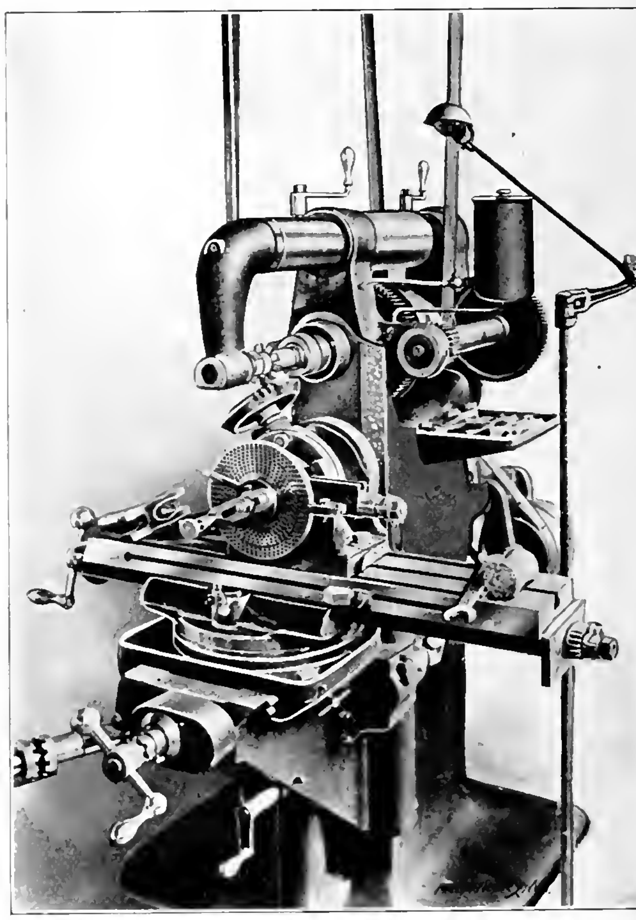

Fig. 19. General View of Machine as Arranged for Cutting Bevel Gear.

their inner ends the right width. If the cutter is too thin to do this, the teeth must be shaved on their sides at the smaller as well as at the larger ends. It is then necessary to observe that neither end is cut too narrow, and the cross-slide adjustments, as well as the rolling of the blank, must allow for shaving the tooth its entire length.

In the gear shown, the cutter was considerably thinner, and the tooth was shaved its entire length. In making the trial cut, the cross slide was offset 0.010 inch, and the blank rolled four holes in the 54-hole circle, and the trial tooth shaved upon both its sides. These amounts were afterward increased to an offset of the cross slide to 0.015 inch each side of the zero line and seven holes in the 54-hole circle. This gave a

tooth that gaged up as desired at its inner and outer ends on the pitch line.

If the teeth of the pinion are not to be filed at their inner end above the pitch line to bring that portion of the tooth more nearly to shape than the cutter will leave it, it may be necessary to widen the space at the inner ends of the gear to give additional room. On the finer pitches, the cutter leaves the teeth so nearly correct that they need not be filed; but in the coarser pitches, filing is quite necessary.

Cutting the Teeth.

Having established the amount off center, and the angle to roll the blank, proceed to cut the rest of the teeth. If the pitch is rather coarse, three cuts may be necessary all the way around each blank. In the finer pitches, however, two cuts around are sufficient. In the case of three cuts, the first is a central cut made as already shown, with the standard cutter, all the way around, and then the two thinning cuts follow. Some gear-makers use a so-called "stocking cutter" in making the central cuts, afterward thinning the teeth with a standard cutter as noted. This undoubtedly leads to less sharpening of the standard, and therefore, less wear.

If the pitch allows two cuts around the blank to be sufficient, the first is, of course, made with the table offset and the work rolled to shape one side of the teeth, and the second, with the machine and work set to shape the opposite side, each cut going all around the blank.

Figs. 16, 17 and 18 show the cross-feed screw index dial, as adjusted for the central cuts, and afterward the thinning cuts.

Fig. 15 shows the amount that the space is wider than the cutting edge of the cutter; and Fig. 19 is a general view of the entire machine as set up.

General Directions.

In closing, it may be well to note some precautions: Mounting the work as shown, with all "overhangs" as short as possible, still leaves the outer end unsupported. Care must therefore be taken to have the taper arbor in the index head well fitted and driven firmly in place; the work must also be mounted upon the outer end of the arbor so that it will not slip under the action of the cutter.

The cutter must be carefully ground sharp, with each cutting edge radial and exact, relative to the center hole. The cutter must also be in coincidence with the center line of the index centers or the teeth will "hook," relative to the apex of the cone as well as to the radius.

In making adjustments of the cross-slide or with the index pin, see that the final motions are always in the same directions. This prevents errors of adjustment due to lost motion or backlash. For example, in Fig. 17 the zero setting was made by moving the cross-feed handle to the right until the dial read to the zero mark. That shown in Fig. 18 was a continuation of this motion, and in Fig. 19 the handle was reversed at least a half revolution, and then turned in a right-hand direction to the required graduation. All milling machines and index heads are provided with means of clamping the several slides and swivels, and these should always be tightened while the cut is being made, and, of course, loosened when adjusting. After the indexing for a cut, place the counting sector in readiness, as shown in the cuts, for the next adjustment.

In turning up the blanks, machine an extra one to use as a "dummy" for setting the machine. This dummy may be used until cut up. Finally, settle upon a regular order of operations, follow it until a habit is formed, and fewer errors will result.

* * *

Prof. Battle, of London, stated in the course of a recent lecture that it is believed that American roller press flour is a prime cause of the great increase of appendicitis noted since its introduction throughout the world. He claims that particles of iron are found in the appendix concretions, etc. Unfortunately for Prof. Battle's theory, machinists show no greater susceptibility to appendicitis than people engaged in other occupations, and surely the machinist swallows a much larger quantity of iron dust every day, while in the machine shop, than he ever gets in the bread he eats.

EXAMINING AND TESTING FILES.*

OSCAR E. PERRIGO.†

In discussing the question of files and their qualities, it may not be out of place, and it should certainly be of interest, to consider briefly the properties of files in general, and more particularly, the characteristics of good files.

While a file is one of the oldest and most ordinary tools of the mechanic, and one with which every machinist is supposed to be perfectly familiar, it is yet the one tool about which the average machinist knows the least, when the fundamental principles of its construction and operation are considered, and with which he is usually less efficient than with almost any tool he uses. In former years this last condition did not exist in nearly as great a degree as at present, for the reason that hand tools were used to a far greater extent. Apprentices were early taught their proper use, and in time became very expert and efficient, particularly with the cold chisel and hammer and the file. It has been well said that "the range of usefulness of a good file is only limited by the skill and efficiency of the operator."

Although the file is one of the oldest tools, it is one whose simple design and primitive construction has seemed to defy all attempts to improve it, except in the form of its teeth

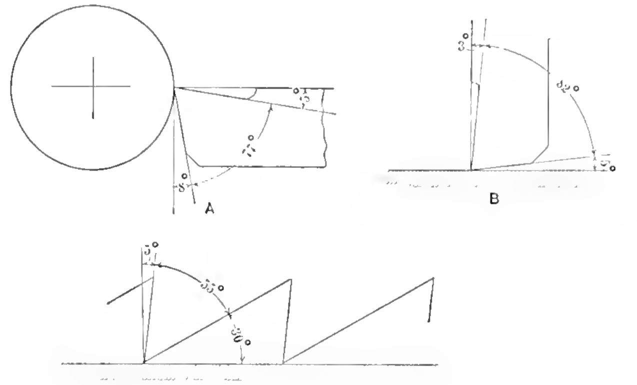

Fig. 1. Cutting Angles of Planer Tool, Lathe Tool and File.

and the methods of its manufacture. Machines have been invented to do much of the work of file-making, which was formerly performed by hand, but still many thousands of files are annually made by the same primitive hand methods that were used hundreds of years ago—the cold chisel and hand hammer. In fact the file that is mentioned in the Bible (1st. Sam. 13 : 21) was probably made in substantially the same manner.

Characteristics of the File.

The file, like many other tools, has three distinct and important characteristics, which demand attention of the manufacturer, the buyer and the user, if quality is to be taken into account, namely: first, the quality of the steel of which it is made; second, the form of its teeth, no matter whether cut by machine or by hand; and third, the temper, no matter by what process it has been hardened.

The first of these questions, the quality, and hence the price, of the steel used, should cut as little figure in producing a really good file as in producing any other good tool. Yet there is more than a suspicion, from the most casual and superficial test, that there is a great deal of poor steel used in the manufacture of files.

The form of the teeth, as will presently be shown, may vary considerably in different specimens, or they may appear in an ordinary examination to be very nearly alike, but when it is considered how little variation there may be between the teeth of a good file and those of a comparatively worthless one, this point assumes much importance.

The tempering of files is another process in which much ingenuity and study may be profitably employed. A good process, properly applied, may almost save a poorly made file and produce a fairly efficient one, while a poor or defective process, or one inefficiently handled, will ruin a file

* For further information regarding testing of files, see MACHINERY, February, 1898, The File and Filing; March, 1898, The Bite of a File.

† Address: 151 Lynnfield St., Peabody, Mass.

of excellent material and, so far, of good workmanship. The tempering should be so performed as to produce *hard*, and at the same time *tough*, teeth, and as nearly as possible *uniformity* of temper over the entire surface of the file, from heel to point.

The essential features and characteristics of files, to which it is advisable to give attention, in a systematic examination and practical test of files of different lengths, forms and cuts, will now be taken up in regular order.

Correctness of Form of File Blanks.

With the exception of the edges of such files as are called "hand, or pottance," "equalling," "pillar," and a few special forms, having the same width through their entire length, there should be no absolutely straight lines lengthwise of a file. All these lines should be convex. The amount of this convexity on the sides of well-made flat, square, round and taper (triangular) files, is substantially 0.08 inch per foot, that is, a six-inch straight-edge placed on the file and touching it at the center will show a space of 0.02 inch open at each end. On the edges of such shapes as half round, crossing, knife, etc., this convexity will be about twice this amount. Special curved files are, of course, excepted. Distortion from these limits should be observed, and files having concave lines, short bends, etc., should be rejected, except when they are to be used on very ordinary or rough work.

Transverse surfaces, nominally flat, should be very slightly convex, more nearly straight on fine cut files than the ordinary kinds. Those having concave surfaces should be rejected.

Surfaces which should be the arc of a circle, such as half round, crossing, round, etc., may be tested for correct form by laying them into drilled holes of various diameters in a thin plate of iron or steel. It will be found that a cheaply made file will hardly ever conform to a true arc, but is liable to have flat places on its surface, which, when in use will not come into proper contact with the work.

Triangular files may be tested for form with a 60-degree thread or center gage, and the corners of square and flat files with a thin steel square.

It will be surprising to note the many inaccuracies that will be brought out by these tests.

Not only the *form*, but the *finish* of blanks should be examined. It will usually be found that American-made files have a finish much superior to that of imported files, in which will be found deep scratches and furrows that detract not only from the appearance, but the efficiency of the file, particularly of the finer qualities.

The blank must not only be *thoroughly* annealed, but it must be *evenly* annealed. If there are hard and soft spots, it is evident that, in the cutting, the chisel will sink deeper in the soft than in the harder portions, thus making an uneven cut and a file comparatively worthless, for good work.

Correctness and Uniformity of Teeth.

The variation in the number of teeth on the different sizes, shapes and cuts, as well as on files of different manufacturers, is very considerable, ranging in files of 14 inches long and shorter, from 20 to over 200 per inch. On ordinary machinist's files, made in this country, the following is a fair average, *viz.*:—bastard cut from 20 to 25 per inch; second cut, 30 to 40; smooth, 50 to 60; dead smooth, 70 to 80.

Of the finer files, whose grade of cutting is indicated by numbers, the Grobet Swiss Files are as follows: No. 0, 40 to 70 teeth per inch; No. 1, 75 to 88; No. 2, 58 to 104; No. 3, 100 to 130; No. 4, 120 to 160; No. 6, 200 to 220.

Of the American made files of similar shapes and sizes as the Grobet files: No. 0, 35 to 60; No. 1, 55 to 75; No. 2, 80 to 95; No. 3, 90 to 120; No. 4, 125 to 135; No. 6, 160 to 200. It will be noticed that there is more regularity in the American system of numbers than the foreign. There is yet room for an improvement, similar to that made in this country in the old time wire gages.

The form of the teeth is a matter of much importance. If we analyze the form and action of a file tooth, we find it to be a straight knife or cutter as, for instance, a broad lathe or planer tool, whose face angle (or top rake) and whose cutting angle (or relief) will determine the amount of pressure necessary to cause it to cut, and which frequently (in the planer tool) has its line of cut set at an angle to the line of motion (as a file tooth), to cause it to cut easier and smoother. If this cutting edge is very thin and sharp, it is evident that the necessary pressure is very much reduced, while it may be so thick and with so little relief as to slide over the work, even under greatly increased pressure.

In the case of the file we have a large number of similar cutting edges, and consequently a proportionately large increase of pressure necessary to produce the desired effect. For this reason, and from the fact that the available pressure is greatly limited, the cutting edges must be comparatively thin and sharp, and the cutting angle (or relief) must be very acute. For instance, in Fig. 1, at *A*, is shown the proper angles for a lathe tool, and at *B*, those for a planer tool.

At *C* are given the ideal angles for file teeth. While these file teeth angles are desirable and would make an excellent file, they are not practically attainable mechanically. If the teeth of files were formed by a tool traveling parallel to their cutting edges we might produce any angle desired. But this is not practical. The teeth are formed with a rather obtuse angled chisel, which raises a portion of the metal above the surface being cut, as well as makes a depression

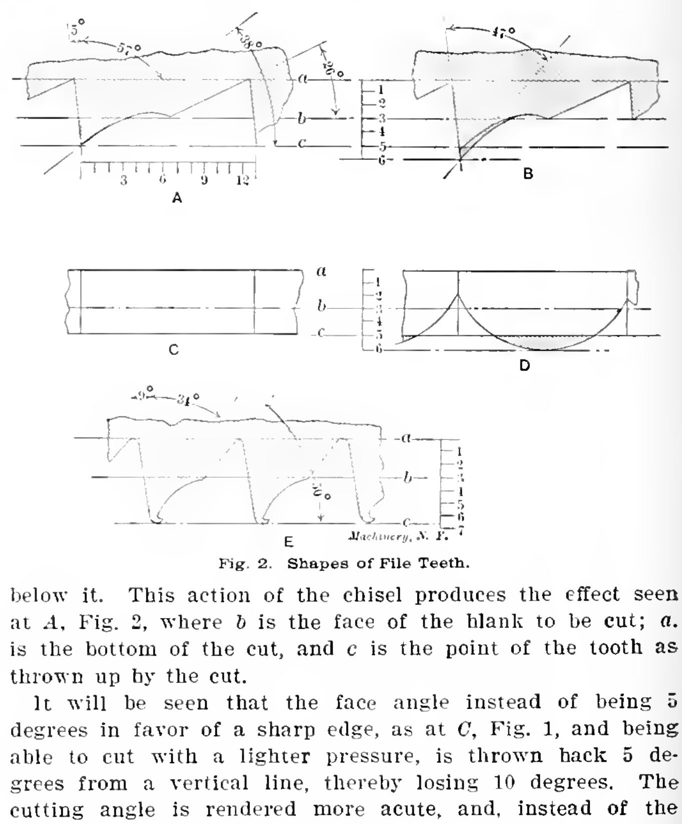

Fig. 2. Shapes of File Teeth.

below it. This action of the chisel produces the effect seen at *A*, Fig. 2, where *b* is the face of the blank to be cut; *a*. is the bottom of the cut, and *c* is the point of the tooth as thrown up by the cut.

It will be seen that the face angle instead of being 5 degrees in favor of a sharp edge, as at *C*, Fig. 1, and being able to cut with a lighter pressure, is thrown back 5 degrees from a vertical line, thereby losing 10 degrees. The cutting angle is rendered more acute, and, instead of the 30 degrees shown at *C*, Fig. 1, a tangent to the curve at the cutting edge shows 38 degrees, thus compensating to a considerable extent for the change of the face angle. At the same time, the angle of 55 degrees for the cutting edges, Fig. 1, becomes 62 degrees ($57 + 5 = 62$).

There is one other element that enters into this condition and modifies it considerably. This is the cross cutting of the file. It may here be remarked that many mechanics fall into the error of supposing that the cross cutting *follows* the regular cut, while in fact it preceeds it, as a strong magnifying glass will readily show.

The influence of this cross-cutting is shown at *B* and *D*, Fig. 2. At *B* the darker shaded portion of the section of the tooth is due to the cross-cutting and when seen from the front causes the tooth to assume the rounded form shown in section at *D*, while in a single cut file the edge of the tooth would appear as a straight line, as at *C*. The cutting edge of a cross-cut file is quite thin, the angle being changed from 62 to 47 degrees, and it is this delicate but very useful, keen, edge that is soon lost by rough usage and too

much pressure on a new file, or by careless handling, allowing files to come into direct contact with each other. It is the custom with many manufacturers to reduce these sharp edges or points somewhat, either by a fine file or emery stick, or similar means before tempering, or by a sand blast in the cleaning process after tempering. One reason for doing this is that these fine points are not all of the same height and therefore give the file a tendency to "scratch" when first used. This is avoided by levelling them down. The better process is to use pulverized clay instead of sand in the cleaning blast.

At *E*, Fig. 2, is shown a cross-section of the teeth of a poorly cut file. In this case the angle of the edge of the cutting chisel is too acute, the pitch of the teeth is too short, the blow too heavy, and the consequent result is that the extreme points of the teeth are turned over in a "burr" which, by the tempering process, will necessarily be much harder than the thicker parts of the tooth, and will soon break off, as may be seen by standing with ones back to the source of light, holding the file on a level with the eye and looking lengthwise of it from the point to the tang, the broken points of the teeth being seen as small glistening spots or fractures.

In examining and testing files the pitch and form of the teeth will call for much careful attention, as much may be learned from their characteristics when viewed through a magnifying glass, which should not be over a half inch focus.

Uniformity of Temper.

There are various simple methods of testing a file for uniformity of temper that will readily suggest themselves to a mechanic, the most common being with the end or corner of a smooth piece of steel hardened very hard and not drawn to temper. This may be rubbed or drawn for a short distance over the file teeth at various points on the surface of the file, and the results examined with the aid of the magnifying glass. To one accustomed to such work the results will be very conclusive, the points of the file teeth being distinctly bent over where the temper is too soft.

Durability on Metals of Different Degrees of Hardness.

If we were to establish a file testing plant it would probably include, as an important factor, a filing machine particularly designed for testing the durability of files on different metals. In this machine provision would be made for a reciprocating motion of the file to be tested; a device for feeding the end of the metal to be filed up to the file; and a recording apparatus which would indicate, by a curved line traced upon a ruled sheet of paper, the number of strokes of the file, the amount of metal cut away, etc.

A machine of this character was constructed and used in Manchester, England, and described by Mr. Edward G. Herbert, who records some valuable data as the result. He claims to have found that with English files there was a great difference in the efficiency of the two sides of these files, amounting in some cases to 30 to 1. Judging from the many cases of distortion of foreign, made files, their methods of tempering do not compare favorably with those in use in the United States, and this may account, to some extent at least, for such results. A difference in the efficiency of the two sides of a file has been often observed, but there is no record in this country of such results as Mr. Herbert has observed. Possibly it is for the reason that we can claim in file making as in many other mechanical processes, great improvements in the details of the work, and demonstrate in many respects the superiority of American products, including files.

In testing the durability of files by hand, comparative tests will, of course, have to be made by the same man, as no two men will handle a file exactly alike. Each file may be used for 500 strokes; then examined under the magnifying glass and the results noted. Then 500 strokes more, and again examined, noted, and so on until the file refuses to cut. The amount of metal filed away should be weighed carefully. These tests should be made on cast iron, wrought iron, soft steel, and steel hardened and drawn so that it will require a fairly good file to cut it at all.

By using pieces of half an inch square, containing one-quarter of a square inch area, and carefully measuring the length before and after each 500 strokes, the careful saving and weighing of the filings may be avoided. Either method may be rendered very instructive, exact and valuable.

Strength and Elasticity.

These two qualities may be tested at the same time. A convenient arrangement for holding files during these tests will be any kind of a vise with jaws in a horizontal instead of a vertical position.

These tests will consist essentially of clamping the tang in the vise and suspending known weights upon the point, noting the degree of flexibility for *elasticity*, and the weight necessary to finally break the file to ascertain the relative *strength*. A good file should bend to the extent of 5 degrees without breaking, and some will bend several degrees more. Those breaking at 2 degrees are too brittle for practical use. If long, slim files break at 3 degrees they should be rejected, as the workmen are likely to break them before they are half worn out.

This article has been prepared with a view to proposing only such methods as are easy of practical application, without any special or expensive apparatus being necessary.

RIFLED PIPE LINES FOR CONVEYING OIL.

A contract has been let by the Southern Pacific Company for the building of a rifled oil pipe line 256 miles long from oil properties in Kern County, in the southern part of California, to tide water on San Francisco Bay. An interesting feature of the line is the character of the pipe used, its "rifled" construction being a radical departure from that of lines now generally in use for conveying oil. Spiral indentations accomplished in the rolling of the pipe constitute the rifling. (See MACHINERY, February and July, 1906, engineering edition.) An exhaustive series of experiments has demonstrated that after a small per cent of water has been added to the oil, and the necessary pressure applied, that the whole will develop a whirling motion, and that the water being the heavier will seek the outside of the pipe, thereby enveloping the oil in a thin film or shell of water, this shell or film of water acting as a lubricant between the oil and the pipe, and thereby greatly reducing the friction and allowing the core of oil to glide through the pipe readily. Throughout the length of 256 miles of pipe there will be twenty-three pumping stations, the equipment of each station being in duplicate so that in the event of a breakage of any part of the machinery of one pump, the other may immediately be put into service. With the size of the pipe, which is 8 inches, and the high pressure carried, and improved facilities in every way, a rapid transmission of the oil has been shown to be possible, and it is estimated that at least 23,000 barrels of fuel oil can be delivered every twenty-four hours.

* * *

A POOR REASON WHY.

"The Creator made the ocean salt to save the land from putrefaction," etc.—*Marine Journal.*

This might be defined as an excellent example of reasoning that runs like a crab—backwards. The flora and fauna of the earth to-day are what they are because the conditions of environment, past and present, have been favorable to their development. If the ocean had been fresh there would have been, no doubt, an entirely different existing order of life, and then some would-be philosopher would have gravely remarked how fortunate it was that the ocean was fresh, etc. The author of the paragraph should take a half-hour course in the elements of world-making and evolution. He might as well assert that it is fortunate that the sun gives light or that rivers always flow through the valleys.

While the above is not precisely germane to the general character of MACHINERY, it was written for the purpose of emphasizing the need for clear thinking, which shall not confuse cause and effect. Perhaps in no business is it required more than in machine design and construction. The qualities that are required in the mental make-up of the designer enable him to quickly understand the absurdity of such reasoning as the above quotation, notwithstanding that many writers indulging in it have acquired some fame.

MAKING SWISS FILES IN AMERICA.—2.

In the September issue was published a description of the methods followed in the manufacture of files by the American Swiss File and Tool Co. of Elizabethport, N. J. Various operations were illustrated and described, leading from the cutting, forging and annealing of the stock, through the grinding and stripping operations, to the store-room, where the blanks await their turn to have the teeth formed on them.

The File-cutting Machines.

Those files which are to be machine cut are taken to the cutting room, located as shown in the plan Fig. 2. (See previous issue.) There was a noticeable absence of noise in this department, compared with what the writer has met with elsewhere; conversation was easily possible with everything going at full blast. Mr. Reichhelm attributes this freedom from noise to the care with which the foundations of the file-cutting machines were laid. They go down 2 feet below those of the building foundations. There is a row of these desired depth, and means for feeding a file blank past the chisel at such a rate of speed as to give the desired spacing of the tooth.

The machine shown is driven by the belt and pulley at *A*. A cam is keyed to the driving shaft which, through a lever, raises the ram in head *C* against the resistance of the India rubber spring *D*, and allows it to fall again freely. The chisel *E*, held in the end of the ram, is thus able to deal a series of very rapid blows on the blank beneath it, the shaft revolving at a high rate of speed, and the cam having several lobes or teeth. The work *F* is laid on a holder *G*, resting on the inclined bed of the machine. It is fed along under the chisel, being drawn by a plate *B*, which is clamped between friction rolls at *H*. These rolls are driven at a uniform rate of speed, through gears and belting, from the main shaft of the machine. No provision is made for varying the spacing in a file, the makers believing that there is no virtue in the "increment" cut, but that there is a decided advantage in having the file uniform from end to end.

Fig. 7. General View of the Cutting Department of the American Swies File and Tool Co.

monolithic bases extending the full length of each side of the cutting room. Only about one-third of the space reserved for these machines is as yet filled. Fig. 7 is a partial view of that side of the room in which the equipment of machines has been completed. The curtains shown hanging from brackets on the wall are used to prevent cross lights, at times when the sun is shining in such a way as to offer difficulties on this score. In order to see just what he is doing, it is necessary for the workman to have the light shining on his work from the front.

Three designs of file-cutting machines are in use in this room. There are the original machines with which the business was begun, made by an American firm, the Hess Machine Co. of Philadelphia; then there is a German machine of quite different construction; and in Fig. 8 is a picture of one of the latest machines which have been installed. This embodies the results of the firm's experience with the two previous types. A file-cutting machine provides, essentially, means for striking a series of rapid blows with a suitably formed chisel to any

The presser foot *J*, under the influence of a weight, follows the work just in front of the chisel and holds it firmly down to the holder *G*. The latter has a cylindrical bearing on a seat in the bed, so that on flat files the blank is free to adjust itself under the presser foot until the surface is parallel to the cutting edge of the chisel. In the case of half-round files, the holder is rocked by handle *K* to bring under the influence of the chisel any part of the surface desired. The distance between the work and the chisel may be altered by crank *M*, so the depth of cut may be varied at will. This is important, and much of the skill of the cutter lies in his adjustment for depth of cut. It is a vital requirement that the teeth be uniform from end to end. On a tapering file, such for instance as the flat side of a half round, a blow on the point of the file of the same force as that delivered in the middle section, where the blank is widest, would make so deep a cut as to almost sever the blank. The workman, then, in running from the point to the heel, starts in lightly, increasing the force of the blow by adjusting the crank *M* as

the width of the blank changes. The setting of the bed on an angle as shown, and the continuous feeding of the blank while the blows are being struck, has the effect of opening up the teeth as the chisel leaves each cut.

Etching of Teeth in Files.

Most mechanics are familiar with the idea of file-cutting with a chisel by hand or machine, but how many of them are aware of the fact that great quantities of the files they use are not made with the chisel at all, but by a grooving process somewhat akin to knurling, and known as "etching"? The workmen shown in Fig. 9 are employed in this work. The file

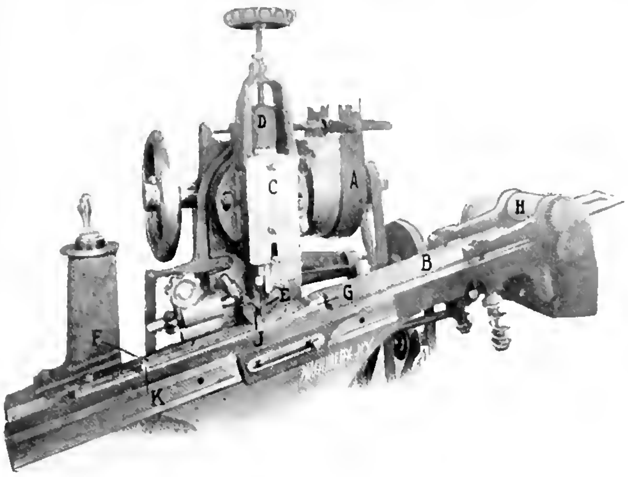

Fig. 8. File-cutting Machine.

being treated is laid in the holder as shown, where it is steadied and guided by the workman's left hand. With his right hand, by the handle which it grasps, he operates the etching tool attached to the swinging framework. This tool is a triangular bar with file teeth cut in each of its three edges. Any one of these edges may be presented to the work. The cutting of these teeth is an art in itself. They have to be made with uniform depth and regularity, since it is necessary for the teeth to "track" in the grooves previously cut in the work. The etching tool is simply swept back and forth across the work at the proper angle and with the proper degree of pressure, as determined by the foot of the operator

Fig. 9. Process of "Etching" Teeth on Files.

bearing down on the stirrup shown hanging from the handle. The teeth on the edge of the tool cut and trace out the grooves which are to form the teeth of the file. Simple as the process sounds, it requires a high degree of skill. No little training is necessary to give the steadiness of movement, evenness of pressure, and sureness of positioning needed. The process, as practiced here, is an improvement over that employed in Switzerland, where two operators are required, one to hold the blank and the other to guide the tool, using both hands for the purpose. In the case of round and half round surfaces, the tool is swept across the blank in a series of strokes from one end to the other on one portion of the surface. The blank is then rotated a trifle and the operation repeated, and so on until the whole surface is covered. So well must the etching tool be made, however, and so careful is the work, that the teeth are continuous throughout the whole surface.

A machine is being tried out in this shop for performing this operation. It is shown in Fig. 10. It duplicates the motions of the workman in the hand operation. The work is held at *A* and the etching tool at *B*. The tool is swept back and forth across the work on the angle desired for the tooth, the pressure being relieved on the back stroke. The blank is turned from time to time, if the surface is curved, so as to bring the whole area of the file under the influence of the etching tool. The process bids fair to be successful.

The shape of the file is the consideration which determines whether a blank shall be etched or cut with the chisel. A flat surface cannot be etched, nor is there any need for it. On round surfaces, however, particularly where it is necessary to preserve accurately the outline of the blank, etching is preferable to cutting. In a round file, the action of the chisel throws up the stock in such a way that the shape is polygonal, rather than round, when the file is completed. In etching, on the contrary, the process is that of cutting out the metal, leaving the original contour undisturbed. The workman cuts in with his etching tool only enough to bring the teeth to a sharp edge, without bringing this edge below the original surface. For this reason, in any curved shape where an accurate outline

Fig. 10. "Etching" Machine.

is desired, etching is the process used. Teeth coarser than No. 1 cannot readily be formed in this way, owing to the difficulty of applying enough pressure, and at the same time guiding the tool with precision.

The Hardening Department.

After the forming of the tooth, either by cutting or etching, the maker's name and the number are stamped on the file, and the extreme end, where the teeth are not perfectly formed, is sheared off. Then it goes to the hardening department. As before remarked, much mystery is made by some file making firms of the heat treating process. There is no mystery visible here, nothing but an application of common sense and long experience in the hardening of tool steel. The equipment of the room consists of two hardening furnaces, with lead baths, suitable brine tanks and brine cooling apparatus, and appliances for cleaning the files by a steam blast carrying a powdered earthen material. This is all shown in the general view of the hardening room, Fig. 11.

In hardening, the following procedure is adopted: A boy stands at the left of the furnace man, as shown in Fig. 12, the furnaces themselves appearing at the right of Fig. 11. The boy has at his left a pile of the files to be treated, and on the table back of him a supply of iron handles with sockets having holes pierced in them to match the tapered shanks of the files. At regular intervals, at such a rate as to always keep a certain number of files in the furnace, he inserts the shank of a file in the socket handle, which he lays on top of the furnace with the file hanging down into the pot of melted lead. The surface of the lead is covered with

coke dust, to prevent oxidation, and the temperature is kept constant at about 1600 degrees by a Bristol pyrometer.

As each piece of work becomes thoroughly heated, the operator removes it, plunges it into the brine tank and then into lime water, where it is cleaned, and then holds it for a moment under a steam jet. This latter heats it so that it dries immediately, thus obviating the danger of rusting. In small files especially, the transfer from the furnace to the brine tank has to be made very quickly, in order to prevent cooling before the water is reached. For this reason two tanks are provided. The small one, close to the furnace, is for small files, which cool too rapidly to permit a long journey through the cool air. The large one, a little further back, is used for larger work. The body of water in the large tank does not heat up so rapidly, and there is less danger of cooling with these files in carrying them the greater distance required.

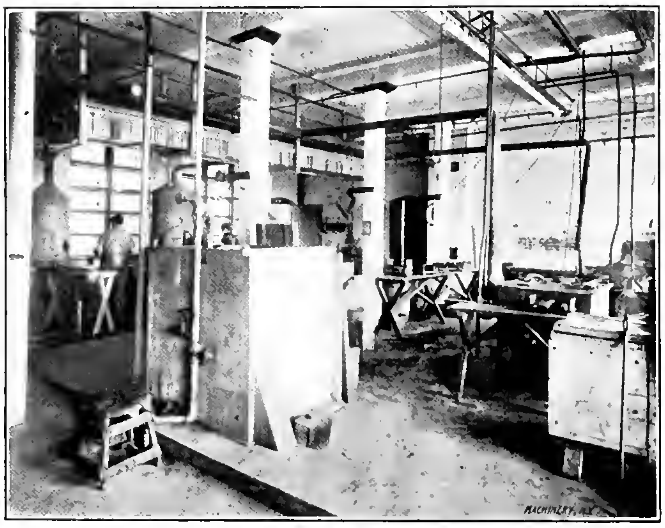

Fig. 11. General View of the Hardening Department.

Mr. Reichhelm is much pleased with the work of the Bristol pyrometer. It seems to do its work very accurately, is comparatively inexpensive in the first cost, and in renewal of the "elements," or that portion of the instrument which is subjected to the heat it is desired to measure. In his work, however, the pyrometer is used fully as much for keeping the temperature from fluctuating as it is for indicating absolute temperature. The condition of the work, as to color and hardness, is the prime consideration. When the bath is of such temperature as to give the required color and hardness, the pyrometer reading is noted and the bath is tried from time to time to see that that temperature, whatever it may be, is kept constant.

The provision for furnishing a cool supply of brine is worth noting. The apparatus used is shown, diagrammatically, in Fig. 13. The underground reservoir contains a saturated solution of salt and water. This tank is of wood, on which, of course, the brine has no injurious effect. Located within it is a box of sheet lead, with an inwardly opening valve of the same material at the bottom, and an air supply pipe and an outlet pipe, also of lead, entering the top. The latter of these two pipes comes nearly to the bottom of the box. The operator at either of the two hardening furnaces, by pulling a cord, can open a three-way valve, which admits air under pressure at the top of the box. The box being full of brine, which has flowed in through the check-valve at the bottom, the air pressure closes this valve and forces the liquid through the outlet pipe into the cooling and supply tank above. This latter tank, seen in the foreground of Fig. 11, is high enough so that the brine flows from it by gravity to the bottom of the tanks at the furnaces. The cooled brine entering at the bottom of these tanks rises and displaces the warmer fluid, which runs through an over-flow at the top back to the reservoir again. In the cooling tank is a coil of pipe, through which water flows continuously from an artesian well sunk on the premises. This serves to keep the supply of brine cooled.

After the hardening there is a slight oxidation of the surface of the file, little more, however, than a stain; it could scarcely be called scale. To remove this the work is taken to the cleaning apparatus shown in the left background of Fig. 11. The sheet metal cases shown contain a quantity of water mixed with a fine clay. This clay is almost impalpable, with no perceptible grit that can be felt between the thumb and finger. A steam ejector draws the mingled water and clay from the bottom of the casing and directs it in a stream upward against the files, of which several at a time are grasped by the operator in a pair of long-jawed tongs. A few seconds' exposure to the blast, first on one side and then on the other, removes the stain from the cutting edges and leaves them bright and sharp. From here the files go to the packing department where they are inspected for hardness and accuracy of cutting, oiled, and wrapped in suitably labeled boxes ready for marketing.

Special Forms of Files.

What we have said of the methods of manufacture followed relates to files with more or less regular outlines, which readily admit of being formed and cut by machinery. Great numbers of special shapes have to be made, however, in which the use of machinery is impossible. In the case of the various forms of rifflers for instance, used by toolmakers and diemakers in working out otherwise inaccessible corners, the whole work of forging, stripping, cutting, etc., has to be done by hand, the surface being too irregular to admit of any other procedure. Other special forms of files are made here for various purposes. One interesting product is a form used in sharpening pins. It will be news to many mechanics, doubtless, to know that the points of pins are filed. The filing is done by square blocks of steel with single cut teeth formed in them, fastened to the sides of rapidly revolving disks. Large quantities of these are made here.

Swiss vs. American Files.

The Swiss file is the outgrowth of the Swiss watch industry, which is nearly or quite 200 years old. These watches have been and are now made quite largely by hand, so that the production of files of the very finest grade early became a vital necessity in that country. To this demand the high standard of the Swiss file may be traced. This excellence is due to the manual skill of the men who form the teeth, and the careful inspection which rejects all which are below the required standard of quality. As intimated, great skill is required to produce teeth of uniform depth and sharpness with the comparatively crude annealing methods used. The workman must be continually varying the force of his blow as he reaches spots of greater or less hardness. In cases where the variation is too great, the file has to be rejected. In a similar way, with the hardening process used, the inspection weeds out a considerable percentage of failures. This care, and the expertness of the help, accounts for both the excellence and the highness of the price of the European product.

Fig. 12. Heating Files in the Lead Bath.

The conditions which make it possible to compete with these makers are: the scientific method of annealing which reproduces the same conditions day after day, and year after year, giving a uniform product requiring the discarding of very few pieces; the use of machinery in cutting the teeth, made possible by this uniformity of annealing and making

possible the cutting of good teeth at a not prohibitive cost; the ability to reproduce the same conditions in hardening day after day by careful attention to the uniformity of the steel, the tempering of the lead bath, and other qualities; and finally the exercise of the same old-fashioned care and conscience that show themselves so plainly in the product of the standard Swiss manufacturers.

In making these files in America, it was decided that no improvement would be attempted, for the present at least, in the shapes and sizes of the blanks and the fineness of the teeth. These designs have been the result of filling the gradually developing needs of some of the most skilled hand workmen in the world, so it is not the task of a day or a year to

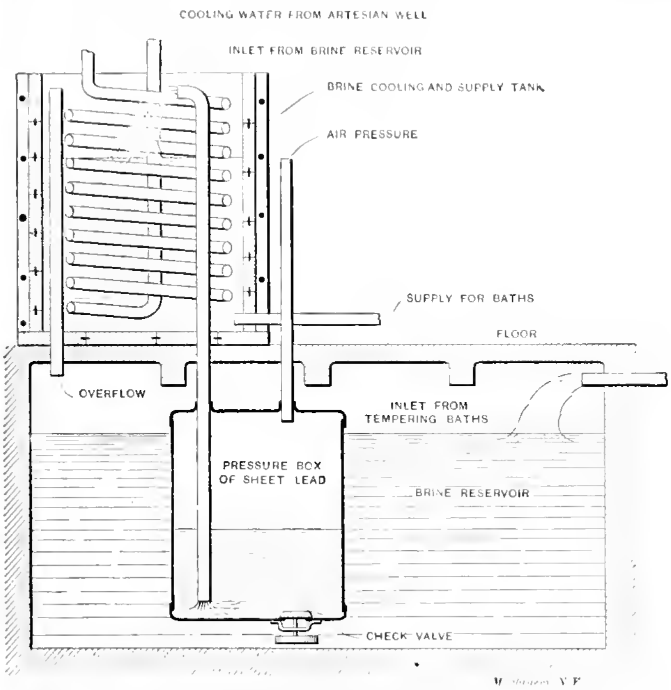

Fig. 13. Diagram showing Apparatus for Storing, Cooling and Transferring Brine.

devise anything better. For this reason, the product of this firm follows exactly in these particulars the product of the best Swiss makers.

This article has been given up largely to a description of machines and processes. Looking at the business in the way Mr. Reichhelm does, these machines and processes, important as they are, take a second place when compared with the necessity of having capable and efficient men to look out for them. It is fitting then that some of these men should be mentioned—the more, from the fact that the writer is indebted to them for the cheerfulness and intelligence with which they answered every question he saw fit to ask. Mr. Hermann Neff, superintendent, Mr. Ibach, the foreman of the forging and annealing rooms, Mr. Poncheron, the foreman of the etching department, and Mr. Kerr of the cutting department, may be mentioned in this connection, though, so far as the writer could judge, the name of every workman he met should also be included in the list. Mr. Joseph Broome, of New York, was the engineer responsible for the design of the buildings and the power plant.

* * *

A hammer, pliers, a cold-chisel or two, and a vise, in almost any old shack may, by courtesy, be called a shop, but the average owner of such an outfit seems to think that it will not be so regarded unless he scrawls somewhere on the inside or outside the legend "No admittance." So, wherever one goes, in town or country, the identity of the little tinker shop is revealed by this insulting and discouraging sign. Scarcely no other business would or could repel business in this foolish way, and why does the mechanic? His tools are not so enormously valuable, and of trade secrets he has none. Is the practice caused by an exaggerated idea of self-importance, or is it a custom inherited as part of the trade? Whatever may be its reason, it is a custom that is best honored in the breach. Common courtesy demands it, and a mechanic should not brand himself a boor by observing it.

THE BURGLAR AND THE SAFE-MAKER.

In the September, 1906, issue an editorial under the above caption appeared, dilating on the struggle that is constantly going on between the burglar and the safe-maker. In view of the statements then made, the following letter on safe-blowing from Consul Thomas H. Norton, Chemnitz, Germany, is of considerable interest to safe makers and users:

The confidence of German manufacturers of safes in the resistance of their wares against ordinary safe-blowing operations has been rudely shaken by the recent achievements of a single unaided robber in Dresden and other cities. The details of his last operation are as follows: A room was secured in a hotel, which was situated immediately above the office of a money changer. At night a hole was pierced in the ceiling of this office. By the use of a drill and saw a circular piece of the flooring was easily raised. Beneath lay a thick layer of cement. A small orifice was made in this and an umbrella shoved down into the space below. The umbrella was attached firmly from above, and when opened received without noise all the fragments of cement which were dislodged as the hole was enlarged so as to allow of the easy passage of a person. By means of a rope ladder the descent was readily made into the office below. Curtains were drawn, and with heavy blankets a tent was constructed around the safe, so thick that no ray of light could pass through. Next the robber brought down two cylinders of compressed oxygen and an acetylene generator charged with calcium carbide and water. With these he was able to produce a blowpipe flame of such intensity that steel fuses in it like lead in an ordinary gas jet. It required but a brief space of time to melt away so much of the door that all the contents of the safe were accessible. They were carried to the room above. At an early hour the robber left his lodgings and disappeared without trace.

The suggestions of the Consul for means to foil the efforts of the safe-cracking gentry are also of considerable interest:

It is evident from this experience that the builders of safes must provide for new contingencies in their constructions. The simple, light, acetylene generators, now in widespread use, and the equally simple oxygen generators, charged with water and sodium peroxide, or the heavier cylinders of compressed oxygen, place at the service of the intelligent crook the possibilities of opening the strongest safes in existence rapidly and noiselessly, provided the operator can be screened from observation.

Some large safes are so disposed that they are under frequent observation by watchmen looking through windows. Usually this observation is confined to the doors of bank vaults or the like, although in the case of the globular safes it practically extends to all exposed sides. In the greater majority of cases existing safes would offer next to no difficulty to a skillful cracksman if able to work without being seen. It is evident that owners will be forced henceforth to adopt such measures as will reduce to a minimum all possibilities of access to free-standing, movable safes, or the hidden sides of safes, embedded in cement or masonry.

Manufacturers of safes will, on the contrary, be impelled to fight the scientific burglar with his own weapons. In somewhat the same fashion by which time-locks prevent the opening of the lock of a safe during certain hours, it will be comparatively easy to introduce into safe construction chemico-mechanical devices which, during a limited time, would render it either fatal or physically impossible to remain in the vicinity of a safe or vault, were the walls or doors tampered with to such an extent as to allow access to the interior. By the use of a very simple form of apparatus containing potassium cyanide and sulphuric acid, a robber would expose himself to the deadly fumes of prussic acid.

Less dangerous, through possibilities of accident to those regularly using a safe, would be the employment of substances crippling a safe-blower or forcing him to an instantaneous retreat. The volatilization of a few drops of ethyl-dichlor-acetate would cause such profuse and persistent weeping that one in the neighborhood would be temporarily blinded if he persisted in remaining. The breaking of a tube of liquid ammonia would render immediate withdrawal imperative under peril of suffocation. Several similar compounds are at the service of constructors. Eventually the daring burglar, with sufficient scientific training, might venture to face the unknown dangers of a safe well provided with more or less effective neutralizing agents for the concealed possibilities of defense; but certainly for some time, at slight expense, effective protection can be devised against the attack of the scientific cracksman with his portable oxy-acetylene blowpipe.

Some of the measures suggested would be more dangerous to safe users than common prudence would permit, and as for all it is scarcely necessary for us to say that the ingenuity displayed by safe-breakers would probably enable them to readily overcome everyone of the obstacles suggested, for the Consul has practically admitted it, already.

REAMERS.—3.

ERIK OBERG.

Jobber's Reamer.

The jobber's reamer, Fig. 11, constitutes a class of reamers by itself. It is provided with a long fluted body and a taper shank, for use in machine; the corners at the point of the reamer body are slightly rounded, as shown at *a*. The radius for this rounded part should be about 1/32 inch for reamers smaller than ¾ inch in diameter, and 1/16 inch for larger

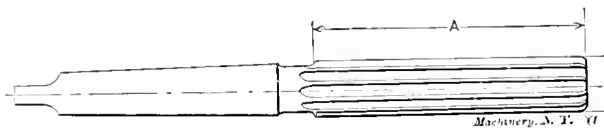

Fig. 11. Jobber's Reamer.

sizes. A neck is provided between the fluted portion and the shank, in order to permit of clearance for the grinding wheel when the shank and the fluted portions are ground. The length of this neck varies according to the size of the reamer. It is customary to make it about ½ inch long for a ¼-inch reamer, 1 inch for a 1-inch reamer, 2 inches for a 2-inch reamer, and 3 inches for a 3-inch reamer. The shank is nearly always made a Morse standard taper shank; the size of the shank used for different sizes of reamers is as follows:

Size of Reamer.	No. of Morse Taper.
From ¼ to ½ inch....................	1
From 17/32 to ⅞ inch....................	2
From 29/32 to 1¼ inch....................	3
From 1 9/32 to 1¾ inch....................	4
From 1 25/32 to 3 inches....................	5

Jobber's reamers are fluted with the same kind of cutters as hand reamers. The number of flutes is also the same as given for hand reamers in the August issue.

Dimensions of Jobber's Reamer.

As the length of the neck usually given to this class of reamers has already been stated, and as the number of the Morse taper shank determines the length of the shank part of the reamer, the only additional dimensions necessary are the length of the fluted portion and the diameter of the neck. The latter should be about 1/32 inch smaller in diameter than either the reamer itself or the largest diameter of the

TABLE X. DIMENSIONS FOR THE LENGTH OF FLUTED PORTION OF JOBBERS' REAMERS.

Diameter of Reamer.	Length of Flute.	Diameter of Reamer.	Length of Flute.	Diameter of Reamer.	Length of Flute.
D	A	D	A	D	A
¼	2	¾	4	1¾	6 11/16
5/16	2¼	⅞	4½	1⅞	6⅞
⅜	2½	1	5	2	7
7/16	2¾	1⅛	5½	2¼	7 5/16
½	3	1¼	6	2½	7⅝
9/16	3¼	1⅜	6¼	2¾	7 15/16
⅝	3½	1½	6⅜	3	8¼
11/16	3¾	1⅝	6½	..	...

Morse taper shank, depending upon which of these dimensions is the smaller; the only object is that the grinding wheel shall clear the neck when grinding the teeth as well as when grinding the shank. The length of the fluted portion may be determined from the formula:

$$A = 4D + 1 \text{ inch},$$

for sizes up to and including 1¼ inch, and from the formula:

$$A = \frac{5D}{4} + 4\tfrac{1}{2} \text{ inches},$$

for larger sizes. In these formulas, A = length of flute, and D diameter of reamer. Dimensions for the length of the flutes, approximately figured from these formulas, are given in Table X.

Shell Reamers.

In order to save the amount of stock which goes into the shank, shell reamers, having a hole through the center by means of which they are mounted on arbors, are quite largely used. As one arbor can be used for a number of reamers, the saving is quite considerable. An ordinary fluted shell reamer is shown in Fig. 12. The arbor on which it is used is shown in Fig. 13. The reamer has a keyway *A* which fits the key *B* on the arbor freely; the reamer, when at work, is rotated by means of this key and keyway. The hole through the reamer tapers, the taper being ⅛ inch per foot. Manufacturers of reamers have adopted certain standard sizes of arbors, and each arbor corresponds to a certain number of different sizes of reamers. Thus, several sizes of reamers are provided with the same size hole through them, and can be used with the same arbor. The arbor, as well as the hole in the reamer, must be ground after hardening, to insure that the reamer will run true. When hardening, if the

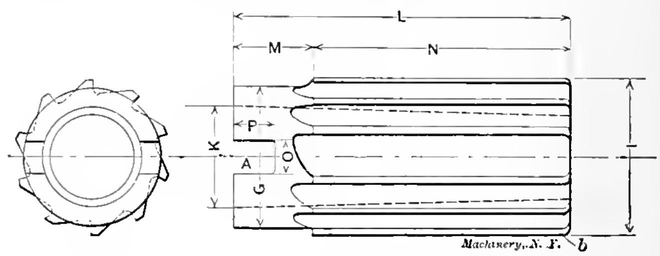

Fig. 12. Fluted Shell Reamer.

reamer is larger than 1¼ inch in diameter, its should be removed from the hardening bath, the same as large hand reamers, when it ceases "singing," and be plunged into a tank of oil, where it should remain until cool. When the tool is removed from the oil bath, or in the case of smaller reamers, from the water bath, it should be held over a fire and slowly revolved until at least partly relieved of the internal stresses, tending to crack the tool, which are due to the hardening process.

The outside of the reamer is provided with flutes and cutting edges for the greater part of the length of the reamer. A short distance at the end provided with the keyway is turned down below the diameter of the cutting edges. This is done in order to prevent any burr which may be set up by

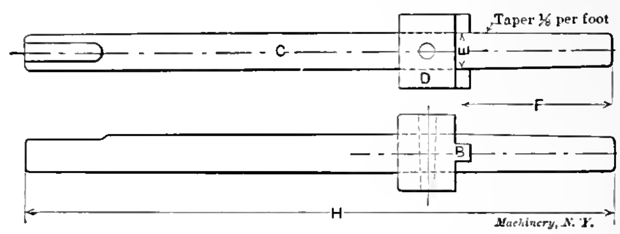

Fig. 13. Arbor for Shell Reamers.

the driving key on the arbor from interfering with the hole reamed, or spoiling the cutting edges of the reamer. Besides, this turned-down portion provides space for marking the reamer with its size, and gives a finished appearance to tool.

Fig. 14 shows a shell reamer fluted in the same manner as the rose chucking reamer. This reamer is termed a rose shell reamer. The cutting edges, fluting, and back taper are the same as described before under rose chucking reamers, September issue, but in all other particulars the tool is the same as an ordinary shell reamer.

Arbors for Shell Reamers.

The arbor used for driving shell reamers when at work consists of a stem, or arbor proper, *C*, Fig. 13, provided with a collar *D*, which is fastened to the arbor by means of a taper pin. On this collar a tongue *B* is milled on the end so as to provide for a key to fit the keyway in the reamer, as mentioned. Precaution must be taken in milling this tongue so that it is exactly in the center of the collar. The same care must, of course, be used in milling the keyway in the reamer, which must be exactly in the center. When grinding the outside of the reamer to size, it should be ground on an arbor similar to those on which it is to be used, and the edge at the front end slightly rounded as at *b*, Fig. 12.

Arbors, as well as driving collars, should preferably be made out of tool steel. The collar should be hardened. The arbors, as manufactured, are made in fourteen sizes, the diameters of each being measured at *E*, halfway between the end

of the key and the solid part of the body of the collar L. The arbor is provided with a flat milled on the shank for the set screws, by which it is clamped when held in position for work. In Table XI are given the most important dimensions for these arbors.

Fluting Shell Reamers.

The cutters used for fluting regular shell reamers are the same as for hand reamers. Rose shell reamers are fluted with the same kind of cutters as rose chucking reamers. The number of flutes in shell reamers must necessarily be greater in the smaller sizes than in corresponding sizes of solid reamers, because the flute cannot be cut so deep, owing to the thin walls of the shell. The number of flutes for regular shell reamers are as follows:

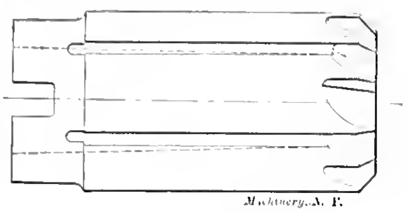

Fig. 14. Rose Shell Reamer,

Size of Reamer.	No. of Flutes.
From 1/4 to 3/8 inch	6
From 13/32 to 5/8 inch	8
From 21/32 to 1 1/2 inch	10
From 1 17/32 to 2 1/4 inches	12
From 2 9/32 to 2 3/4 inches	14
From 2 25/32 to 4 inches	16
From 4 1/32 to 5 inches	18

The number of cutting edges on the beveled end of rose shell reamers are equal to the nnmber of flutes in the regularly fluted kind. The number of grooves on the cylindrical part of the rose reamer is, of course, half that of the number of cutting edges, there being one groove for every second cutting edge.

TABLE XI. DIMENSIONS OF SHELL REAMER ARBORS.

(See Fig. 13 for dimensions denoted by letters.)

Diameter at Size Line.	Length from Size Line to End of Arbor.	Total Length.	Diameter at Size Line.	Length from Size Line to End of Arbor.	Total Length.
E	F	H	E	F	H
1/8	1 1/2	6	1	3 1/2	12
3/16	1 3/4	7	1 1/4	3 3/4	13

3 1/32 — 3 1/2	1 3/4	4 1/2	1	3 1/2	5/16	3/8
3 17/32 — 4	2	5	1	4	5/16	3/8
4 1/32 — 4 1/2	2 1/4	5 1/2	1	4 1/2	5/16	3/8
4 17/32 — 5	2 1/2	6	1	5	5/16	3/8

Dimensions of Shell Reamers.

The over all length of the shell reamer must evidently be the same as the length F on the arbor (Fig. 13), from the size line to the extreme end. As the same arbor is used for a number of different size reamers, these arrange themselves in certain groups with the same total length. The length of the fluted portion in each such group is, of course, also the same, as well as the dimensions for the keyway. The only dimension which varies in each group besides the size of the reamer itself is the diameter of the turned down part G (Fig. 12). This dimension should be as much less than the diameter of the reamer, as stated below:

Diameter of Reamer.	Amt. Diam. of Recess should be less than diam. of Reamer
1/4 — 3/8 inch.	0.006 inch.
7/16 — 3/4 inch.	1/64 inch.
13/16 — 1 inch.	1/32 inch.
1 1/16 — 1 1/4 inch.	1/16 inch.
1 5/16 inch and upward.	1/8 inch.

In Table XII are given the dimensions for the various groups of shell reamers corresponding to the different arbors.

* * *

PATCHING DRAWINGS.

In the January, 1906, issue of MACHINERY was described the drafting-room practice of a large machine tool building firm in the matter of making extensive changes on drawings. In the drafting-room in question tracing cloth is not used, bond paper being employed instead. On this paper pencil drawings are made, which are afterward inked in and used to take blueprints from. Paper can be used of such quality as to be not much inferior to tracing cloth in the matter of rapidity and clearness in printing. The writer of that article referred to the matter of the ease of making changes as being one of the points of superiority of bond paper over tracing cloth. The method employed is to cut out with a sharp knife the portion affected, if the change is at all extensive. With the removed portion as a templet, a new patch is cut out from unused paper, about 1/16 inch larger in every dimension than the hole it is to cover. This is pasted in place on the back of the drawing by the margin thus left around it.

Since seeing the above, the writer's attention has been called to the practice of another large drafting-room engaged in machine tool design in which, also, bond paper drawings are largely used. Here, when drawings have to be patched, a sheet of clean paper is laid under the affected portion, which is removed by cutting with a sharp knife. The knife passes through both sheets of paper, thus providing a patch to fill the opening at the same time. To fasten this to the main body of the drawing, a sheet of transparent paper spread with clear mucilage is used, if the patch is small. If of considerable size, the joint is neatly covered with thin strips of gummed transparent paper about 1/8 inch wide.

The advantage of this method is the smoothness of surface produced. The patch is flush with the main body of the drawing paper and the drawing instruments pass over the joint between the old and new portions without difficulty. It would be especially useful in cases where alterations are made on thick drawing paper. When neatly done with a sharp knife, the joint in such cases is almost invisible. The writer has employed it on tracings, where it worked very well, although it has been found that ordinary library paste is not permanently effective in making the joint. A good clear mucilage should be used.

* * *

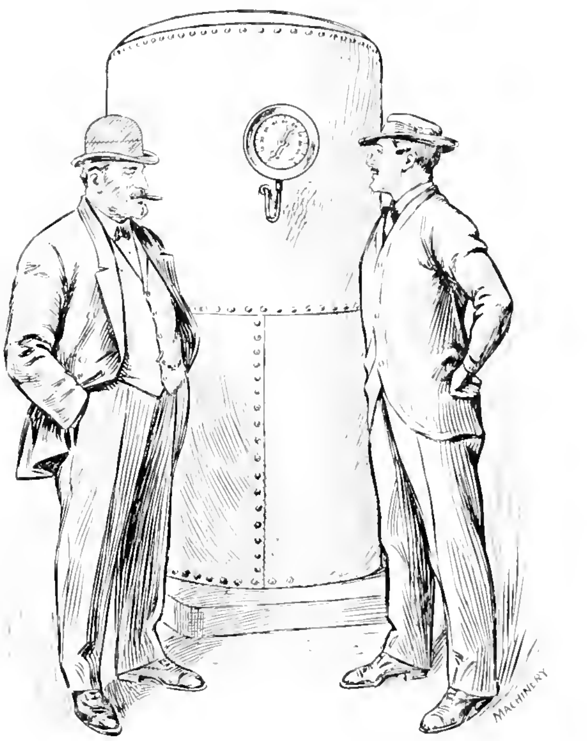
In our September issue we described a course of instruction for draftsmen at the American Locomotive Co., Schenectady, N. Y. The General Electric Co. at Schenectady also has an apprenticeship system for the training of draftsmen, conducted along similar lines. For admission, the apprentice is required to pass a stiff examination in arithmetic, which most of the candidates fail to pass. Those admitted first spend about three months in the blue-printing department, then six months in the tracing department, this latter period being considered sufficient for turning out an expert tracer. After that the student is kept for a year in the factory, being transferred as a rule from department to department every three months. After that the final two years are spent in the drafting room. During the whole time the student is required to study algebra, geometry, trigonometry, projections, strength of materials, etc., and to draw and trace fifty instruction sheets from sketches furnished to him. The pay of the apprentice during the four years' training ranges from \$3.40 per week during the first six months to \$7.50 a week during the last year.

PIPING AN AIR GAGE.

M. E. CANEK.

Jim Peters learned his trade at Clark Bros.' engine works, and continued to work there after his apprenticeship was served. He was considered a good man, capable of doing almost any job from boring a cylinder to setting up an engine, hanging a boiler or running a line of steam pipe. He was steady, sober and industrious, but had one fault that sometimes led him into blunders; and that was, he did not always find out the "reason why." He had learned almost everything he knew about the trade by experience, and had accepted many shop practices without fully knowing why they were followed. One of his blunders—the last—was piping an air gage, and what he learned from that experience was much more valuable than the actual facts, for after that day he made it a rule never to do anything without knowing *why* he did it.

Ben Clark, the junior member of the firm, was the superintendent and general foreman of the machine shop. When an



". . . the air gage showed not a pound of pressure, although the pneumatic hammers were making a merry din."

air compressor plant was put in to operate pneumatic hammers and riveters in the boiler shop, the "super" put Jim on the job, which included the erection of the air compressor in the engine room, lines of piping to the shops, and a big storage drum in the boiler shop. An air gage on the drum was called for by the specifications, and Jim duly put it up in the usual manner that he had learned was the correct thing for steam boilers, that is, with a siphon-shaped pipe connection. Why the pipe was made this way Jim did not know or care—then.

The job was completed late in November, and all went well for several weeks, until one frosty morning in December the foreman of the boiler shop called the super's attention to the fact that the air gage on the drum showed not a pound pressure although the pneumatic hammers were making a merry din. One glance at the pipe connection told the super what was the matter. Going into the machine shop he walked up to Jim and said:

"Did you ever stop to think?"

"W-w-what's the matter now?" said Jim, growing red in the face, for he "smelled a rat," as the boys say.

"Why do you connect a *steam* gage with a siphon pipe?"

"I-I-I don't know," confessed Jim.

"Just what I thought," said the super, "for if you did you wouldn't have been such a fool as to put one on an air gage, especially in a cold boiler shop. Have you worked all these years here without learning that the siphon loop is simply a trap for condensation to protect the works from the hot steam? Pretty thing, though, to put on an air drum to freeze up over night. Looks nice, doesn't it—and *so-o-o* useful—but you'd better straighten it."

The super said no more; the boys attended to that very well, and Jim did not hear the last of his air-gage siphon for many months.

Jim is nearly through with his correspondence course now, and he is growing to think that perhaps the air gage job was a good thing after all. A mental jolt sometimes works wonders on the right sort.

* * *

TINNING CAST IRON.

J. E. K.

The process of tinning cast iron is not understood by a great many persons who it seems would be familiar with the process, and for the benefit of these, I will briefly outline the method generally employed for this work. Of course, the castings must be absolutely clean and free from sand or oxide. Time spent in thoroughly cleaning the castings at the outset is time well spent, because many troubles which sometimes occur later in the process, causing loss of time and material, could be obviated if the castings had been thoroughly cleaned. The scale or oxide should be removed so the clean metal will be exposed to the tin. After passing through a "rattler" which removes a great deal of the scale, the parts are placed in a pickle of dilute muriatic acid until a clean surface is obtained. This pickle is warmed in some shops by means of a steam jet, and a quicker result is obtained. The castings can be examined occasionally while in the pickle, and any sand or black spots removed by means of a wire brush. The castings after coming from this pickle are washed in clean water. If for any reason it is desired to keep the cleaned castings for any length of time, they may be preserved from oxidation by being left under water. For a flux, the castings are dipped in a mixture composed of four parts of a saturated solution of sal-ammoniac and one part of muriatic acid.

The best block-tin should be used for tinning. Melt this in an iron pot, taking care that it is not burned or overheated in melting. After the tin is melted, it should be cleaned of all impurities. This can be done by taking a piece of green or wet wood secured to a pointed iron rod, and fastening it so that the wood will be kept at the bottom of the pot of melted metal for one or two hours, depending on the amount of impurity in the metal. The surface of the metal is skimmed occasionally by means of a perforated iron skimmer. To protect the surface of the metal from oxidation it can be covered with sal-ammoniac. There is nothing to be added to the tin. Tallow or palm oil may be used for covering the surface instead of sal-ammoniac.

The casting is taken up by means of suitable tongs, dipped in the flux, and then immersed in the melted tin, and held for a sufficient time to allow the surface to be tinned. The tin should not be so hot as to discolor when the casting is removed. If desired, the casting can be held for a time in another pot, which is kept partly filled with tallow or palm oil and kept at a temperature that will melt tin. The bath of grease will allow the casting to retain an even coating of tin, and allow any superfluous metal to drain off. The castings may be cleaned from the grease by rubbing with sawdust and then with bran.

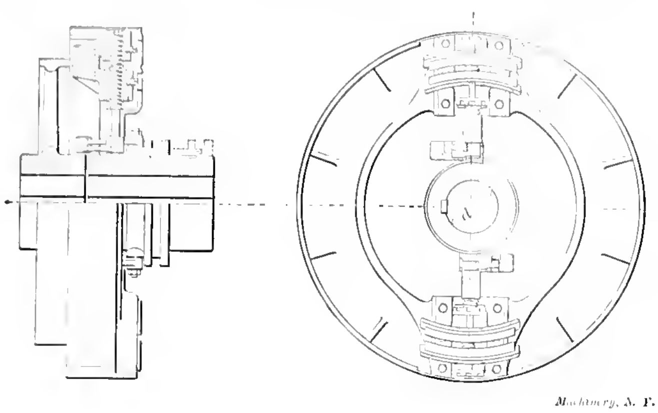
* * *

The Arthur Co. has a clock face on the exterior of its building on Front St., New York, the hands of which are driven by a "grandfather" type clock in the office. A novelty of the arrangement is a face with hands on the "back" of the clock facing the interior, the numbers being arranged in reverse to the usual clockwise order, of course. This very unusual feature never fails to attract the attention of visitors—and that is its principal object. The reversed clock face may be made to serve another useful purpose, according to an exchange. A barber in St. Louis has a clock so arranged for the benefit of his customers who when in the chairs can thus readily tell the time from the reflection in the mirrors. Ordinarily one so situated has to perform a mental somersault to tell the time from the reflection, but this innovation makes the reflection the same as the real thing.

ITEMS OF MECHANICAL INTEREST.

NEW FORM OF GRIP-JAW CLUTCH COUPLING.

A German firm, the Peniger Maschinenfabrik und Eisengiesserei A. G., Penig, Saxony, is manufacturing a new form of clutch coupling based on the old principle of jaws, actuated by a right- and left-hand screw, gripping the rim of a pulley. The cut herewith shows plainly the construction and action of this device. A sleeve, traveling back and forth on the hub of the pulley which is keyed to the shaft, and actuated by a shifting lever, not shown in the cut, turns by means of a lever

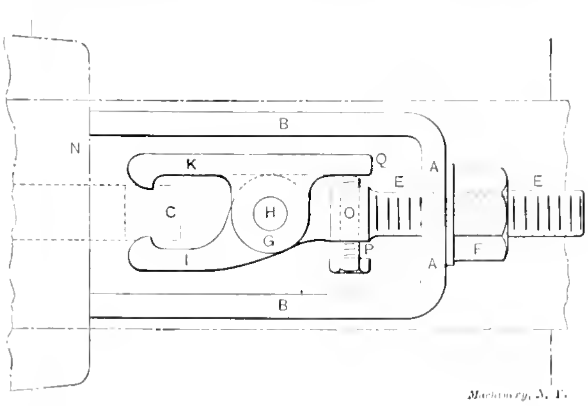


Grip-jaw Coupling.

and crank, the right- and left-hand threaded screw, thereby causing the jaws to grip the loose pulley and drive it. The jaws are made of wood, and fastened by wood-screws to cast iron brackets in the driving pulley. The dotted lines at the end of the hub of this pulley indicate the position of the operating sleeve when the jaws release the loose pulley, and the sectional view of the sleeve indicates its position when the jaws are brought in contact with, and drive, the loose pulley. The cut shows a pulley with only two pairs of jaws, but larger sizes are made with four pairs of jaws also, to provide for greater efficiency.

KEY-EXTRACTING DEVICE.

The accompanying cut, taken from the *Mechanical Engineer*, August 10, 1907, shows a device for extracting keys from their seats in pulleys, etc. It has been patented by Messrs. T. Barnes and J. E. Walpole, of Chester, England. The device consists essentially, as seen from the cut, of a bridge piece, a screw supported by the bridge piece, and a clamp adapted to grip the key. The bridge piece *A* has two legs *B*, the ends of which rest against the boss of the pulley or other object from which the key *C* is to be ex-



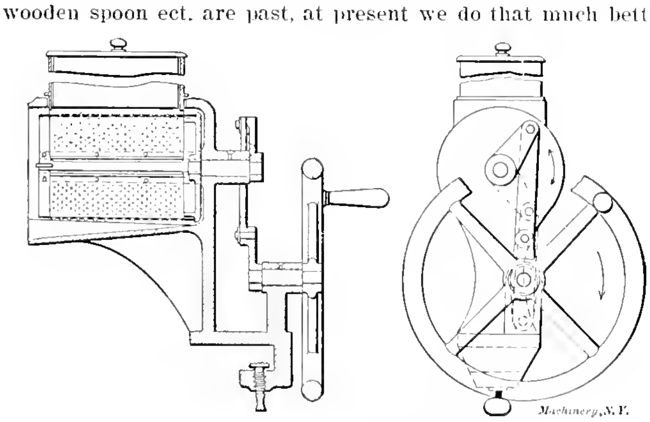
Key-extracting Device.

tracted. A screw *E*, provided with a fine pitch thread passes freely through a hole in the bridge piece *A*. On the outer end of the screw *E* is mounted a nut *F*. The inner end of the screw is provided with a boss *G*, and with an arm *I*, for gripping the key. Through a hole in the boss *G* is passed a pin *H*, which pin carries the arm *K*, forming the gripping jaw opposite the arm *I*. The extreme ends of the jaws are provided with inwardly projecting V-shaped edges which engage with grooves formed in the vertical sides of the key *C*. These grooves must be provided for in the key before it is originally driven into the keyway of the pulley. The screw *E* is also provided with a boss *O* through which passes a set screw *P*, bearing against the heel *Q* on the arm *K*, so that on turning the set screw the jaws are caused to grip the key. The device can lay very close to the shaft when it is required to extract a key from a boss located on the lineshaft. When the parts are engaged in the manner just stated, the nut *F* is turned on the screw *E* with a wrench, and the legs *B* are forced against the boss *N* of the pulley or other object from which it is wanted to extract the key. A further turning of the screw withdraws the key from the keyway. The device, during use, rests upon the shaft carrying the pulley.

A POTATO-RASPING MACHINE.

The following cut and description are taken verbatim from the English edition of a German periodical called "The Sun." This typographical luminary radiates information relating to German patents, with the hope of attracting American and English investors to them. We feel no hesitation in reproducing this matter, being given *carte blanche* for so doing by the following note on the title page of the paper: "For the press: The original essays published in the *Sun* may be used and copied, without mentioning the authority at will. Stereotypes to the reddition of the drawings are send with obligation for free sending back gratis and frank, if wanted."

Here follows the description: "To Mr. Gieler, Weida, has been granted a patent for a new potatoe-rasp in Germany and other countries, as it is shown in the drawing. The times where the potatoes in the kitchen had to be squashed with a wooden spoon ect. are past, at present we do that much better



German Potato-rasping Machine.

and quicker with a machine. Till now we have made known with several rasps, but we can say, without enlargement that Gielers' system belongs to the best ones. It is indeed emminent simple and comfortable too. It has the profit that the pap can be made refined and grossly. You only have to change the raspingroll. Except this the machine is to make in pieces very easily, to clean it in the most commode manner, what also is a great profit. You spend not too much time by cleaning it and it is absolutely necessary. Each lady of the house, who has been acquainted with Gielers rasping-machine can not be without it."

We can't help wondering if the translations into German of some of *our* trade literature, may not be almost as interesting as the sample given above.

* * *

In a paper presented before the annual convention of the National Electric Light Association by Mr. Paul Lüpke of Pittsburg, some reference was made to the question of selecting help and building up an organization, and the ideas put forth are well worth being repeated. "The right time," said Mr. Lüpke, "to look out for your head fireman is when you hire a coal passer; for your chief engineer when you hire an oiler; for your chief electrician when you hire a machine wiper. This plan avoids much shifting. Floating help is a most serious hindrance to economy and good service. Any bully can discharge a man, but it takes a sage to hire a better one in his place."

REGISTERED IN UNITED STATES PATENT OFFICE.

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

49-55 LAFAYETTE STREET, CORNER OF LEONARD,
NEW YORK CITY.

The receipt of a subscription is acknowledged by sending the current issue. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

OCTOBER, 1907.

PAID CIRCULATION FOR SEPT., 1907, 23,967 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year—contains all the matter in the Shop Edition and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

The yearly indexes of the engineering and shop editions of MACHINERY and RAILWAY MACHINERY are now ready, and copies may be obtained upon request.

* * *

VALUE OF SAFETY APPLIANCES.

The steam gage, the safety valve and the water gage of the steam boiler are essentially safety apparatus, but they are no longer looked upon as simply safety appliances, but as necessary features of any complete boiler installation. So it should be with many other features of mill and factory equipment. The tendency is to regard a feature which is designed merely to prevent injury to employes as something of a philanthropic nature, which is to be grudgingly applied, perhaps. A reason that the safety appliances of a boiler are regarded as necessary is because that the enormous damage done by boiler explosion is something to be feared, and most factory owners seek to safeguard their property in this and other respects as much as possible. In the same way they should seek to safeguard the safety of employes, for it is as much to common interest, directly and indirectly, that they be protected from injury, as it is that the plant itself should not suffer. Employers are slow to learn that in a well-established business their most valuable asset, oftentimes, is the employes rather than the plant. The fact that one is a tangible asset, and the other an intangible asset, does not alter the fact.

* * *

THE REACTION.

The present business situation is more than ordinarily perplexing. Some lines of trade report business good and orders ahead of last year. From many points, especially in the West, we hear that money is plentiful and not a speck visible on the business horizon. New York seems to be the only point where money is scarce, although we have managed to subscribe several times over for the last city loan.

The opinions of machinery manufacturers agree that a recession of business in our line is actually here; but they also agree that this recession will be a benefit instead of an injury, because it will allow them to get down to a normal basis, to handle their orders more promptly, and to reduce the cost of their product so that it can be marketed at prices more satisfactory to purchasers, especially those abroad, than has been possible for the past year or two. Very few people of good judgment expected that business would continue at the recent pace, and now that the pendulum has begun to swing backward, all prudent manufacturers will put their business in such shape that, when the inevitable upward swing starts, they will be prepared to take advantage of it.

The immense amount of wealth accumulated in this country during the past ten years or more has made impossible a recurrence of the panics and hard times we formerly had. The changing conditions imply a moderate reduction in total output and a healthy readjustment of values, which will enable us to continue on a firm basis.

* * *

THE EXTRA DATA AND SHOP OPERATION SHEETS.

The popularity of the data sheets and of our shop operation sheets, and the large amount of matter contributed for use in this form, have made it necessary for us to issue extra sheets of both, which, on account of the additional cost, cannot be included in the paper, but which MACHINERY readers can obtain by merely extending their subscriptions. The data sheet in this issue of MACHINERY (engineering edition) is No. 80, although the September data sheet was numbered 73, the intervening numbers, 74 to 79, representing six 4-page data sheets, comprising twenty-four 6 x 9-inch pages, published during October.

The twenty-four extra shop operation sheets are now ready, and are numbered 19 to 42, following numbers 16, 17 and 18 in this number of MACHINERY. The shop operation sheets in the November number will begin with 43, the intervening numbers representing, as we explained above, extra sheets which will be furnished without charge to MACHINERY subscribers who continue their subscriptions.

MACHINERY'S regular data sheets, as our readers have noticed, are now bound in the paper instead of being folded in as supplements. This change enabled us to comply with certain restrictions of the post-office governing supplements issued with periodicals, and allows us to furnish our readers with a great amount of valuable data which we were not permitted to mail in the loose supplement form.

* * *

MISPLACED ECONOMY.

The tendency of some people to begrudge every expense for shop equipment is so old and well-known a condition that it is needless to repeat it, excepting as a matter of fact. This tendency, however, has had an unfavorable influence on the estimation of the actual value of the milling machine. The successful operation of this machine depends to a great extent, or one might well say chiefly, upon the kind of tools with which it is used. In the successful use of the milling machine on anything excepting the very plainest class of work, the cutters and fixtures used play a role fully as important as that of the machine itself. The firms who begrudge every penny that is spent upon accessories, and simply install a milling machine in the shop provided with plain cutters and arbors, and one or two ordinary vises, and then expect the operator to take any kind of a job and prove the excellence of the machine as compared with a planer or shaper, are greatly mistaken as to the best way of getting the full efficiency out of a milling machine. In such a case one might even say that a great deal of the money paid out for the machine itself is practically wasted. Still, the idea that when a high-grade milling machine is installed in the shop, all that is necessary has been done, is a greatly prevalent view, and one which is altogether too common where men, not directly acquainted with the mechanical operations of a shop, and all the little details combined with it, consider themselves able, with little or no advice from the actual operators, to equip the shop in the manner tending to give to each machine its greatest efficiency. In such cases a good machine, which would prove an excellent tool if equipped in the best way, might prove less efficient than older methods. The result is a greatly reduced output and the machine, and sometimes the operator as well, are blamed, when really the cause of the trouble is to be found in the inexperience, and perhaps stinginess, of the very persons who would be most benefited by the additional outlay necessary for proper cutters and fixtures.

AN APPALLING BRIDGE FAILURE.

Never has the engineering world been so inexpressibly shocked as by the awful collapse of the partially built Quebec cantilever bridge spanning the St. Lawrence River. On August 29 the completed south cantilever span, with a section of the suspended span went crashing down into a mass of inextricably tangled wreckage. Of the 85 men at work 74 lost their lives and all the remaining 11 were badly hurt. The loss of life and property is enormous, but still greater is the loss of engineering reputation and prestige. The world regards with amazement and horror an engineering work costing millions, on which years of presumably the best engineering talent of America had been employed with a result so pitifully futile. One-half of the greatest bridge of its type ever designed, having a clear span of 1,800 feet and requiring 38,500 tons of structural steel in its entirety has collapsed of its own weight.

The disaster loses little of its stunning force or reproach to the engineering profession because it apparently suggests that an unknown source of weakness exists in very large and long compression members. That such a condition may exist is what the *Engineering News* would have us believe from reading its seven-page report and masterly editorial (issue of September 5) which are technical efforts seldom surpassed. But it is hard to understand how the deductions of engineers in regard to members carrying compression loads could have been so signally at fault, notwithstanding the absence of experimental data on very large columns. Such an admission would suggest that our entire theory of the strength of materials may need revision. Rather would we accept the suggestion that chord *A9L* had been structurally or molecularly disorganized by the several accidents befalling it before erection, or that a serious mistake was made in its design, especially in the matter of side-staying. The fact that it was the apparent initial source of failure will go a long way with the layman, notwithstanding any engineering testimony to the contrary implying that its various mishaps were of no important ultimate effect.

* * *

THE STATUS OF THE DRAFTSMAN.

From several points of view, the draftsman occupies a more peculiar position in the modern shop than many of the other workers who make up the organization. The draftsman is considered by many a manager as a kind of necessary evil, a dead expense, which he cannot avoid. For behold! the drafting-room is a non-productive department. At the same time the drafting room of any well-organized shop is recognized as the heart of the industrial end of the business, in which the planning and systematizing forces, at least to a large degree, are located. The draftsman himself occupies a very different ground in different shops, according to whether the former or the latter view expressed is the prevailing one in a particular organization. Of course, there are draftsmen and draftsmen. There are those that are valued at $10 a week or less, and those that are valued at $40; and this fact, too, tends to place the knight of the T-square in a peculiar position. There are no very well defined limits to his trade. He is more or less what one might call a free lance. In many a case he is not even a distinct part of the regular organization. He is called in when a new design is to be turned out in the drafting-room, and when that is done he is "laid off." At least, this is the case in the majority of smaller shops, specializing on one or a few kinds of standard machines. The last contention may, perhaps, not apply to the leading designer, but it most certainly applies to the ordinary draftsman.

The conditions outlined are by no means very satisfactory, but it is difficult to propose a remedy. It has been suggested that men in the shop, having training in drafting, be temporarily taken into the drafting-room to help out when business there is pressing, rather than to hire draftsmen for short terms. But this course would be subject to many objections. In the first place, nobody does the draftsman's work as well as a trained draftsman, constantly working at his trade. In the second place, it is not at all sure that the very men with drafting experience, wanted from the shop, can be spared there at a particular time, and last, but not least, the man, who at first would be only temporarily taken from the shop for drafting-room work, would soon find a certain attraction in his new occupation, and, in nine cases out of ten, he would not return to the shop again, but continue on what, at first sight, seems to him the rosy road of the draftsman. To the ordinary shop worker, the drafting-room has at first many attractions. The work is cleaner, the duties, at first, less exacting, the surroundings more pleasing, and the hours generally shorter. In the long run, however, it is evident that the draftsman, having passed through the stages of assistant to that of independent designer, finds the limitations greater in this department than in the productive departments in the shop. That is why we find so few old draftsmen. We do not realize where they go to; all we know is that they disappear from the drafting-board as they grow older.

The cause for this is perhaps the kernel of the matter of the comparatively unsatisfactory status of the draftsman. After long years of close attention to business, he has become an expert designer, and his work requires all the mental qualities present only after years of training and experience. His general intelligence, measured in units of logic, is greater than that of most of his cooperators in the industrial organization. He is the ingenious planner and schemer of profit-making devices, and even though, in certain cases, some ideas are furnished him by "the man higher up," these ideas, as a rule, are furnished in such a crude form that the draftsman is but little helped in his work. When the device is completed, however, the honor of the successful working does, curiously enough, not fall upon the one to whom the most of the credit is due. When we also consider that the compensation paid to the most skillful of machine designers is often, not to say nearly always, less than that of department foremen, many of whom in intelligence and general ability are far inferior to a trained designer, then it is easily seen why we find the draftsmen leaving the chosen trade, as soon as they have reached middle age, to seek more congenial occupations. This, however, is a distinct loss to the industries as such. The best and ablest men, the most experienced designers, are lost to the craft at the very time when their services would become most valuable. If the draftsman were considered a more integral part of a shop organization, if his merits were recognized, rather than usurped, by his superiors, and if his compensation stood in a more equitable proportion to his achievements, he would be less tempted to leave that place in the industrial organization where he serves the best, for other occupations, far better compensated, but requiring no more intelligence, judgment or ability.

* * *

An item of mechanical interest appeared in the June issue illustrating the power of a small force to displace plastic substances such as asphalt, cobbler's wax, etc. Another illustration that is of considerable scientific interest is the alleged cause for the winding grain of certain trees. It is asserted that the cause for the twisting grain of trees having wide-spreading branches is the rotation of the earth on its axis. It is well known that the rotation of the earth causes whirlwinds or cyclones in the air, and vortices in water. In the northern hemisphere these always move in a counter-clockwise direction, and it is claimed that the trees are twisted in the same direction by the same force. The cause of whirling motion in air and water is the slight difference in the earth's motion between any two points on a line of longitude. A railroad train, for example, running on a straight track toward the north, in the northern hemisphere, crowds over to the right-hand or eastern rail, and when running to the south it again crowds to the right-hand rail, but which is now the western rail. The reason is that the inertia of the train causes it to move ahead of the earth's motion, or fall behind it, depending upon whether the travel is north or south, on account of the velocity of the earth's surface decreasing as we approach the poles, or *vice versa*. The influence of the counter-clockwise air currents and the inertia of the sap, rising from the roots and flowing from the trunk out towards the limbs, is believed sufficient, though slight, to give tree trunks, plants, etc., a twist counter to the motion of the hands of a clock.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

On the German state railways accumulator cars have been running since last February on three railway lines. The new cars run four to six times a day over a distance of about eight miles. The cars are three-axle cars built especially for this purpose. The batteries consist of 180 cells of 200 ampere-hours capacity. A car battery weighs about 10 tons and yields 685 kilowatt-hours. The car complete weighs 38 tons.

In our issue of May, 1907, we gave a general description of the system of transmission of photographs which has been developed and brought to comparatively high perfection in Germany. It is now reported that successful experiments have been carried out over a line of 320 miles from Munich to Berlin. The photographs were clearly transmitted over a commercial wire loaned to the experimenters by the government.

Speed trials were made during the month of August with the first-class battleship *Connecticut*, the first battleship of this class built at a government shipyard. In a series of fourteen runs over a measured mile, she averaged, according to *Engineering News*, for the best five runs, a speed of 18.73 knots. The *Louisiana*, her sister ship, built by the Newport News Shipbuilding Company, attained only 18.59 knots as the average speed of her best five runs.

Liquid fuel for locomotives is becoming more and more common in the southern portion of the United States as well as in Mexico. It is reported by the *Torreon Star* that the Mexican Central Railway is using 4,000 barrels of fuel oil daily, and is steadily increasing the number of oil-burning engines in its service. All new engines purchased are equipped for the burning of oil, and old engines are constantly being remodeled.

As a result of the Postal Union Congress held at Rome in 1906, when international postage stamps were authorized, France issued an international postage stamp on October 1, and it is expected that a British stamp will also be issued. The stamp can be sent to most of the countries in the Union to prepay a reply to a letter, and also in payment of small accounts (up to 20 cents). Orders for four million stamps were placed, and if the experiment is a success the issue will be continued.

In a recent issue of the *Annales des Ponts et Chaussées*, Mr. M. H. Le Chatelier contributes an article regarding the action of sea water on cement and concrete, in which he states that all hydraulic binding agents without exception may be decomposed by sea water, although the rate of this action varies within wide limits. The most essential condition to render cements immune from decomposition in the sea is to reduce as much as possible the volume of water employed in gaging the cements.

The navigable dimensions of the Suez Canal have been practically doubled during the last twenty years. Taking the canal as a whole, its width at the water level in the northern half is from 300 to 360 feet, and in the southern half from 240 to 300 feet. In 1902 the maximum draft was raised from 25 feet 7 inches to 26 feet 3 inches, and in 1906, to 27 feet. The mean duration of transit is about 18 hours for all vessels, but the general effective rate for mail steamers is 15 hours. The length of the canal is 100 miles, and the ordinary rate of speed thus is 6 2/3 miles per hour.

A miniature head telephone has been developed in Sweden, according to a consular report. The receiver is said to measure ½ inch by ⅝ inch, and over the diaphragm may be screwed a cover continued into an ear tip. The connection to the receiver may be a fine flexible cord carried like an eye-glass cord. No helmet or other attaching device is required to hold the receiver in place. The instrument is thought to be valuable both to telephone operators and to individuals with defective hearing, the latter also carrying a transmitter, etc., on the person. The device was invented by the chief of the government telephone department.

The immense 41-story tower of the Singer Building on Broadway, New York, is rapidly going upward, and by the time this item is printed the entire framework will be completed. When the tower is completed, the flag-staff will be 652 feet above the ground. The unique appearance and great height of the structure will make it one of the most noticeable buildings in New York. On account of the great wind pressure that the structure will be required to withstand, the tower is built in a manner somewhat analogous to a bridge on end, so far as the bracing is concerned. It was designed to withstand a maximum wind pressure of not less than 30 pounds per square foot.

A correspondent to the *Times Engineering Supplement* describes the results of the trials of the Field-Morris system for increasing the thermo-dynamic efficiency of the steam engine. He states that by this system a saving of 24 per cent in fuel has been effected. The system consists of adding to the steam a certain proportion of air under pressure, this mixture then being superheated before being allowed to pass into the steam cylinders. The theory, upon which the saving claimed for this invention is based, is not manifest, but it is stated on good authority that the saving in several tests has been considerable, after due allowance has been made for power expended in compressing the air.

The new steel plant of the United States Steel Corporation at Gary, Ind., will be developed immediately on even a greater scale than was originally contemplated. It was originally intended to appropriate $75,000,000 for the construction of the steel plant and the adjoining new industrial town, but it has been decided that an additional $45,000,000 shall be set aside to be used in widening the scope and extent of the steel plant itself. When it is considered that in the neighborhood of $120,000,000 is to be expended in the establishment of what might be called one single industrial plant, the magnitude of the new steel works can hardly be compared with anything else of that kind that has so far been contemplated in this or any other conntry.

A subterranean canal, 4.3 miles in length, is, according to news dispatches from Paris, projected to connect the valley of the Rhone with the port of Marseilles. This tunnel will be, in point of quantity of material excavated, the largest in the world. It is estimated that 2,840,000 cubic yards will be excavated, against about 1,375,000 cubic yards for the Simplon tunnel. The latter is 13.8 miles long, but only 24 feet wide and 18 feet high; while the canal tunnel would be, with the towpaths on either side, 66 feet wide and 42 feet high. The canal would permit two barges to pass at any point. The cost of the tunnel, rendered necessary because the hills between the Rhone and Marseilles are too high for lock operation, is estimated at $6,900,000. The total cost of the canal will be $15,200,000.

A remarkable performance of a steam locomotive on a run between Munich and Augsburg is reported from Germany. The engine drew a load of 165 tons (150 metric tons) and developed 2,000 horse-power, maintaining for a considerable time a maximum speed of 96.5 miles per hour (154.5 kilometers). The whole journey of 40 miles was performed at an average speed of 81 miles per hour. It is claimed that the speed of 96.5 miles per hour is the highest speed that has ever been attained on a European railway with a regular train. The locomotive weighs 90 tons, and with its tender 147 tons. The Bavarian minister of transportation made the trip on the engine during the trials. The locomotive is of the 2—6—0 type, four-cylinder compound. The general

dimensions of the locomotive are: Diameter, high-pressure cylinder, 16 inches; low-pressure cylinder, 24 inches; stroke, 25 inches; diameter, driving wheels, 7 feet 2½ inches; diameter, truck wheels, 3 feet 3½ inches; total heating surface, 2,702 square feet; steam pressure, 210 pounds.

The vibration of the after-part of high-speed ocean liners driven by reciprocating engines is a serious trouble that has not been successfully overcome by any system of engine balancing. One of the swiftest of the ocean greyhounds, the Deutschland, has been most troublesome in this respect, although the engines are balanced by the Schlick system. The defect was recently largely overcome in an interesting manner. The pitch of the blades of the port propeller was reduced slightly, the effect being that the port engine runs eight revolutions faster than the starboard propeller in order to give the same effective thrust and speed of propulsion. This throwing of the engines out of step minimized the vibration of both the engines and the propellers. It long has been known by marine engineers that throwing the engines of twin-screw ships out of step tends to reduce vibration, but the trouble of doing this with propellers of the same pitch is the difficulty of steering, there being a tendency of the vessel to run in a circle, owing to the difference in thrust of the two propellers.

A peculiar action affecting the status of apprentices in Pennsylvania has been started by Thomas Carlin Sons Co., of Allegheny, Pa. The company has sued the fathers of six apprentices for $2,500 damages each under a law passed in 1713 which is known as the "White Slave Act." The boys were apprenticed to the firm for a term of 10,800 hours, divided into eight periods of 1,350 hours each, the pay being graded from 7½ cents per hour up to 16 cents per hour. Under the agreement the boys had the privilege of breaking the contract during the first period only, and after that they were bound to continue until the end of the term. The boys quit at the time of a machinists' strike, and refused to complete their contract; hence the action of the company to establish the rights of employers in apprentice indentures. If the suits fail, a precedent will be established that will make such contracts valueless in Pennsylvania, and will probably affect their standing in other states also. The defense will be that the contracts were burdensome, and that it would be an injustice to the minors to hold them to fulfill an indenture made by their parents.

The accompanying table, taken from *Zeitschrift des Vereines deutscher Ingenieuren*, gives some interesting figures regarding the estimated life of electric power and light installations. While being primarily of interest to electricians, this table has much of value for any one having to deal with depreciation of machinery and plant of this or similar character. The figures are collected from six different sources, from two English and two German authorities, and from the practice of English municipalities. On some points they will be found to vary widely, but, in general, all the various sources seem to agree fairly well.

Length of Life in Years of	Robert Hammond.	J. F. C. Snell.	Local Government Board.	London County Council.	German Sources.

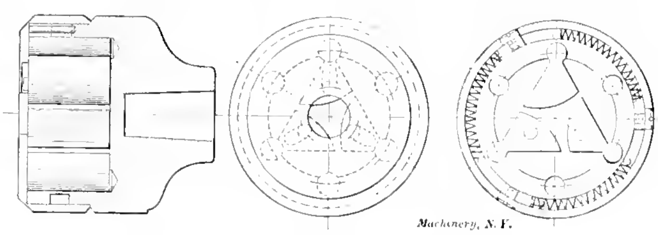
WIRELESS TELEGRAPHY ADVANCE.

The Poulsen selective system of wireless telegraphy, to which we referred in our engineering review in the February and March issues of MACHINERY, seems to be making rapid strides, and in one instance even to have established a record. The Poulsen system has been installed on board the *Hellig Olaf*, a liner belonging to the United Shipping Corporation of Copenhagen, and recently when that vessel was more than 2,000 miles distant in mid-ocean, a message of 21 words was despatched by her transmitter and successfully received at the Steglitz wireless telegraph station near Berlin, Germany. This is claimed to be the greatest distance a wireless message has ever been sent from ship to shore. In its career it passed over the ocean, across Great Britain, the North Sea, and again over the Continent to Berlin. This is the first time the Poulsen system has been worked on board ship. The American De Forest Company has, it is stated, covered 1,500 miles—from the West Indies to New York—and the Marconi system is continually doing long-distance work. But such messages have been from station to station or from shore to ship, not, as in the present case, from ship to shore, which is considered to be a much more remarkable feat.

GRIP CHUCK FOR STRAIGHT SHANK DRILLS.

Engineering, May 10, 1907.

A drill chuck working on the well-known eccentric clamping principle has recently been placed on the market by Ludwig Loewe & Co., Ltd., Farrington Road, London, E. C. The principle of this chuck is plainly shown in the accompanying cut. It is intended for instantaneous and automatic gripping of drills with straight shanks. The chuck takes drills from ⅛ inch to ½ inch in diameter. No key is employed to tighten or loosen the jaws, and there are no internal gears or screws in its construction. The milled cap covering the jaws has three radial slots in its inner face, which engage with pins on the respective jaws. The jaws terminate in cylindrical portions, about which they rock when the cap is rotated. Inside the cap are springs, which, acting



Grip Chuck for Straight Shank Drills.

between stops on the body of the chuck and other stops fixed to the cap, tend to cause the rotation of the latter, and so to close the jaws. The latter are serrated on their working faces, and these faces are so curved that the torque of drilling will clamp the drill and increase the tightness with which it is held. It is claimed that the grip is so efficient that high-speed drills may be driven with their full cutting efficiency, and in actual tests ½-inch drills of high-speed steel have failed under the work before the shanks have slipped in the chuck.

THE COST OF POWER PRODUCTION.

Western Electrician, June 8, 1907.

Prof. Charles E. Lucke, of Columbia University, having made a study of the subject of the comparative cost of various methods of producing power, with special reference to electric power stations, has collected some figures which he presented in a paper read before the American Electrochemical Society. He compared water-power development, oil engines, gas engines and producers, and steam engines, assuming a 24-hour continuous load in each case. In the case of the oil engines, 250-horse-power units coupled to 160-kilowatt generators were taken for example, and the station was supposed to contain six such units. As typical of steam engines, a plant of six 5,000-kilowatt units was selected, while for gas engines a station containing six 1,000-horse-power units

driving 600-kilowatt generators was chosen. Steam turbines were not considered in the steam plant, the author saying that the net result would not be very different from that of the reciprocating engines. Under these assumed conditions the comparison of power cost was figured as follows:

Water-power—First cost per kilowatt rating, \$75 to \$200; total power cost per kilowatt-year, \$8.50 to \$25.

Oil Engines—First cost, similarly, \$217; cost of power per kilowatt-year, \$78.64.

Gas Engines and Producers—First cost, \$270; annual cost of power per kilowatt-year, \$65.54.

Steam Engines—First cost, \$110 to \$150; power cost per kilowatt-year, \$85.50 to \$97.50.

The hydro-electric plant shows up very favorably, although it is to be noted that the cost of transmission is not included. The author thinks it likely that gas power will be cheaper than steam when the load factor is high, and that the difference will be greater as the cost of coal is greater. The figures given, of course, are only correct in a general way, "for," says the author of the paper, "the determination of power costs is not only a question of geographical location, a question of the generating system, a question of the size of the apparatus, a question of the perfection of its design, a question of the load location, but it is also a question of accounting, and the engineer engaged upon a question of this sort must not only be an engineer, but something of a financier and an accountant."

CENTRIFUGAL PUMPS FOR DEEP WELL PUMPING.

Abstract of Paper read by Mr. C. B. Burdick before the Western Society of Engineers, June 5, 1907.

This paper contains some interesting information relating to a new development of the centrifugal pump—namely, its use for lifting water from deep, driven wells. The first one built in this country was made by Mr. John W. Alvord as an experiment for a client, in 1902. The pump was so designed that various forms of impellers could be tried. This pump, fitted with the best impeller, showed an efficiency of 50 per cent when operating at 1,640 revolutions per minute, and discharging 835 gallons per minute against a head of 38 feet. The experimental pump had one impeller only and was designed to be used in a 12-inch hole. One of the most satisfactory features of this design was the means taken for handling the down thrust. Not only is there the weight of the long shaft and the wheel to be considered, but the reaction as well, due to the lifting of the column of water against the static and frictional head. The balancing was effected by means of a chamber in which pressure was maintained by leakage from the discharge side of the pump. When the pressure became great enough to lift the impeller and its attached shafts from the thrust bearing, by which it was hung at the top, discharge ports were opened by this movement which relieved the pressure so as to allow the parts to settle again. In the tests it was found that as soon as the pump came up to speed, the shaft was lifted about 1/16 inch and rode entirely clear of the balls in the thrust bearing provided at the top of the shaft. In this design both the impellers and the balancing chambers can be compounded for high lifts.

The water works at La Grange, Ill., are supplied with centrifugal pumps of this kind built by Mr. Byron Jackson, of San Francisco, Cal. His company is believed to be the first to place this type of machine on the market. The preliminary investigations seem to indicate that the pump efficiency is about 50 per cent, and the efficiency of the motor by which it is driven about 85 per cent. The motor is, of course, a vertical one, being a 25-horse-power Westinghouse three-phase induction type running at 112 revolutions per minute. It is connected to the shaft by a flexible leather link coupling.

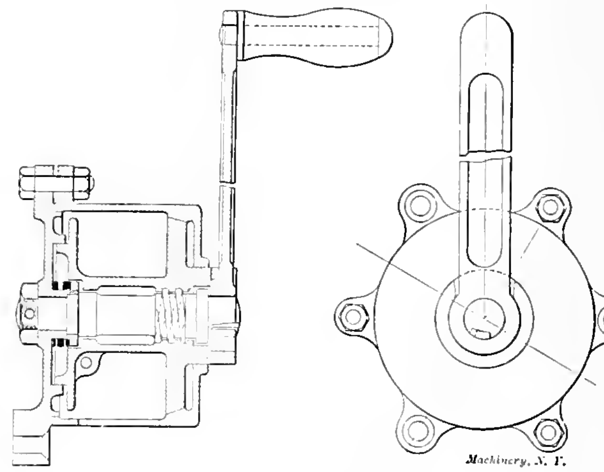
The obvious advantage of a pumping equipment of this kind is in its simplicity and compactness. It also has the advantage over the reciprocating pump of moving the column of water at a constant speed, not requiring it to be started and stopped at each end of the stroke.

SELF-SUSTAINING WINCH.

Page's Weekly, June 28, 1907.

The accompanying cut shows an ingenious, but simple, form of winch, originated in Great Britain. The chief features of the winch are that it is direct-driven, and that the drum is forced against and locked to the casing by the tension on the wire rope. In consequence of the latter feature, the greater the weight suspended, the more secure the hold will be.

The winch is provided with a common casing. This casing has at its central part a bearing, which supports one end of the shaft. The outer portion of the shaft is provided with a screw which engages with a corresponding screw thread in the drum. The periphery of the outer flange of the drum is coned and normally engages with a coned surface on the inner side of the outer part of the casing. The outer portion of the drum has a central boss which is supported in the casing and slightly projects beyond it. The end of the boss is recessed at its center to receive a crank handle. The hole



Self-sustaining Winch.

of the crank handle has an inwardly projecting lug, which engages with a slot cut in the end of the threaded shaft. This slot is made wider than the lug to allow the crank handle, during winding, to first move freely on the shaft, while the drum is being unlocked from the casing before the two move together. A portion of the metal around the recess in the center of the boss is removed so that the crank handle can drive the drum in one or the other direction, the gap so formed being of such width as to allow, during unwinding, an initial movement of the shaft with respect to the drum. A spring is placed between the inner end of the shaft and the casing to create a slight retarding movement on the spindle.

To use the winch the handle is placed on the outer end of the threaded shaft, the lug or key in the handle passing into the slot of the threaded shaft, and the web of the handle into the gap in the outer portion of the boss. To raise a load the handle is turned forward. This causes the handle to engage with the forward face at the end of the gap, and the drum to be turned on the shaft until the lug in the hole of the handle comes against the forward face of the slot in the shaft, when the drum and shaft will revolve as one. To unwind the drum, the handle is turned in the opposite direction. In this case the lug in the boss of the handle first bears against the forward face of the slot in the shaft, and forces the drum inward, after which the drum and shaft revolve together. Immediately the handle is released, either during winding or unwinding, the tension on the cord causes the drum to be turned on the shaft and to be forced against the casing. This device is made by Bernard Metz, Great Winchester St., E. C., London, England.

ROPE DRIVE FOR MACHINE TOOLS.

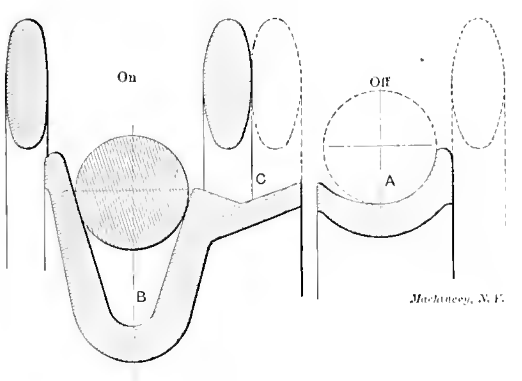
The Engineer (Chicago), July 15, 1907.

Hitherto rope drive has not been practical for machine tools of the variable speed type, such as lathes, shapers, drills, and drilling tools, because speed changes were usually procured by coned pulleys modified by throwing in or out the back gear. While a power rope can be shifted from one groove to

another, the operation is so tedious and time consuming, that it cannot be applied to the often swiftly succeeding speed changes of modern machine shop practice. Hence belts have generally been used for these varying transmissions.

Of late, however, a number of single pulley drives have been introduced on tools of this class, in which speed changes are effected by lever-controlled change gears. This system has the great advantage of increasing the power delivered to the cutting tool by high initial belt speed. With a constant speed for the driving shaft, the cutting power is the same at high or low speed. Speed changes can be made very quickly, and a far greater range of changes can be obtained than with stepped pulleys. As the new design of speed changing is meeting with much favor among manufacturers on account of its advantages, and as transmission rope offers the ideal means for supplying power to constant speed shafts, we may look for a great increase in rope driving in future machine shop installations. This will result in marked economy of space, as the rim surface for rope sheaves is much less than that required for belting, which in turn means more rigidly supported shafts, as there will be less spring between the closer spaced bearings. It will also greatly decrease the noise of driving, and the loss of power from slipping. Properly laid and lubricated rope is not only much cheaper than belting, but requires no expense to speak of for dressing, lacing, cleaning and taking up slack.

Though we are not accustomed in this country to see driving rope shifted from an idle to a working pulley, it can be done just as well as with a belt, and is a matter of common occurrence in England. In a number of large cotton mills in the Lancashire district, the power is conveyed from a line shaft running the whole length of the room to numerous ring frames by means of ropes instead of belts, the ropes operating on fast and loose pulleys mounted within guard boxes.



Rope Drive for Machine Tools.

In this combination a shifting arrangement is used, illustrated in the cut, which could well be adapted for the drive of constant speed machine tools. The idle or loose sheave *A* has practically all of its flange cut away on the side towards the working of fast sheave *B*. To throw the machine into action, a curved rope shifter or fork is used, shown in section in the cut. It is bent to the curve of the sheave with very small clearance above the sheave flanges, and is operated with a pivoted hand lever. Referring to the cut, as the arm of the fork engages the driving side of the rope, it pushes the latter clear of its reduced flange onto the intermediate groove *C*, cut in the fast sheave. The shifter continuing toward the left, presses the rope into the groove *B*, whence it is readily forced out by reverse movement of the fork whenever the machine is to be stopped.

One objection is that to secure sufficient speed, the sheave on the lathe would have to be so small in diameter that quite a number of ropes would have to be used, which would make the face of the sheave as wide, if not wider, than a belt pulley for the same power. As the drive contemplates a lathe equipped with gears for changing speed, this objection falls away because one single rope can carry a great deal of power to a tool provided with a large sheave, and as gearing is going to be used anyhow, the speed of the first driver shaft can be varied at will. That almost any machinist can lace a belt, whereas practically none can splice a rope is an objectionable feature of constantly diminishing weight, because in the first place a rope does not need to be spliced nearly as often as a belt needs to be laced, and with the rapidly increasing use of transmission rope, the practice is growing of having at least one expert drive rope splicer attached to each large industrial establishment.

METAL AND RAW HIDE PINIONS FOR MOTOR DRIVES.

Wilfrid L. Spence, in *The Mechanical Engineer*, July 13, 1907.

In regard to the question of pinions, ordinarily a raw hide or paper pinion is much better than a metal one. Both materials named, apart from their surroundings, are utterly unmechanical; they depend absolutely on outside support to carry load, and whenever axial compression is relieved, the teeth bend over, lose their true form, become noisy, and rapidly deteriorate unless the load is light out of all proportion to dimensions. The weak point of most built pinions is the shrouding—the side plates are not usually stout enough to hold the hide or paper up to its work.

The very few failures (all several years ago) out of an extremely large number of applications of which the author has cognizance, were due to thin side plates necessarily accompanied by inadequate compression. This question is, of course, very much one of the point of view, for if, as indicated, the general wheel dimensions are chosen so large that the tooth load is light, then correspondingly lighter side plates may answer, but unquestionably that is expensive design. The author's practice, which has been quite successful in respect of smallness of wear, has commonly been to load the pinion as if it were of cast iron, and under such conditions the standard side plates are not adequate. Without being able to justify it theoretically, he has found that the empirical formula

$$t = 0.5\ P + 0.025\sqrt{D} + 0.25 \text{ inches,}$$

where

t = thickness of side plate, in inches,

P = circular pitch of teeth, in inches,

D = pitch diameter of pinion, in inches,

agrees closely with heavily loaded successful pinions designed in a wide range of sizes by eye—*i. e.*, to look right mechanically when drawn out full size.

In the design of any pair of motor gears the determination of the ratio, width of face to pitch of teeth, is of prime importance. For cheapness, the ratio must be small; for every other consideration it should be large. The old mill-wrighting proportion of 3 to 1 or thereabout, appropriate with cast wheels, is inadequate to meet present-day requirements, and it is no uncommon thing to find the working width of wheels equal to or greater than six times the circular pitch. The problem is to find a mean between the cheap, but noisy, and the more expensive silent wheels. The determining factor is the peripheral velocity in ordinary wheels and the speed of meshing in complex forms. Starting with a minimum ratio of 3 to 1 for no velocity, ending with $6\frac{1}{2}$ to 1 for 2,500 feet per minute, and aiming at between 5 and $5\frac{3}{4}$ to 1, which are known to be good proportions for the range of moderate speeds ordinarily met with, the author sketched out some years ago a curve to systematize his work. This curve agrees with

$$R = 3 + 0.05\sqrt{V}$$

where

R = ratio of wheel face to pitch of teeth,

V = peripheral velocity or speed of meshing in feet per minute.

This rule is again empirical, and has no other justification than that it agrees with a lot of successful and economical examples, and cannot in any case be very far from basic fact. In applying it the limitation of available shaft length has to be kept in view, as also the possibility that with great overhang an outer bearing may be necessary.

Regarding the strength of, or permissible loads on, spur gear teeth, the writer has for many years used with complete success the methods of Wilfred Lewis, and would confidently recommend their adoption to those who, and their number is legion, in the design of gearing have hitherto relied

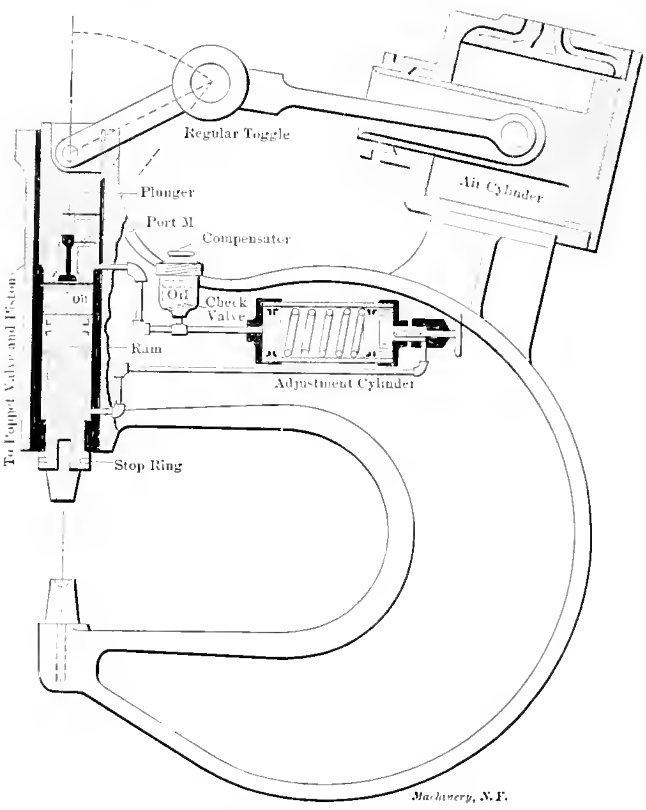
on mill-wrighting data which take no account of either peripheral velocities or of the number of teeth as affecting the permissible tooth load.

[The Lewis formula and tables for the strength of gear teeth are given in the following MACHINERY DATA SHEETS: No. 22, July, 1903; No. 62, October, 1906; and No. 64, December, 1906.]

SOME LATE IMPROVEMENTS IN COMPRESSIVE RIVETERS.

Paper read before Engineers' Society of Western Pennsylvania by Chester B. Albree

The comparative advantages of the various forms of compressive riveters—hydraulic, hydro-pneumatic, direct pneumatic and pneumatic toggle-joint—have been considerably discussed and are fairly well understood. Each of them has certain advantages not possessed by the other. In a paper read by Mr. Chester A. Albree before the Engineers' Society of Western Pennsylvania is described a new riveter in which some of the advantages of the various forms are combined.



Pneumatic Toggle-joint Riveter, with Automatic Adjustment for Thickness of Work.

together with some additional improvements not hitherto attained. This riveter has the action of the toggle-joint type, with its increasing pressure towards the end of the stroke, where pressure is most needed in heading the rivet. It also has the valuable feature of the plain hydraulic machine in not requiring adjustment of the riveting jaws for work of different thicknesses. The machine is self-adjusting in this respect, and always gives the same terminal pressure, even though the thickness riveted may vary from one stroke to another. The following paragraphs are a digest of the paper referred to.

In the cut is shown the perfected form. The piston in the air cylinder is connected to the plunger by a toggle mechanism of the usual construction. The pressure from the toggle is transmitted to the top of the ram and also through a pipe to the adjusting cylinder. The ram being small in area and free to move, advances rapidly and continues until the rivet die on its extension strikes the projecting rivet. As the plunger continues, the pressure in the cylinder is limited by the pressure due to the spring in the adjusting cylinder, there being free communication to it through port *M* and the pipe shown. This pressure is only 20 pounds per square inch, insufficient to upset the rivet beneath the ram. Hence the liquid will now displace the piston in the adjusting cylinder, the ram remaining stationary.

Referring to the cut it will be noted that the extension of the plunger, when fully up, still projects into the smaller area of the ram cylinder; and that cup leathers are used to pack it. In the interior of this extension is a valve of the poppet type, but having a stem carrying on its end a small piston. This valve is normally held open by a spring. So long as the pressure above and below this small piston is the same, the spring holds the valve open, but when the pressure below is greater than above the piston will move up, closing the poppet valve. This occurs only when the port *M* leading into the space below the small piston is closed, due to its passing from the large diameter bore to the smaller ram bore. When closed, the toggle pressure acts on the liquid below the plunger extension, raising the pressure sufficiently to move the small piston and connected valve, and later exerting very high pressure on the poppet valve, shutting it perfectly tight.

During the downward motion of the ram the liquid beneath it is forced into the opposite end of the adjusting cylinder, against the spring pressure. It is obvious that the ram may move its whole adjusting stroke, or not at all, up to the time when port *M* is closed by entering the smaller diameter of the cylinder; after which the further travel of the ram is that of the plunger, until the ram meets opposition greater than the pressure of the toggle, when it will stop. This arrangement, therefore, automatically adjusts the point of maximum pressure to suit the work. On the return stroke we have the direct pressure beneath the ram, as well as the suction of the plunger, to raise the ram to its original position.

Leakage of the liquid is made up from a small storage, or compensating cylinder, full of liquid, having a piston with a spring behind it, connected to the larger bore of the plunger by a pipe, having a check valve in it. Whenever there is pressure in the plunger cylinder, the check valve remains closed; but when the toggle is fully back, and the piston in the adjusting cylinder is against its cylinder head, so that no pressure due to its spring is exerted on the liquid, any loss of liquid will tend to create a vacuum in the plunger cylinder, and then the check valve will open, and oil flow out of the compensating cylinder, under the pressure of the spring acting in its piston, to replace that lost.

This riveter is built by the Chester B. Albree Iron Works, Pittsburg, Pa.

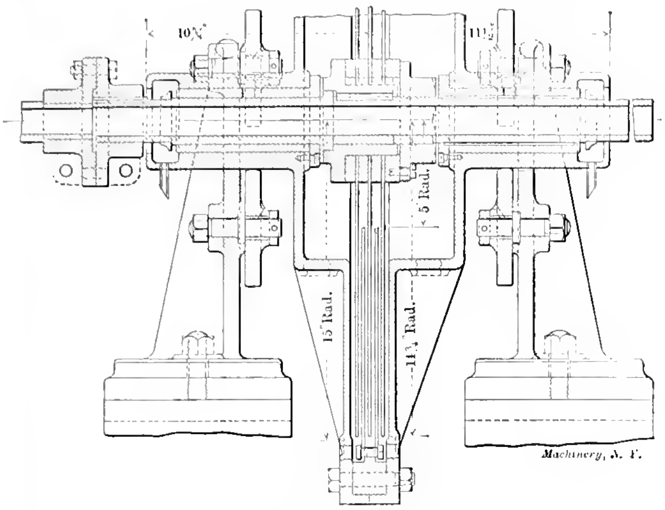
ABSORPTION DYNAMOMETER.

Engineering, May 31, 1907.

A novel form of dynamometer, made by Peter Brotherhood, Belvedere Road, Westminster Bridge, S. W., London, England, is illustrated in the cut herewith. This device is intended for comparatively high speeds, say from 300 to 1,200 revolutions, and is specially suitable for the testing of petrol motors, but its uses extend to the testing of motors of all classes. It is self-contained and independent, and may be made portable and be used anywhere, provided only that a supply of water is available. The dynamometer has been designed to supersede the unreliable and crude brakes of the Prony type, and at the same time to avoid the necessity of external appliances, and consequent complications of calibration associated with electrical and other forms of absorption brakes. As regards electrical testing sets, those most extensively in use require external resistances, volt and ammeters, etc., for the proper adjustment and reading of the load, and all these parts are liable to damage and deterioration. In the form of brake illustrated, there is no part liable to injury through neglect or rough usage, and the only external fittings required are flexible pipes for water supply, and a spring balance. Further, all the work given to the brake is definitely recorded, and no losses have to be reckoned. The principle employed is that of skin friction between plates and moving water.

The apparatus consists of a cast iron casing carrying long trunnions, supported on friction disks or ball bearings, about which the casing is free to rotate within limits. An arm, not shown in the cut, which is attached to the casing and projects to a fixed distance from the center, carries a spring balance to register the turning effort of the casing. The

shaft runs in bronze bushes in the trunnions, and carries one or more smooth disks of steel plate, of a diameter sufficient to occupy nearly the full diameter of the interior of the casing, there being placed between each pair of plates a ring of similar plate fixed in the joint of the casing. The fixed and revolving disks are separated and never come into contact. The brake is partially filled with water, and on the disks rotating, the water is carried out to their extreme edges, rotating with the disks, but at a slower speed. The energy of the motor under test is entirely dissipated by the friction of the fluid against the fixed and moving plates. Tho moment of this force tends to rotate the casing about the trunnions, the effort being measured by the spring balance fixed to the arm. It is evident that any friction of the



Absorption Dynamometer.

water, as well as of the shaft bearings, is duly shown on the spring balance, and the readings, therefore, always give a true record of the work given to the brake.

The water is introduced at the center of the casing, through a regulating cock, and drawn off at the rim. The quantity of water is adjusted, when the brake is in use, by a tube which may be set to project inward to any point toward the center of the shaft. The water inside this radius is discharged by centrifugal force, thus regulating the depth of the ring of fluid round the periphery of the disks. With a given quantity of water in the casing, and at all but the very lowest speed, the torque on the casing bears a fixed relation to the speed of rotation of the shaft, so that by increasing or reducing the water contents any conditions of torque and speed can be obtained.

MILLING MACHINE OUTPUT.

P. V. Vernon, in *The Engineer*, (London), May 31, 1907.

The reputation of the milling machine as a metal removing tool for enginering work is spreading, and it is, therefore, important to ensure that further progress shall be along the right lines. It is with this object that the following observations are offered, not with any intention of advocating a particular type of machine, but to note some of the conditions to be observed if the best output is to be obtained from any reasonably well designed machine.

The early milling cutter was called a fraise from a fancied resemblance of the toothed surface of the cutter to the rough exterior of the strawberry, and it may be owing to this that many milling machines are operated so as not to remove much more material than could be rubbed off with a hardened steel strawberry, instead of a properly designed milling cutter. The fact that each tooth is a cutting tool, with capacity for removing metal in much the same way as other metal-cutting tools, has been obscured by the association with it of many similar teeth on the same cutter, very little inquiry being made, as a rule, as to whether each tooth is doing fair duty, and the output of the cutter, as a whole, being judged by comparison with other milling cutters, and not by comparing the work of each cutting edge with that of other cutting edges of equal strength and with equal power behind them.

An examination into the question of the amount of cut taken by each tooth of a milling cutter shows that even when good milling, as generally understood, is being done, each tooth is taking a surprisingly small cut, and it is very seldom that the cutting edges fail through the heaviness of the cut when properly made and properly run. The accompanying Table I contains particulars of a number of milling cuts which are regularly performed, and which may be said to represent a good output (A. D. 1907) although not by any means the maximum possible output of the various cutters. It will be seen that although the feeds are fairly thick, yet the feed per tooth is quite small, and it may be fairly inferred that the cutters themselves might be made to do a great deal more work if other conditions permitted. The feeds are tabulated in three different ways, showing that the feed per tooth does not bear any fixed relation to the feed per minute, or to the feed per turn, neither of which, therefore, can be taken as a gage of the possibilities of output of the cutter, the feed per tooth and the cutting speed being the really important factors in the problem.

The usual limitations of output, when milling, are caused by spring or chatter due to weakness of the work, lack of driving power, weakness of the machine, or of the cutter arbor; weakness of the feed motion; weakness of the body of the cutter, not of the teeth; or insufficient room for chips. In order to get the maximum amount of work then from each tooth of the cutter, it is necessary to give attention to the following requirements, assuming that the work is massive enough to stand the heaviest cut that will be taken:—

(1) Sufficient driving power.

(2) A strong enough machine.

(3) A stiff enough arbor.

(4) A regular and powerful feed.

(5) Enough metal in the body of the cutter.

(6) Ample room for chips; in other words, teeth of coarse pitch.

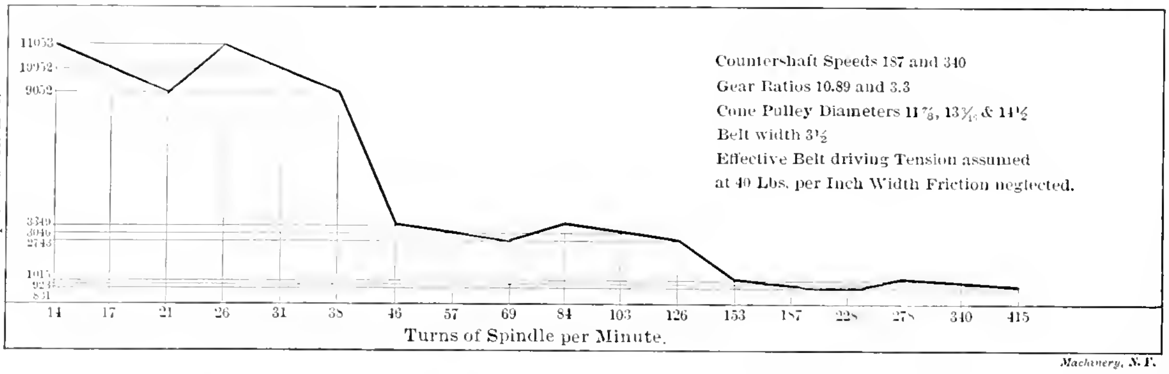
I have no hesitation in stating my belief that the above six factors have very much more influence on the output of a milling cutter than the actual power of the tooth to resist the stresses that come on it. In order to determine the importance of each of these six vital factors in relation to the work of the cutter, it is best to consider them one at a time.

1. *Sufficient Driving Power.*—The maximum power deliverable to the machine is merely a matter of dimensions of its driving parts, but a much more important matter is the power available at the cutter on the different spindle speeds. The accompanying torque diagram is for a modern milling machine of cone pulley type, with all the latest improvements in the way of wide belts, large pulleys and double back gears, and it will be seen that the actual torque or driving effort available at the spindle varies in a more or less irregular manner. Now, assuming the number of teeth in cutting contact with the work to be constant, the torque required for a given cut per tooth is perfectly regular, and varies directly as the width of cut and as the diameter of the cutter. It is, therefore, important when doing fast milling to select a cutter of such diameter that, when running at its correct cutting speed, its driving torque will not be at the bottom of one of the valleys of the curve in the cut unless the power of the machine is enough to give ample torque even in the deepest valley. Subject to this and other reservations to be dealt with later, the diameter of the cutter should be as small as possible.

2. *A Strong Enough Machine.*—That is to say, a machine of which the frame, spindle, slides, and other parts are sufficiently strong to enable the whole of the driving power provided to be utilized at the cutter without chatter, flexure, or vibration. This factor is one of correct proportion, not of absolute dimensions, and a single faulty element will seriously affect the work of the cutter.

3. *A Stiff Enough Arbor.*—A milling cutter arbor must be strong torisionally and transversely, as the arbor is the only connection between the cutter and its driving power. In general terms, it may be said that arbors for heavy milling are often too small to transmit the power which the milling ma-

chines possess, and which the cutters could utilize but for the weakness of their arbors. The torsional stress on the arbor due to driving a given cut varies directly as the diameter of the cutter, whereas both the torsional and the transverse strength of the arbor vary directly as the cube of the diameter. It therefore pays in many cases to increase the coarse pitch teeth occupy less space in proportion to their weight than thin chips, thus further favoring the coarse pitch cutter. Most of the published tables of milling cutter dimensions specify too many teeth in the cutters, and users of modern machines will be well advised not to rely on such tables, but to favor very much coarser pitches.



Variation of Torque with Change of Speed in a Modern Cone Pulley Driven Milling Machine.

diameter of the cutter, provided that the increase in diameter is also added to the arbor. The arbor, in fact, gains very much more than the cutter loses by the increase. Arbors should therefore be large.

4. *A Regular and Powerful Feed.*—The general experience of milling machine makers has decided in favor of a screw feed for heavy milling. It is not necessary to enlarge on various methods of feeding in this article, as the matter has been fully dealt with previously. It is enough to say that the feed must be sufficient in rate and in power to give as much feed to each tooth of the cutter as the other conditions will allow.

5. *Enough Metal in the Body of the Cutter.*—This condition further modifies the general maxim that cutters should be as small as possible. It is often desirable to make the cutter solid, so as to perform the double function of cutter and arbor. This may be said to give the smallest possible cutter with the largest possible arbor. Where, for reasons of cost or interchangeability, this cannot be done, ample thickness should be allowed, as nothing is gained in output by the use of a cutter so thin that it will not survive the maximum cut which the tooth will stand, which the arbor will transmit, and which the machine will drive.

The following table has been found satisfactory for general use, but is put forward more as a suggestion than with the idea that it is a final statement of ultimate possibilities:

TABLE II. NUMBER OF TEETH IN MILLING CUTTERS.

Diameter of Cutter.	No. of Teeth, Ordinary Finishing and Roughing Cutters.	No. of Teeth, Cutters for Heavy Roughing only.
⅛ in. to 3-16 in.	5	—
¼ in. to 13-16 in.	6	—
⅞ in. to 1¼ in.	8	—
1⅜ in. to 1½ in.	9	6
1⅝ in. to 1⅞ in.	10	6
2 in. to 2⅜ in.	12	7
2½ in. to 3⅜ in.	14	8
3½ in. to 3⅞ in.	16	9
4 in. to 6 in.	18	10

With roughing cutters made as per the last column, only one tooth will be cutting at a time on all ordinary roughing work. The spiral must, therefore, be such as to ensure continuity of torque, or the result will be an intermittent cut. A good angle of spiral for general work is 27 deg. with the axis of the cutter. It must not be forgotten that coarse pitch of teeth necessitates short pitch of spiral.

There are many more questions in connection with milling, on which definite information is required, if milling is to take its proper place in the economy of the machine shop, such as the effect of the feed per tooth on the cutting speed for different materials, the proper cutting and clearance angles for milling cutter teeth, and the proper ratio between power consumed and metal removed under the best conditions; but enough has perhaps been said to indicate that there may be points in connection with milling which do not receive attention from the average user, and that the successful use of milling machines depends upon a proper appreciation of these points. The labor-saving possibilities of milling machines properly designed, built, tooled, and handled, are perhaps greater than of any other metal cutting tools, and it is for the present generation of engineers to avail themselves of these possibilities to the fullest extent.

TABLE I. OUTPUT OF MILLING CUTTERS.

Cutter.				Cut.		Speed.		Feed.			Material Removed.	Material Milled.
Type.	Steel.	Diam., in.	No. of Teeth.	Width, in.	Depth, in.	Turns per min.	Feet per min	Inches per min.	Inches per turn.	In. per tooth.	Cubic in. per min.	
Face	High speed	2	12	1.125	0.187	200	105	9	0.045	0.0038	1.9	Cast iron

6. *Teeth of Coarse Pitch.*—A milling cutter will do more work when each tooth gets well under the surface; in other words, when the feed per tooth is sufficient to enable a cut rather than a scrape to be taken. With coarse pitch cutters, less teeth are cutting at one time, and a given feed power is more effective on each tooth than in the case of fine pitch cutters. There is also more room for chips. The space per tooth available for chips varies approximately as the square of the pitch of the teeth, and the total space for chips all round the cutter varies directly as the pitch. Coarse pitch cutters can also have stronger teeth than fine pitch cutters, as they permit of a wider land behind the cutting edge, without unduly robbing the space available for chips, and incidentally the thicker tooth is not so easily affected by heat generated while cutting. In addition to this, the thicker chips taken by

COOPERATIVE COURSES IN ENGINEERING AT THE UNIVERSITY OF CINCINNATI.

Abstract of Paper by Prof. Herman Schneider, read before the Society for the Promotion of Engineering Education.

The plan of combined theoretical and practical instruction, followed in the mechanical engineering course of the University of Cincinnati, was described in the March, 1907, issue of MACHINERY under the title "Unique Experiment in Technical Education." The paper, of which this is an abstract, gives further information as to the plan of this course, and tells something of the success that has attended it so far.

About six years ago the writer began what might be called a pedagogical research into the problem of engineering education. After a time he sifted the problem down to three question:

What requirements should the finished product of an engineering school fill?

Where and how shall we get the raw material to make the required finished product?

Through what process shall we put the raw material, in order to acquire the finished product?

The thorough investigation of these questions, carried on by visits to the largest manufacturing concerns in the Eastern and Middle States for six years, and still in progress, resulted in certain conclusions which seemed so radical that the writer hesitated to promulgate them until they had been actually tested. The present six-year course at the university is the outgrowth of these investigations, and it seems to have worked well enough so that the writer feels warranted in giving more publicity to the idea.

The length of the course is six years. During this period the students work alternate weeks in shops of the city throughout the scholastic year, and in the summer full time. Two facts are emphasized in this connection. First, the entrance requirements are precisely the same as for the four-years course; second, the university instruction under the cooperative plan is just as complete, thorough, broad, and cultural as the four years course. In fact it is rather more so. The course is not a short-cut to salary.

Young men desiring to enter this course are required to enter the shops in June or July preceding their entrance to the university. The process of elimination takes place during the summer work, which weeds out the weaker and more undecided ones, and leaves a residue which can be depended on for results. Last year 60 young men made application for entrance, and 45 of them undertook the shop work after learning the conditions of the course. Fifteen of these quit after they began, leaving a class of 30 in September. Three of these men have been dismissed for poor scholarship. This year about 400 inquiries and applications for admission to the course were received. Most of these faded away when they learned of the conditions. Up to this writing, 50 men had been placed in the shops for this year's class. There will probably be between 50 and 75 when the class is formed.

It is interesting to note the reasons which prompted these young men not to apply for work, or if they did apply, to quit work. Some of the reasons were: "It looked too hard"; "I had to get up too early in the morning"; "the work was too greasy"; "I'd rather be a lawyer"; "I want to complete my education in four years instead of six"; "my father said they did not pay me enough"; "my mother was afraid I'd get killed'"; "the boss spoke gruffly to me"; and so on. Some of the young men who withdrew from the cooperative course are in the four-year course.

A comparison of the work of the four-year freshman with that of the six-year freshman is interesting. The six-year cooperative students, though but working half the time of the regular students, have accomplished three-fourths of the work done by them, including all the mathematics and science of the freshman year. The course has been applied to the department of electrical, chemical and mechanical engineering. Attention is called to the fact that under this scheme the college is operated at the highest efficiency. Being given a certain sum of money to train a certain number of men, only those who by mental, physical and temperamental adaptability are worthy of the expenditure made, are retained.

[A recent report from the Cincinnati University states that nearly 60 young men have undertaken the course this year. This is double the number that began last year. About half of them are from Cincinnati and its immediate vicinity, the balance coming from all over the United States, as far west as Idaho, and as far east as Connecticut. The machine shops of the city appear to be much interested in the work, and enter into hearty cooperation with the University.]

COMPARATIVE COSTS OF GASOLINE, GAS, STEAM AND ELECTRICITY FOR SMALL POWERS.

William O. Webber, in *Engineering News*, August 15, 1907.

The comparative cost of the various sources of power is a matter of very great interest in installations of small power where any one is equally available and the sole determining factor is expense. In the usual determination of these relative costs it has been assumed that the total cost of a new plant was merely the cost of the machine plus the cost of the material required to run it, and that the additional cost of depreciation, interest, insurance, etc., would be the same in each instance. It is also generally assumed that the power costs just so much per horse-power regardless of the amount used. These are both very erroneous impressions.

The following tables give the itemized cost of 1 horse-power per hour on 2, 6, 10 and 20-horse-power plants, respectively, for gasoline, gas, steam and electric power.

Table I shows the cost of gasoline power, and is based on fact, not theory. All gasoline engines do not run on one-eighth of a gallon of gasoline per brake horse-power per hour, and to get at fair comparative results, proper allowances must be made for depreciation, repairs and insurance, as well as taxes, and the room occupied by the plant must be taken into account.

Table II shows the costs for the same powers driven by electricity It will be noted that proper allowance must be made for attendance, although this item is not generally charged as it should be. In this case nothing is charged for room, as separate power rooms are not required.

Table III gives the cost of gas power, using illuminating gas of 760 B. T. U. No estimate is made on the cost of gas power, using producer gas, as it would not pay to put in a gas producer for so small a unit.

In Table IV are given figures on the cost of steam power, from 6 to 20 horse-power, but no estimate is made on the cost for 2 horse-power, for the reason that such a plant would be too small to consider. The figures in Table V show a summarized comparison between the annual cost of power per brake horse-power for various kinds of motive power.

TABLE I. COST OF GASOLINE POWER.

Size of plant in H.P..	2	6	10	20
Price of engine in place	$150.00	$325.00	$500.00	$750.00
Gasoline per B.H.P. per hour	1-3 gal.	1-4 gal.	1-6 gal.	1-8 gal.
Cost per gallon.....	$0.22	$0.20	$0.19	$0.18
= cost per 3,080 hours	$451.53	$924.00	$975.13	$1,386.00
Attendance at $1 per day	308.00	308.00	308.00	308.00
Interest, 5%..........	7.50	16.25	25.00	37.50
Depreciation, 5%.....	7.50	16.25	25.00	37.50
Repairs, 10%.........	15.00	32.50	50.00	75.00
Supplies, 20%........	30.00	65.00	100.00	150.00
Insurance, 2%........	3.00	6.50	10.00	15.00
Taxes, 1%............	1.50	3.25	5.00	7.50
Power cost.......	$824.03	$1,371.75	$1,198.13	$2,016.50

To these figures should be added charges on space occupied as follows:

Value of space occupied	$100.00	$150.00	$200.00	$300..0
Interest, 5%..........	$5.00	$7.50	$10.00	$15.00
Repairs, 2%..........	2.00	3.00	4.00	6.00
Insurance, 1%........	1.00	1.50	2.00	3.00
Taxes, 1%............	1.00	1.50	2.00	3.00
Total annual charge for space	$9.00	$13.50	$18.00	$27.00
Total cost per annum.	$833.03	$1,385.25	$1,516.13	$2,043.50

Cost of 1 H.P. per annum, 10 hour basis	416.51	239.87	151.61	102.17
Cost of 1 H.P. per hour	$.1352	$0.0780	$0.0492	$0.0331

TABLE II. COST OF ELECTRIC POWER.

Size of plant in H.P.	2	6	10	20
Cost of motor in place	$83.00	$118.00	$216.00	$270.00
With wiring, etc.	100.00	130.00	240.00	300.00
Cost of electricity 3,080 hours	$529.56	$976.00	$1,425.00	$2,450,00
Attendance	20.00	30.00	50.00	50.00
Interest, 5%	5.00	6.50	12.00	15.00
Depreciation, 10%	10.00	13.00	24.00	30.00
Repairs, 5%	5.00	6.50	12.00	15.00
Supplies, 1%	1.00	1.30	2.40	3.00
Insurance, 2%	2.00	2.60	4.80	6.00
Taxes, 1%	1.00	1.30	2.40	3.00
Total cost per annum	$573.56	$1,037.20	$1,532.00	$2,572.00
Cost of 1 H.P. per annum, 10 hour basis.	286.78	172.86	153.20	128.60
Cost of 1 H.P. per hour	$0.0928	$0.0558	$0.0497	$0.0417

The costs for the electric current which are used in Table II are figured from the discount table shown as follows:

COSTS OF ELECTRIC CURRENT.

Base Price = 13½ cents per K.W. hour. Discounts on Monthly Bill.

Monthly Bill.	Discounts.	Monthly Bill.	Discounts.
$5	10%	$100 to $125	40%
$10 to $20	15%	$125 to $150	45%
$20 to $25	20%	$150 to $175	50%
$25 to $50	25%	$175 to $200	55%
$50 to $75	30%	$200 to $500	60%
$75 to $100	35%	$500 and over	65%

For 2 H.P. plant:

$$\frac{3{,}080 \text{ hours} \times 2 \text{ H.P.} \times 0.746}{82 \text{ per cent Efficiency}} = 5{,}604.1 \text{ K.W. hours per annum,}$$

then $5{,}604.1 \times \$0.135 = \$756.55$, annual cost without discount.
Monthly bill = $63. Discount = 30 per cent.

$$\$756.55 \times 70\% = \$529.56 = \text{annual cost.}$$

For 6 H.P. plant:

$$\frac{3{,}080 \text{ hours} \times 6 \text{ H.P.} \times 0.746 \times 0.135 \times 45}{86 \text{ per cent Efficiency}} = \ldots\ldots\ldots \$976.00$$

Monthly cost = $180. Discount = 55 per cent.

For 10 H.P. plant:

$$\frac{3{,}080 \times 10 \times 0.746 \times 0.135 \times 40}{87 \text{ per cent}} = \ldots\ldots\ldots \$1{,}425.00$$

Monthly cost = $298. Discount = 60 per cent.

For 20 H.P. plant:

$$\frac{3{,}080 \times 20 \times 0.746 \times 0.135 \times 35}{88.5 \text{ per cent}} = \ldots\ldots\ldots \$2{,}450.00$$

Monthly cost = $585. Discount = 65 per cent.

TABLE III. COST OF GAS POWER.

$1.50 per 1,000 cubic feet of gas less 20 per cent, if paid in 10 days = $1.20 net, gas 760 B. T. U.

Size of plant in H.P.	2	6	10	20
Engine cost in place	$200.00	$375.00	$550.00	$1,050.00
Gas per H.P. hour in cubic feet	30	25	22	20
Value of gas consumed, 3,080 hours	$221.76	$554.40	$843.12	$1,478.00
Attendance, $1 per day	308.00	308.00	308.00	308.00
Interest, 5%	10.00	18.75	27.50	52.50
Depreciation, 5%	10.00	18.75	27.50	52.50
Repairs, 10%	20.00	37.50	55.00	105.00
Supplies, 20%	40.00	75.00	110.00	210.00
Insurance, 2%	4.00	7.50	11.00	21.00
Taxes, 1%	2.00	3.75	5.50	10.50
Power cost	$615.76	$1,023.65	$1,387.62	$2,237.50
Annual charge for space	9.00	13.50	18.00	27.00
Total cost per annum.	$624.76	$1,037.15	$1,405.62	$2,264.50
Cost of 1 H.P. per annum, 10-hour basis.	312.38	172.86	140.56	113.22
Cost of 1 H.P. per hour	$0.1014	$0.0561	$0.0456	$0.0367

TABLE IV. COST OF STEAM POWER.

Size of plant in H.P.	6	10	20
Cost of plant per H.P.	$250.00	$220.00	$200.00
Fixed charge, 14%	$35.00	$30.80	$28.00
Coal per H.P. hour, in pounds	20	15	12
Cost of coal at $5 per ton	$154.00	$103.00	$82.50
Attendance, 3,080 hours	75.00	50.00	30.00
Oil, waste and supplies	15.00	10.00	6.00
Cost 1 H.P. per annum, 10-hour basis	$279.00	$194.80	$146.50
Cost of 1 H.P. per hour	$0.0906	$0.0832	$0.0475

TABLE V. ANNUAL COST OF POWER PER BRAKE HORSE-POWER.*

B. H.P. of Unit.	Steam	Electricity.	Gas.	Gasoline.
1	$600.00	$312.50	$380.00	$487.50
2	500.00	282.00	312.50	416.00
3	437.50	252.00	260.00	350.00
4	375.00	227.50	220.00	300.00
5	320.00	207.50	192.50	262.50
6	280.00	192.00	172.50	240.00
7	250.00	179.00	160.00	210.00
8	230.00	168.00	152.50	182.50
9	210.00	158.00	145.00	165.00
10	195.00	152.00	140.00	152.00
12	175.00	140.00	132.50	137.50
14	165.00	133.00	126.00	122.00
16	157.50	128.00	120.00	112.50
18	150.00	126.00	116.50	107.50
20	146.00	123.00	113.00	102.00
22	140.00	121.50	110.00	98.00
24	137.50	119.50	107.50	95.00
26	133.00	117.50	105.00	92.50
28	130.00	116.50	102.50	90.00
30	127.50	115.00	102.00	87.50
35	124.00	113.50	100.00	85.00
40	120.00	112.00	98.00	82.50
50	112.50	110.00	96.00	80.00
60	105.00	108.00	94.00	78.00
70	100.00	106.00	92.00	76.00
80	95.00	104.00	90.00	74.00
90	90.50	102.00	88.00	72.00
100	86.40	100.00	86.00	70.00

* Unit costs: Coal, $5 per ton; electricity, $0.135 per K.W.-hour; gas $1.20 per 1000 cubic feet, at 760 B. T. U.; gasoline, $0.20 per gallon.

* * *

UNUSUAL POWER HOUSE.

The most unusual power house of which we have ever heard has recently been completed for the Patapsco Electric & Mfg. Co., Ilchester, Md. This power house is located inside of a dam. The dam is of reinforced concrete and hollow, leaving a considerable amount of waste room which it seemed advisable to make use of in some way. The installing of the turbines and generators in this space reduced materially the cost of the installation, resulting in shorter and more direct passages for the water, and less expense for buildings. The part of the dam used for housing the plant is fitted with a false ceiling, hung 5 feet from the main shell of the structure so as to protect the apparatus from any water that might leak through the deck. The side next to the tail water is fitted with windows. These windows furnish plenty of light, even when the water is flowing over the dam two feet deep. The water for operating the turbines is taken through the deck 5½ feet below the crest of the spill-way. This helps to keep the trash rack free from drift wood, etc. Two waste gates are placed near the bottom of the dam, with the water passages under the floor.

* * *

According to the *Times Engineering Supplement*, Switzerland possesses in all about 1,000,000 horse-power of water power, which can practically be developed. Of this, one-fourth is already utilized, and new installations of large capacity are being erected for the purpose of generating electricity. The generating stations are situated in different places far apart from one another, but the districts served by the systems border on each other and can be connected with very little expense, so that if one generating station is short of power for one reason or another it can be supplied from another system, and *vice versa*. Thus, it is possible to supply current to one part of Switzerland from another part, and this, in general, improves the load factor of the generating stations.

FORMULAS FOR FORCE REQUIRED TO MOVE CRANE TROLLEYS.*

JOHN S MYERS †

In designing crane trolleys and similar constructions the force required to move them is not always calculated to a nicety, and the design then based upon the figures. This may be the conception of the man fresh from college, but it more frequently happens that past experience of a case similar to the one in hand is relied upon entirely.

This is both a safe and quick method, when conditions make it possible, provided good judgment is exercised in allowing for differences between the past construction and the proposed new one. The designer is, however, often confronted by a problem in which he has no past experience to draw upon and for which he has no applicable data at hand, or the design may be of a type similar to that of past experience, but so different as to sizes that he is compelled to calculate from elementary principles. Two troublesome questions then arise: First, what theoretical conditions should be taken into account and what ones may be safely neglected? and second, what values should be assigned to the various constants and assumed factors entering into the calculations? The practicability of his designs will depend almost entirely upon the manner in which the above questions are answered.

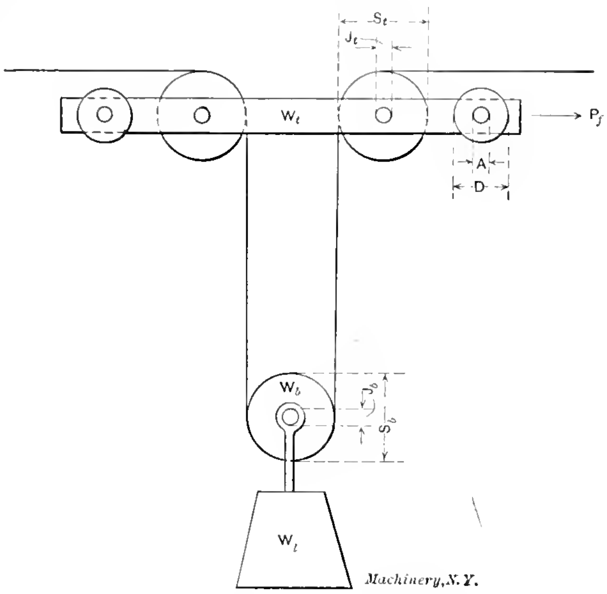

Fig. 1. Trolley with Sheave Suspended by Two Parts of Rope.

Taking up the subject of crane trolleys, of the type in which the load is suspended by ropes passing over sheaves in the trolley and hanging block, as illustrated in Figs. 1, 2, and 3, the above questions may be considered as mutually dependent upon each other, and might be answered as follows:

Take into account journal friction of the trolley wheels, trolley sheaves and hanging block sheaves; also the separate weights of load to be carried, hanging block, and trolley.

Neglect friction of ropes in grooves of sheaves, power necessary to bend ropes over sheaves, and the rolling friction of the trolley wheels on the track, allowing these to be taken care of by the assumed coefficient of journal friction.

Neglect inertia, also, for the usual speeds of crane trolleys, since the difference between the coefficient of rest and of motion is sufficient to produce the necessary acceleration.

In choosing the coefficient of friction consider the general conditions of lubrication as being poor, and consider that it is the coefficient of rest which is required. Assume this coefficient to be the same for all journals. A fair value is 0.1. Having settled these preliminary considerations, general formulas may be developed.

CASE I. (See Fig. 1.) The conditions are: Two parts of rope supporting the load, one sheave in hanging block, and two sheaves in trolley.

Let W_l = weight of load to be carried.
W_b = weight of hanging block.
W_t = weight of trolley.
P_f = pull on trolley to overcome friction.
S_b = diameter of sheave in block.
J_b = diameter of journal in block.
S_t = diameter of sheave in trolley.
J_t = diameter of journal in trolley sheaves.
D = diameter of trolley wheels.
A = diameter of trolley axle journals.
C = coefficient of friction.
F_b = friction of hanging block sheave.
F_{ts} = friction if trolley sheaves.
F_{tw} = friction of trolley wheels.

For Case I,

$$F_b = (W_l + W_b)\, C \frac{J_b}{S_b} \qquad (1)$$

The load being supported by two ropes, the load in each is ½ $(W_l + W_b)$ and, the arc of contact of the rope on the trolley sheaves being 90 degrees (α) the resultant pressure on the journals of each of these sheaves is ½ $(W_l + W_b)\, 2 \cos \frac{\alpha}{2}$ = ½ $(W_l + W_b)\, 2 \cos 45$ degrees.

For the two sheaves the resultant pressure amounts to

$$1.4\,(W_l + W_b).$$

From the above we get:

$$F_{ts} = 1.4\,(W_l + W_b)\, C \frac{J_t}{S_t} \qquad (2)$$

For the friction of the axle bearings of the trolley wheels, the weight of the load, hanging block, and trolley must be considered, thus:

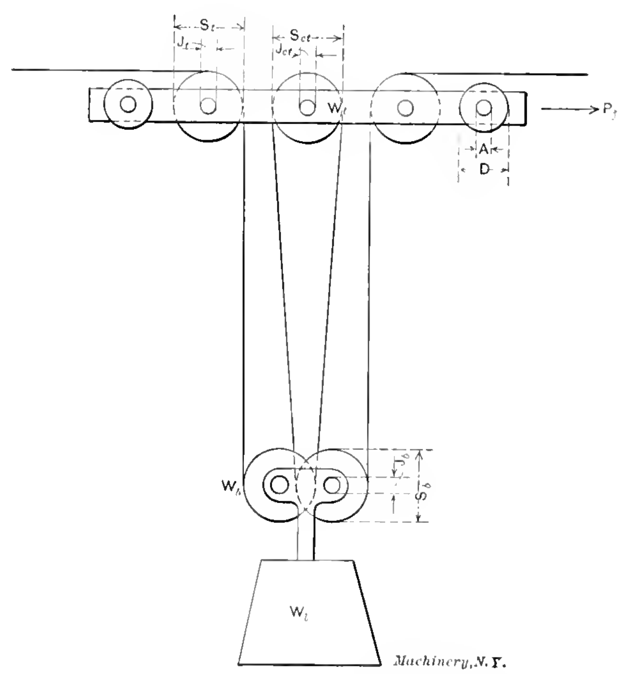

Fig. 2. Trolley with Sheave Suspended by Four Parts of Rope.

$$F_{tw} = (W_l + W_b + W_t)\, C \frac{A}{D} \qquad (3)$$

We have, then, for the total friction

$P_f = F_b + F_{ts} + F_{tw}$, or

$$P_f = C\left[(W_l + W_b)\left(\frac{J_b}{S_b} + 1.4\frac{J_t}{S_t}\right) + (W_l + W_b + W_t)\frac{A}{D}\right] \qquad (4)$$

CASE II. (See Fig. 2.) The conditions are: Four parts of rope supporting the load, two sheaves in the hanging block, and three sheaves in the trolley.

Let the notation be as for case I with the addition of:

S_{ct} = diameter of sheave at center of trolley.
J_{ct} = diameter of journal for this sheave.

Then, F_b = same as for case I (equation 1).
F_{tw} = same as for case I (equation 3).

* For previous articles on this and kindred subjects, see "The Efficiency of Mechanism," by Mr. C. F. Blake, March and April, 1903.
† Address: 1925 Hunting Park Ave., Philadelphia, Pa.

The friction of the two end sheaves in trolley is one-half of that in case I or

$$0.7\,(W_1 + W_b)\,C\,\frac{J_t}{S_t}.$$

The friction of the central sheave is

$$0.5\,(W_1 + W_b)\,C\,\frac{J_{ct}}{S_{ct}}.$$

The total friction of the trolley sheaves is then

$$F_{ts} = (W_1 + W_b)\,C\left(0.7\,\frac{J_t}{S_t} + 0.5\,\frac{J_{ct}}{S_{ct}}\right) \qquad (5)$$

The total frictional resistance of the trolley is:

$P_t = F_b + F_{ts} + F_{tw}$ or

$$P_t = C\left[(W_1 + W_b)\left(\frac{J_b}{S_b} + 0.7\,\frac{J_t}{S_t} + 0.5\,\frac{J_{ct}}{S_{ct}}\right) + (W_1 + W_b + W_t)\,\frac{A}{D}\right] \qquad (6)$$

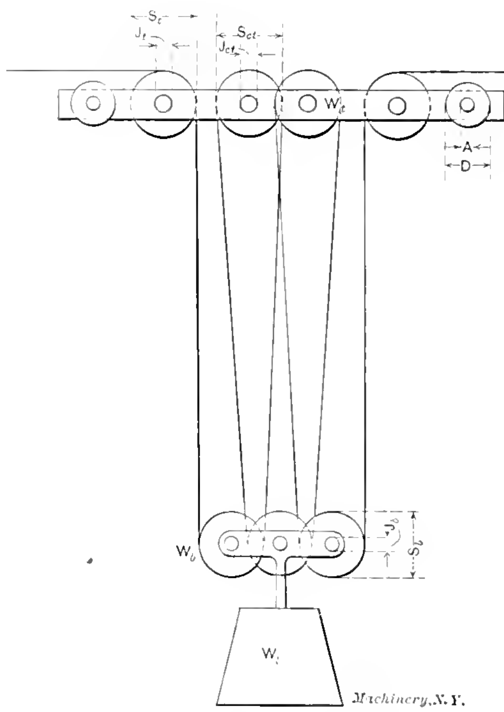

Fig 3 Trolley with Sheave Suspended by Six Parts of Rope.

When $\frac{J_{ct}}{S_{ct}} = \frac{J_t}{S_t}$, as it often will be, equation 5 becomes:

$$F_{ts} = 1.2\,(W_1 + W_b)\,C\,\frac{J_t}{S_t} \qquad (7)$$

Under these conditions equation 6 reduces to

$$P_f = C\left[(W_1 + W_b)\left(\frac{J_b}{S_b} + 1.2\,\frac{J_t}{S_t}\right) + (W_1 + W_b + W_t)\,\frac{A}{D}\right] \qquad (8)$$

CASE III. (See Fig. 3.) The conditions are: Six parts of rope supporting the load, three sheaves in hanging block and four sheaves in trolley.

Notation the same as for cases I and II.

F_b = same as case I and II. (equation 1).

F_{tw} = same as case I and II. (equation 3).

The load in each rope is 1/6 $(W_1 + W_b)$.

In case I the load in each rope was 1/2 $(W_1 + W_b)$.

The frictional resistance of the two end sheaves is therefore 1/6 ÷ 1/2 = 1/3 as much for this case as for case I, and is equal to $0.47\,(W_1 + W_b)\,C\,\frac{J_t}{S_t}$. The friction of the two central sheaves is $2/3\,(W_1 + W_b)\,C\,\frac{J_{ct}}{S_{ct}}$. The total friction of the trolley sheaves is then

$$F_{ts} = (W_1 + W_b)\,C\left(0.47\,\frac{J_t}{S_t} + 0.67\,\frac{J_{ct}}{S_{ct}}\right) \qquad (9)$$

The total friction of the trolley is $P_f = F_b + F_{ts} + F_{tw}$, or

$$P_f = C\left[(W_1 + W_b)\left(\frac{J_b}{S_b} + 0.47\,\frac{J_t}{S_t} + 0.67\,\frac{J_{ct}}{S_{ct}}\right) + (W_1 + W_b + W_t)\,\frac{A}{D}\right] \qquad (10)$$

When $\frac{J_{ct}}{S_{ct}} = \frac{J_t}{S_t}$, as would usually be the case, equation 9 reduces to

$$F_{ts} = 1.14\,(W_1 + W_b)\,C\,\frac{J_t}{S_t} \qquad (11)$$

Under this condition equation 10 becomes

$$P_f = C\left[(W_1 + W_b)\left(\frac{J_b}{S_b} + 1.14\,\frac{J_t}{S_t}\right) + (W_1 + W_b + W_t)\,\frac{A}{D}\right] \qquad (12)$$

If we assume that the ratio of journal diameter to sheave diameter is the same for all sheaves and also the same for the trolley wheels and their axle journals, *i. e.*, that $\frac{J_b}{S_b} = \frac{J_t}{S_t} = \frac{J_{ct}}{S_{ct}} = \frac{A}{D}$, or that this condition is approximately true, and let R = this ratio, the foregoing formulas for the value of P_f may be reduced to the following form:

For case I, $P_f = C\,R\,[3.4\,(W_1 + W_b) + W_t]$ (13)

For case II, $P_f = C\,R\,[3.2\,(W_1 + W_b) + W_t]$ (14)

For case III, $P_f = C\,R\,[3.1\,(W_1 + W_b) + W_t]$ (15)

It is seen from the above that the friction is nearly the same for the three cases, provided the value of R be the same. Equation 14 being the intermediate condition may then be considered as representative of all.

* * *

UNIQUE MEANS FOR POWER PRODUCTION.

Mr. Frank Shuman, Tacony, Pa., has developed a power scheme that is attracting some attention. It works on the principle of the common hot-bed used for growing vegetables in winter, the heat rays of the sun being concentrated in exactly the same manner. The power hot-bed is 18 x 60 feet, and is covered by a double top of glass with 1 inch air space between the layers. In the bed are coils of iron pipe painted black. These pipes are filled with ether and are connected with a 3½-horse-power engine. The circuit is closed, the ether after having been evaporated in the pipes passing through the engine thence to a condenser and back to the hot-bed pipes. It is claimed by Mr. Shuman that this apparatus in the tropics could use water successfully as the high temperature acquired from the direct rays of the tropical sun would be amply sufficient to boil water under considerable pressure. It is probable, however, that this idea, while productive of small power, can scarcely be of any great commercial value because of the large investment necessary. Greenhouses might utilize the idea profitably if there is need of small power for pumping, etc., but to deliberately construct a power plant on this plan would seem quite out of the question.

* * *

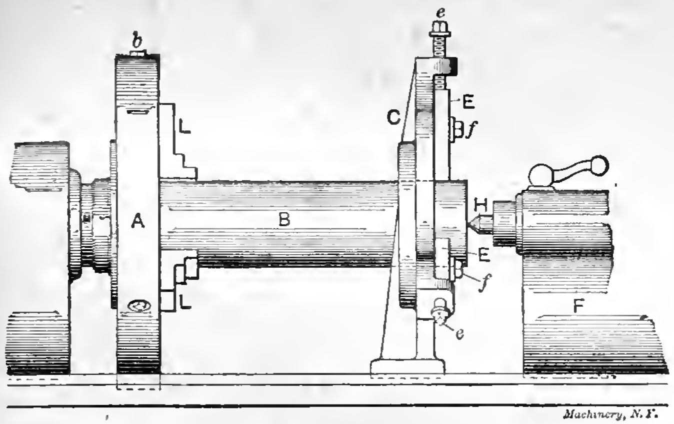
The *Mining World* describes a new remedy for burns discovered by one Dr. Thierry, a physician in the Paris Charity Hospital. He was in the habit of using picric acid as an antiseptic, so that his hands were impregnated with the solution. One day in lighting a cigarette he dropped a portion of the burning match on his hand, but instead of it hurting him, he felt no pain whatever. A short while afterward, while sealing a letter, some of the burning wax stuck to his finger, and though it cauterized the skin, he felt nothing. He began a series of experiments in healing burns with a saturated solution of picric acid. All pain instantly was suppressed. After having bathed the wound in a solution of this acid, blisters did not form, and a cure was effected after four or five days. The only inconvenience was that the acid colored the skin yellow, but this is rapidly remedied by washing with boric acid. The cheapness of picric acid, and the ease with which a proper solution is prepared, have induced many Parisian manufacturers to place jars within easy reach of their workmen.

PUNCH PUNCH PUNCH PUNCH PUNCH PUNCH

These operation sheets, covering every class of shop work, are a feature of all Editions of MACHINERY, and appear every month. They may be cut along the top and margin lines for filing and binding. Suitable binders of sufficient capacity to hold four years' issues will be supplied by THE INDUSTRIAL PRESS, 49-55 Lafayette Street, New York, for 25 cents each, including postage.

SHOP OPERATION SHEET NO. 16.

Oscar E. Perrigo. MACHINERY, October, 1907.



To Hold a Piece in Chuck and Center-rest (Steady-rest), for Drilling and Reaming.

1. Provide, if possible, a three-jawed chuck, the screws of which are connected by a ring bevel gear within the casing. This form is commonly known as a "universal" chuck.

2. Clean the threads of chuck and spindle, and screw the chuck firmly in place. Jaws *L* should preferably face as shown.

3. Lay off and prick punch the exact center of piece *B*.

4. Put the opposite end of *B* in the chuck jaws, and tighten screws *b* just enough to support the work in the chuck.

5. Set up center-rest *C* as shown, and clamp it in place; jaws *E* should not yet be in contact with work *B*.

6. Clamp tail-stock *F* in position as shown. Tap the free end of piece *B* until the prick-punch mark is brought to center *H*; then set up the tail-center just enough to hold the work in place.

7. Tighten the jaws of the chuck, in rotation, enough to hold the work firmly in place.

8. Bring the two lower jaws *E* of the center-rest up to a good contact with casting *B* by setting up jaw screws *e* lightly; then bring down top jaw *E*, clamping all three with nuts *f*.

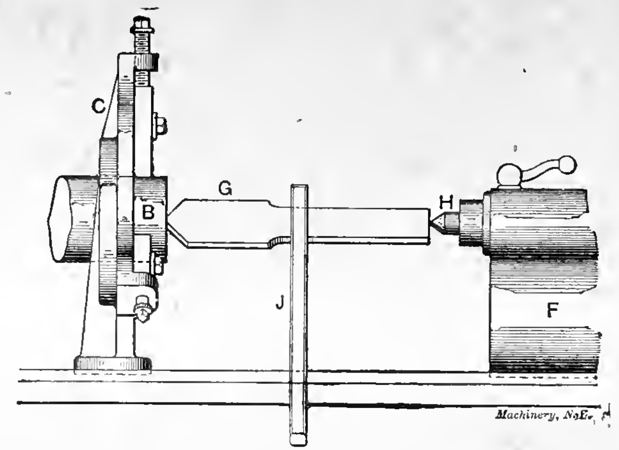
9. Loosen the tail-stock *F*, run it back, remove center *H*, and replace it by any convenient form of centering or starting tool. Move up the tail-stock again, and clamp it as shown.

10. Start the lathe up slowly. Feed the centering tool by the tail-stock hand-wheel until a proper center is made.

Note.—The center-rest jaws must bear as firmly as possible and still permit the work to revolve. Keep the points of the jaws well oiled. For accurate work, the prick-punch mark should be drilled and reamed for a center hole, center *H* inserted, and a short space on the work turned to furnish a true bearing for the center-rest jaws.

SHOP OPERATION SHEET NO. 17.

Oscar E. Perrigo. MACHINERY, October, 1907.



To Drill a Piece Held in a Chuck and Supported by a Center-rest.

1. With the work centered for the drill and properly mounted in chuck and center-rest, move tail-stock *F* to the position shown, and clamp it there, at the proper distance for the drill used.

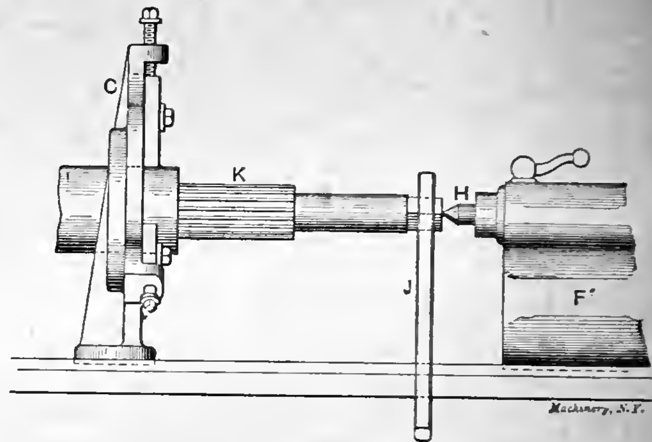
2. Select a flat chucking drill *G*, about 0.005 inch smaller than the finished hole. Place it in position as shown, with its point in the hole made in the work *B* by the centering or starting tool, and with the tail-center of the lathe in the center-hole in the rear end of the drill. Place on the drill a drill-holder or wrench *J*, to prevent it from rotating when the lathe is started.

3. Start up the lathe and bore the hole as deep as desired, keeping the drill-holder *J* in place with the left hand, while feeding the drill by the tail-stock hand-wheel with the right hand. If the hole is deep, the drill must be occasionally removed to clear it of chips. It is best to stop the machine when doing this, to avoid the danger of getting the drill cramped between holder *J* and the hole in the work.

Note.—If the hole in the casting is of considerable diameter, say 2 inches or more, it should be cored out to within 1/4 to 3/8 inch of the finished diameter, in which case a three-lipped chucking drill should be used instead of the flat drill. It will make the hole smoother, and avoid the tendency of the flat drill to chatter. It is often well, when using a flat drill, to bore a small directing hole, say one-fourth the diameter of the finished hole, for the flat drill to follow. This directs the point of the flat drill, and makes the pressure required for feeding very much less, as well. For cleaning the chips from deep holes, it will be found convenient to use a piece of 1/8 by 1/2-inch iron or steel, bent at right angles at a point 1/4 inch from the end.

SHOP OPERATION SHEET NO. 18.

Oscar E. Perrigo. MACHINERY, October, 1907.



To Ream a Drilled Piece Held in a Chuck and Supported by a Center-rest.

1. With the work properly mounted in chuck and center-rest, clamp tail-stock *F* in the position shown, ready for the reamer. The work is supposed to have been drilled ready for this operation.

2. Select a reamer *K*, of the proper diameter for the finished hole. Place it in position as shown, with the center hole in its shank on the dead center of the lathe, and with the slightly tapered end of its cutting edges in the drilled hole in the work. Select a wrench or holder *J* that will fit the squared end of the reamer, and place it in position as shown.

3. Start up the lathe slowly, and proceed to ream the hole, holding the wrench *J* in the left hand to steady it, and at the same time feel the resistance which the material is offering to the cutting action. The reamer is carefully fed forward by the tail-stock hand-wheel, with the right hand. The reamer should be occasionally removed and wiped clean, to prevent clogging with chips and "roughing up" the hole.

4. When the reamer has been fed to depth, remove it, clean out the hole, and test it for diameter with a plug gage or inside caliper, to see that it is of the required diameter.

Note.—If there is a tendency to bind or "squeak" when starting a reamer, we know that the cutting edges are dull. If we are using an ordinary solid reamer, it will be proper to "stone up" the cutting edges, using the oilstone very slightly on the tops of the teeth, and more on the front of each cutting edge. If the reamer is of the expansion type, the blades should be carefully set out, and the cutting edges accurately ground to the proper diameter in a good grinding machine made for the purpose. This is ordinarily done in the tool-room.

OPERATIONS IN MANUFACTURING SMITH'S ADJUSTABLE REAMER.

The "one-lock" adjustable reamer shown in Figs. 1 and 2 is manufactured by the Wm. J. Smith Co. of New Haven, Conn. The accompanying half-tones illustrate operations followed in its manufacture. In Fig. 2, *A* is the body of the reamer;

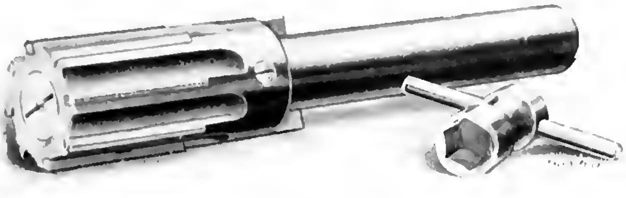


Fig. 1. The "One-lock" Reamer Assembled.

B, the shank; *C*, the driving key; *D*, a screw, loosely fitting a hole in *A*, for holding the parts together; *E*, the blades; *F*, a cam bolt, performing the two functions of adjusting the blades and locking them in place; *G*, the locking nut; and *H*, a wrench used with it.

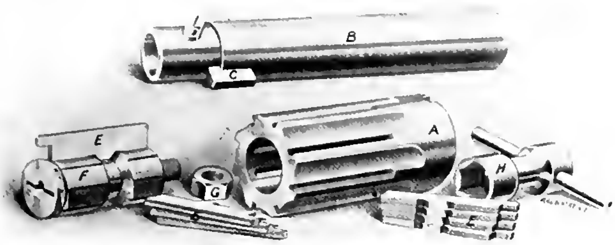

Fig. 2. Details of the "One-lock" Reamer.

Fig. 3 shows the method of holding the stock from which the reamer shell or body is made, for the first operation, that of boring. The work is held at three points, being tightened in place by adjusting the two set screws which back one of the contact strips. The tool on the left is a boring head, fitted with detachable high-speed cutting blades.

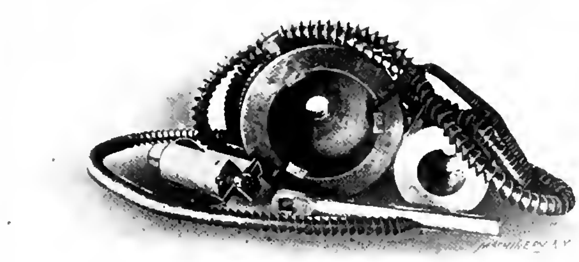

Fig. 3. Three-bearing Chuck, Boring Head, Work, and Chip Produced.

These, it will be seen, are set in the head in such a way as to give a sharp cutting angle. The work shown at the left of the cut has a small hole drilled through it previous to the boring operation. The chip shown is produced by the boring tool.

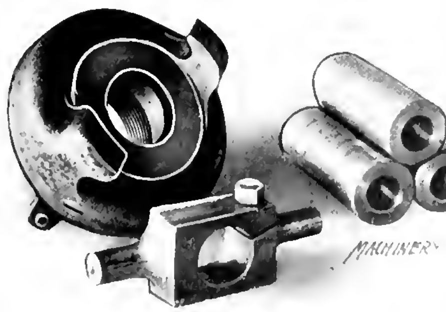

Fig. 4. Special Holder and Two-tailed Driver for Boring in the Turret Lathe.

For boring the other end of the reamer shell, a carrier is used for holding the work in the turret lathe. This carrier, shown in Fig. 4, screws onto the nose of the spindle. It is provided with locking wings which engage the two-tailed dog shown in the foreground. This construction equalizes the strain on the reamer shells, thus preventing cramping, and insuring the alignment of the holes bored from either end.

Fig. 5 shows a special device for graduating the end of the reamer shells. The shell is mounted on a taper split bushing, by which it is clamped to the index plate of the device. This index plate is operated by a ratchet, which accurately spaces the work for the required graduations. On the top of the frame is mounted a cross bar carrying a slide, with a cutter for marking the graduations provided for by

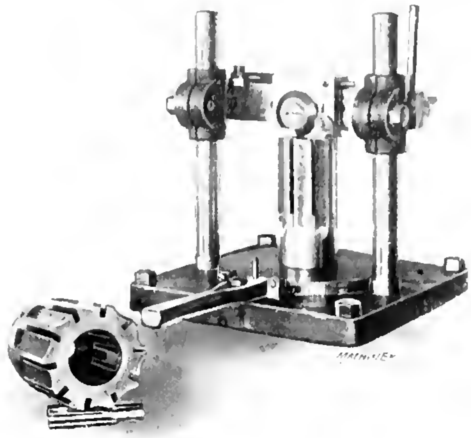

Fig. 5. Fixture for Graduating on the End of Reamer Bodies.

the index plate. The travel of this head is effected by a lever, and the movement is limited by an adjustable stop, varying in position for different cuts, so as to regulate the length of the graduations.

In Fig. 6 is shown the operation of milling the cam surfaces on the cam bolt. As shown, this is held between index centers in the milling machine, and shaped by a form cutter of small diameter. A smaller cam bolt with its cutter is shown on the table of the machine.

For machining the undercut by which the blades engage the cam bolt, the peculiar cutter, shown in Fig. 7, is used. This cutter, which reproduces the outline of the undercut on the cam bolt, has its cutting edge on the interior face. As shown, the work is set up in a hand milling machine.

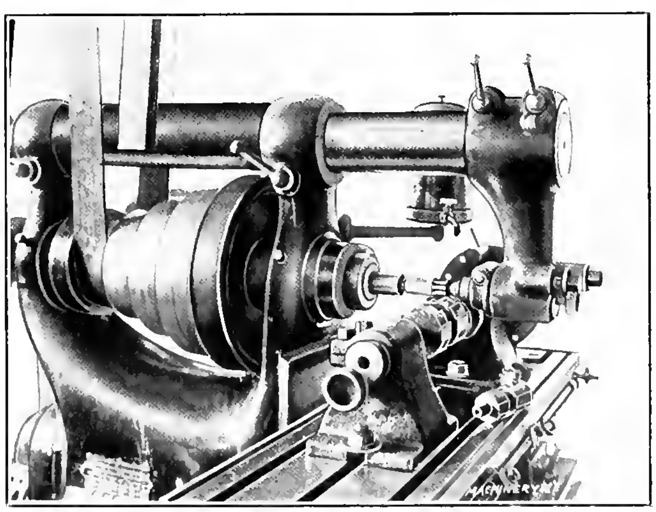

Fig. 6. Milling the Cam Surface on the Cam Bolt.

Fig. 8 shows a fixture used for holding the blades when grinding them. The blades are held in this fixture by the same means as provided for them in the reamer, the same cam bolt being used to engage projections at the bottom of the blades, which are set in slots in a cylindrical shell. These slots, however, are set at a slight angle with the radial position of the blades in the reamer, so that when the fixture with its blades is placed in the grinding machine and finished to a cylindrical surface, the tops of the blades, when replaced in the reamer, will clear the surface of the hole which they ream. This form of cutting surface is much superior to the flat shape given by the ordinary cutter and reamer grinder.

The shank of the reamer is slotted clear through for the

key by which the shell is driven. This operation is performed on the ingenious oscillating miller, built by the Hendey Machine Co., described in the April, 1905, issue of MACHINERY.

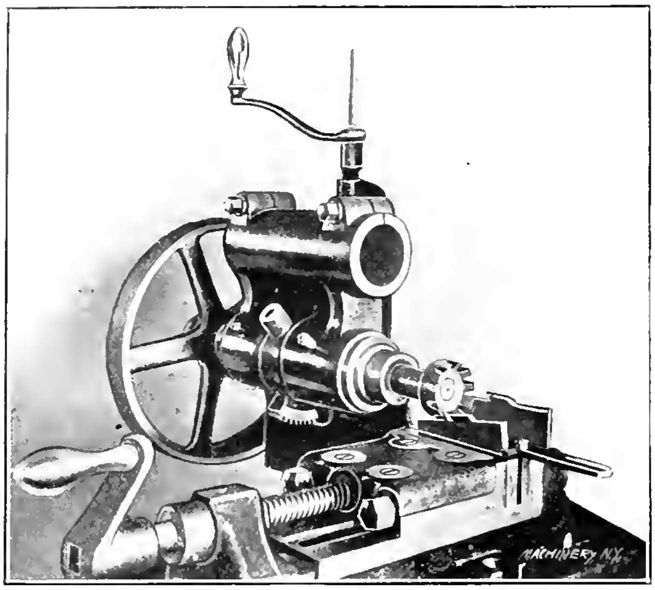

Fig. 7. Milling the Locking Undercut in the Blades.

The operation is shown in Fig. 9. The cutter has fine teeth, forming only a portion of a circle, and is held by a dove-tail in an oscillating bar, operated by an eccentric movement

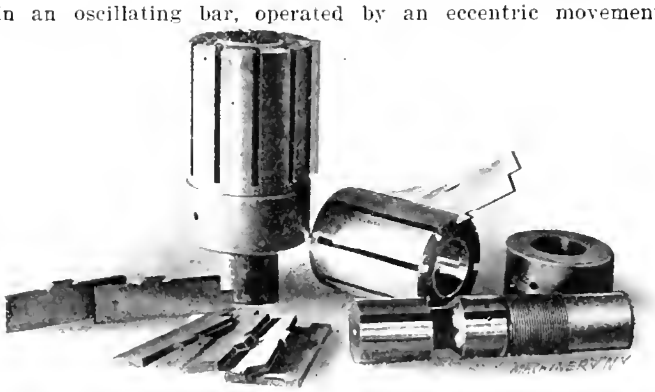

Fig. 8. Special Arbor or Fixture for Sharpening and Grinding Relief on the Blades.

from the spindle. This arrangement is capable of working a rectangular slot clear through a bar in one operation, provided the teeth are kept clear of chips. In the case shown,

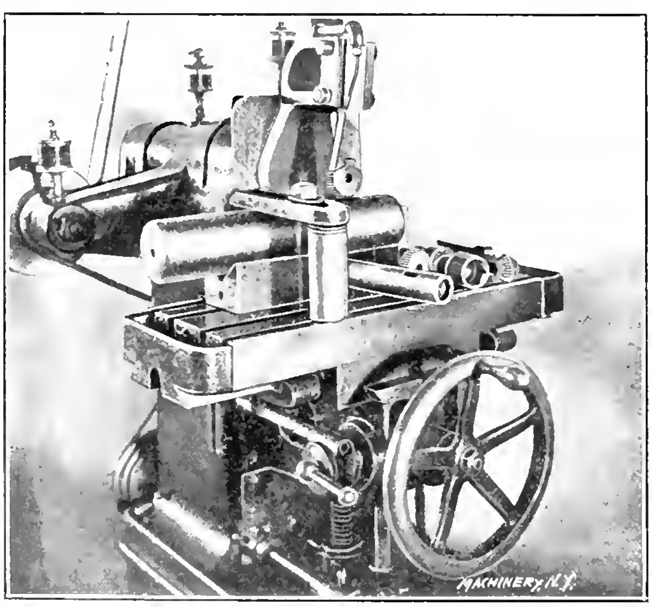

Fig. 9. Cutting a Slot with the Oscillating Milling Machine.

however, the slot is first roughly drilled to shape, and then finished by the oscillating process. The rectangular outline is obtained by this means at one cut.

A DRAFTSMAN'S TOOL CHEST.

I. G. BAYLEY.*

It is no unusual sight to see a draftsman carrying his tools tied up in a sheet of wrapping paper or even newspaper, while other craftsmen such as pattermakers or machinists, for instance, invariably carry their belongings in some kind of a box or case, though their tools are by no means so delicate or in need of so much protection as the draftsman's. The tool chest here described need not necessarily be a standard for size, shape or design; it can be changed to suit each individual taste or whim.

On account of its lightness and the ease with which it can be worked, poplar was chosen to make the box and nest of drawers complete, though it would be better, perhaps, if

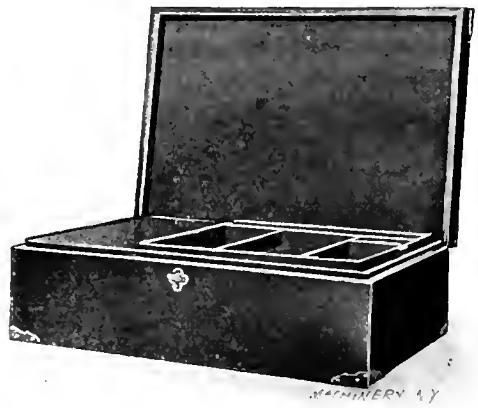

Fig. 1. The Draftsman's Tool Chest Finished.

the box were made of oak or other hard wood, and the nest of drawers and tray of poplar. It may be said, by the way, that the writer made the two latter with no other tools than a penknife and small iron plane; the chest or box was made by a cabinetmaker. Lepage's glue and fine nails were used to join the parts together; brass screws were used for the corner pieces, hinges and the name-plate. These trimmings may be either of brass or nickel. If poplar is used for the box, a mahogany finish outside, and shellac inside would look well, but a dull mission finish would be more serviceable if the box is made of oak.

It is sometimes convenient to have a secret drawer for money, stamps, etc., so one is here shown, though by the time the readers of MACHINERY have read this article it will

Fig. 2. The Tool Chest and its Contents.

be secret no longer. However, the suggestion can be altered or an entirely new design made.

The finished size of the box is 12 x 18 x 6 inches deep, outside dimensions. The box was nailed together, top, bottom, and sides, and then the top of lid neatly cut, one and a half inches down, with a fine saw, following a pencil line accurately drawn all around the box. On account of this saw-cut, the sides are ordered one-eighth of an inch deeper, as noted in the list of material. The bottom was let in, as it were, the sides being nailed around it. The top was made to cover over all. The sides were mitered so as to bring the joints exactly at the corners. After the lid was cut off, the edges were planed and sandpapered down to correct

*Address: 2509 North College Ave., Philadelphia, Pa.

dimensions. A strip of wood is nailed part way around the box, one-eighth of an inch from the top, to keep out the dust and help in binding the lid when closed.

The nest of drawers at one end of the box is built up flush with the top of this strip of wood, so that the strips stop where the drawers occur, as shown in Fig. 2. The top, bottom and sides of the box are made of half-inch material. The strip of wood around the top is one-eighth inch thick.

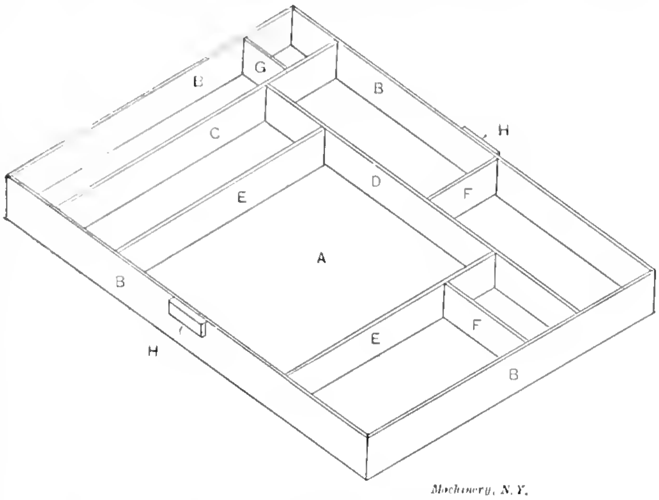

Fig. 3. The Tray for the Tool Chest.

The tray and the nest of drawers were made of one-eighth inch material, except the front of each drawer, which is one-quarter inch to give depth for securing the handles. There are three small drawers and one long one, the latter being for the instruments. The instruments were laid in the drawer in correct position, and blocks of wood, cut to suit, put between. The drawer was then covered with velvet, after the instruments had been removed and the whole given a coat of glue. The other drawers can be divisioned off or not to accommodate the smaller tools described in the list. At the front end of the nest of drawers a recess was made to accommodate the scales, these being a foot or more in length. The large triangles were put in the recess of the lid, the smaller ones kept in the body of the box or in the drawers. At the rear end of the nest of drawers is shown a small cupboard for the inkstand, a block of wood with three holes sunk in, to take as many small Higgin's ink bottles, black, red, and blue.

The secret drawer can also be put in this end, as shown in Fig. 4. This drawer can be omitted if desired and the false front of the small top drawer corrected to take its place. An elastic band holds the door shown, and also keeps the inkstand in place. The holes in the inkstand are three-quarters of an inch deep and one inch and three-quarters in diameter, and they must stagger with each other as shown or there will be difficulty in boring them. The tray, Fig. 3, fits the body of the box and is kept from falling in by the lugs at either end. The longest narrow space is for the penholders; the small space for the pens. The large space in the center is for the instruments. The pencils are kept in the space between this and the one for the penholders; on the other side of the large space is one made the same size as the inkstand; next to it is a smaller space for the tacks, pins, etc., the two remaining divisions being for the rubbers and pencil stubs, respectively. The idea is to fill the tray with the necessary tools, etc., when working, and placing it near the board or table for convenience.

Referring to the half-tones and line-cuts herewith, Fig. 1 shows the box open with the tray in position when not in service; Fig. 2 shows the box open, with the tray to one side to allow the drawers and cupboard to be seen. The inkstand is shown in the tray, and the tools, books, etc., are shown surrounding the box; Fig. 3 shows the tray with the various parts of which it is made, plainly marked, to agree with the bill of material; and, finally, Fig. 4 shows the nest for the drawers, with the latter as well as the cupboard door and the top of the nest removed. The pieces are marked to agree with the bill of material which follows. It would be well to cut all the material first.

Chest or Box. (Figs. 1 and 2.)

1.—Piece 12" x ½" x 18", top.
1.—Piece 11" x ½" x 17", bottom.
2.—Piece 6⅛" x ½" x 18", front and back.
2.—Piece 6⅛" x ½" x 12", sides.
3.—Strips ¾" x ⅛" x 11" (mitre joints).

Tray. (Fig. 3.)

1.—Piece 10⅜" x ⅛" x 10⅜", bottom *A*.
4.—Piece ⅞" x ⅛" x 10⅝", sides *B*.
1.—Piece ¾" x ⅛" x 10⅜", partition *C*.
1.—Piece ¾" x ⅛" x 9", partition *D*.
2.—Piece ¾" x ⅛" x 7¾", partition *E*.
2.—Piece ¾" x ⅛" x 2½", partition *F*.
1.—Piece ¾" x ⅛" x 1¼", partition *G*.
2.—Piece ⅜' x 3/16" x 1", lugs *H*.

Nest for Drawers. (Fig. 4.)

1.—Piece 6⅛" x ⅛" x 11", top *A* (not shown).
1.—Piece 4" x ⅛" x 11", back *B*.
2.—Piece 4" x ⅛" x 6", sides *C*.
(One side to be cut as shown, if secret drawer is used, otherwise both sides will be alike.)
1.—Piece 2½" x ⅛" x 6", side *D*.
1.—Piece 1½" x ⅛" x 6", partition *E*.
1.—Piece 1⅛" x ⅛" x 6", partition *F*.
4.—Piece ⅜" x ⅛" x 8", partition *G*.
2.—Piece ⅜" x ⅛" x 5¼", partition *H*.
6.—Piece ⅜" x ⅛" x 5¼", guides *I*.
1.—Piece 1" x ⅛" x 5¼", guides *J*.
1.—Piece 2⅝" x ⅛" x 4", cupboard door *K*. (Not shown.)
1.—Piece 2⅝" x ⅛" x 5⅞", bottom of cupboard *L*.
2.—Piece, ⅛" x ⅛" x ½", lugs for cupboard door *M*.
1.—Piece 1⅛" x ¼" x 2⅝" front of drawer *N*.
1.—Piece ½" x ⅛" x 1", stop for secret drawer *O*.

The front of false drawer (*N*) must be well secured to allow for the pulling it will get. If no secret drawer is used, the false front must be changed, a regular drawer taking its place.

Drawers.

1.—Piece 1⅛" x ¼" x 8", front long drawer.
1.—Piece 1" x ⅛" x 7¾", back long drawer.
2.—Piece 1" x ⅛" x 5¾", sides long drawer.
1.—Piece 5¾" x ⅛" x 8", bottom long drawer.
1.—Piece 1⅛" x ¼" x 5¼", front top drawer.
1.—Piece 1" x ⅛" x 5", back top drawer.
2.—Piece 1" x ⅛" x 5¾", sides top drawer.
1.—Piece 5¼" x ⅛" x 5¾", bottom top drawer.
1.—Piece 1⅜" x ¼" x 5¼", front bottom drawer.
1.—Piece 1¼" x ⅛" x 5", back bottom drawer.
2.—Piece 1¼" x ⅛" x 5¾", side bottom drawer.
1.—Piece 5¼" x ⅛" x 5¾", bottom drawer.
1.—Piece 1⅛" x ¼" x 5⅝", front secret drawer.
1.—Piece 1" x ⅛" x 5⅜", back secret drawer.
2.—Piece 1" x ⅛" x 2", side secret drawer.
1.—Piece 2⅛" x ⅛" x 5⅝", bottom secret drawer.

Ink Stand.

1.—Piece 2½" x 1" x 5⅞".

Ink stand to have three holes for bottles. Stand to be sandpapered and varnished black. The drawers are furnished with handles as shown; of necessity they must be small, and if flush with the front of the drawers, so much the better,

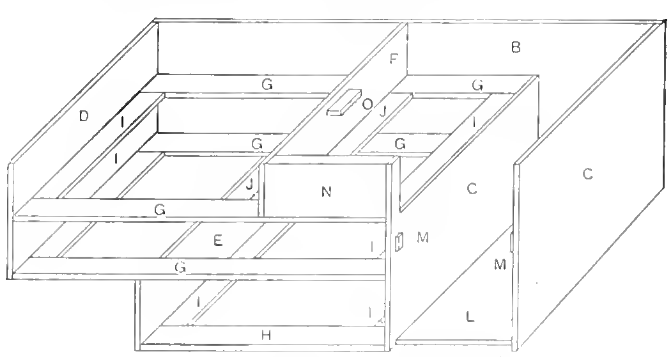

Fig. 4 The Nest for the Drawers.

in which case two lugs will be required to hold the tray up from falling into the body of the box; otherwise one end can rest upon the handles as in the case in hand.

The box can be carried by means of a strap when packed for shipping, or when moving from place to place.

A list of the tools, books, etc., contained in the box is given below.

5½", compass, pen, pencil, and lengthening-bar.
5½" hair-spring divider.
5½" plain divider.
3½" compass, pen and pencil legs.
2½" spring-bow instruments, pen, pencil and divider.

5" ruling pen.
4½" ruling pen.
Proportional dividers.
Small size beam-compass fixed needle-point leg, with pen and pencil legs, micrometer adjustment.
6" protractor, nickel-plated lead case.
Two triangular scales.
Trautwine's, Kent's, and Carnegie's handbooks, Data sheets from MACHINERY.
Instep's tables, sketch and note-books.
Four triangles, large and small, 45 and 60 degrees.
Pentagraph, 2 irregular curves, slide rule.
Three bottles Higgins' ink, black, red, and blue.
Three penholders, assorted pens, penwiper or rag.
Ink eraser, shield, scratcher, soapstone.
Pencils, HB, H, HH, HHH, HHHH, HHHHHH, pencil stubs.
Stub-holder, copying pencil, red and blue pencils.
Sponge rubber, or art-gum, several rubbers.
Tack-hammer, tack-lifter, package of 1-ounce tacks.
One dozen thumb-tacks, paper fasteners, clips, and pins.
6' folding rule, tape measure, calipers, knife.
Oil-stone, oil-can, file, dust brush, pencil sharpener.
Crayons, paint brush, paint box, pallet, magnifying glass.
Sheet horn for centers, fine needles.
Rubber bands (assorted), adhesive tape, pot of paste.
Pair of shears, string, gummed labels, tags, sealing wax.
Fountain pen, writing pad, blotters, small calendar.
Writing paper, envelopes, postage stamps.

Address book and visiting cards, complete the list, with room to spare for needle, thread and a few buttons, if you are an old bachelor.

* * *

METHOD OF GRADUATING IN THE LATHE.

WM. C. FORCE.*

If we have, say, 80 teeth in the cone gear of the lathe, it becomes easy to index for any number by which 80 can be evenly divided, by placing a pawl in contact with the teeth of the gear and counting as many teeth as required for each graduation. Fig. 1 represents the lathe head with the pawl bracket clamped to the bed, and the pawl in such a position

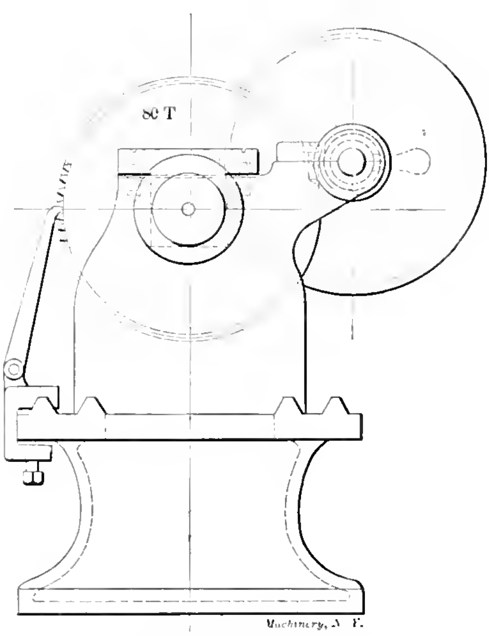

Fig 1 Direct Indexing

that when the gear is pulled forward, the pawl becomes locked between the teeth. The work to be graduated may be placed on the centers, in the chuck or on the face-plate, as circumstances will permit. Supposing, for instance, you desired to lay out a cast iron collar, dividing the circumference into four equal parts. You place the collar on an arbor, put a driving dog on in the regular way, and place the graduating tool in the tool-post, setting the point of the tool about at the same height as the lathe centers. The first thing to do after this is to find out the number of teeth to index, to obtain the four divisions on the collar. Divide the number of teeth in cone gear, assumed to be 80 in our case, by the number of divisions, 4, and we obtain 20 as a quotient, which is the required number of teeth to index on the cone gear. If we have a number of pieces to graduate in this way, it is well to place a chalk mark at each division on the cone gear so that it will not be necessary to count the teeth for each indexing. A cone gear with 80 teeth may be utilized with this method to obtain the following divisions, *viz.*, 2, 4, 5, 8, 10, 16, 20, and 40. If one wishes to graduate long and short lines on the work, it will be necessary to clamp a parallel to the bed of the lathe, using this parallel as a stop for the carriage to go against for long lines and using a distance piece between the carriage and the parallel for short lines.

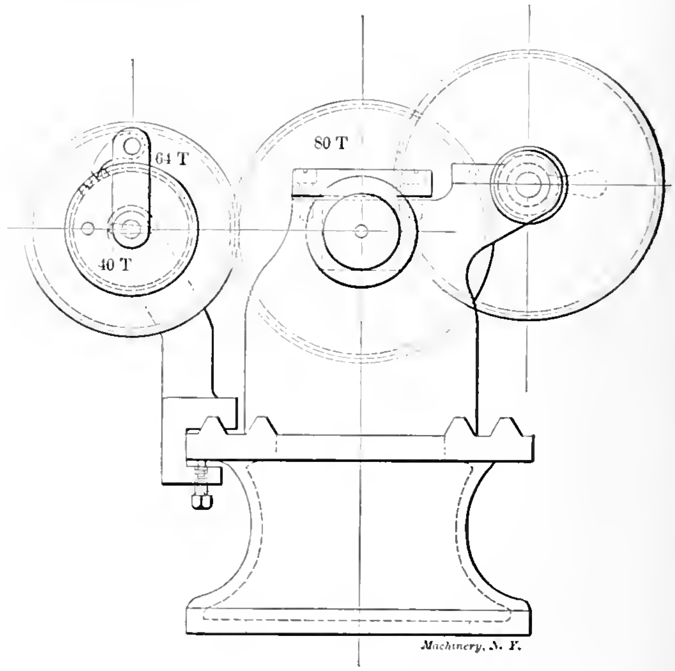

Fig. 2. Indexing through Compound Gearing.

In graduating a dial which is to give measurements of one-thousandth inch, when used with measuring screws having 20 threads and 40 threads per inch, it will be necessary to proceed as shown in Fig. 2. In the first place we will find that the number of thousandths of an inch in 1/20-inch equals 50, and the number of thousandths of an inch in 1/40-inch equals 25. As will be seen from cut, there are two gears keyed or pinned together and mounted on a bracket in such a manner as to be free to revolve on the stud in the bracket, one gear meshing with the cone gear. Fastened to the stud by a taper pin is the pawl-carrying bracket and pawl used to index the number of teeth on the index gear. It becomes a simple example in proportion to find the gears necessary for 50 and 25 divisions. Taking 50 divisions for example, and assuming 64 as the number of teeth in the stud gear meshing with the cone gear, the proportion becomes $x : 64 = 50 : 80$,

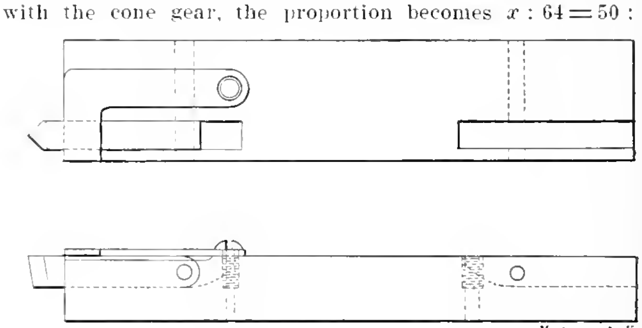

Fig. 3. Graduating Tool.

x being the number of teeth in the index gear. From this we find the number of teeth in the index gear to be 40. By indexing one tooth on the indexing gear we obtain 50 divisions, and by indexing two teeth we obtain 25 divisions. If we desire any other divisions than this combination of gears will give, it will become necessary to figure out a new combination and use another stud and index gear.

In Fig. 3 is illustrated a graduating tool which will be found to give better satisfaction than an ordinary sharp-pointed tool. As will be seen from the cut, it is a spring tool, relieving the tool on the back stroke, thereby preserving the point. It can be used either right or left hand, as the holder has a groove in one side on each end.

LETTERS UPON PRACTICAL SUBJECTS.

SECTIONAL SUB-PRESS DIE.

In the May issue of MACHINERY appeared a description of a sectional punch and die by A. C. L. There is no doubt that such a die could be simplified by making it on the sub-press principle. Every detail seems to have had attention and everything seems to have been done, except the one fundamental and essential thing necessary for rapid production of accurate work.

In the cuts herewith are shown dies and punches for sub-press work, which may be of interest to the readers of MACHINERY. In the assembled view, Fig. 1, the die is shown.

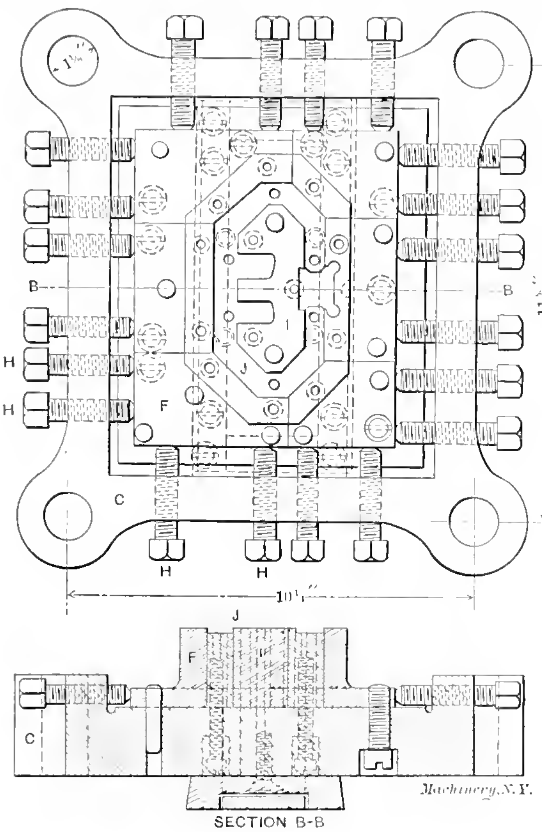

Fig. 1. Sub-press Die

It will be seen that the blanks can be changed to different shapes by simply inserting different die sections in different places of the die. At *A*, Fig. 3, is shown a modification of the blank, possible with this die. Another of the principal features of the sub-press sectional die is the means for stripping the scrap and ejecting, when it is wanted to produce punchings in quantities. The die shown in the cut may appear to be unduly light in construction, but several sets have been built on these lines, and given full satisfaction. Their light weight materially lessens the cost of handling, as well as the cost of making. The holder *C* is of good, close grain cast iron, planed on both sides. At the top, a recess is milled with an end mill in a vertical miller. In this recess are held the sectional parts of the die, which are fastened to the body from the bottom. After having made the necessary templets, the various die sections are shaped. A few thousandths of an inch is left on the adjoining surfaces to permit finishing by grinding. The cutting edge of the die sections must be left as hard as possible. Die section *F* is shown in detail in Fig. 3. It will be noticed that two small holes are drilled in the center of the two screw holes in the piece *F*. This is done to enable transferring the screw holes to the cast iron holder when assembling the die. The bottoms of the die sections are left soft in order to be able to drill all the screw and pin holes through the cast iron holder at the same setting. The dove-tailed slot in the holder *F* is made for the purpose of marking the punching. Each section is reinforced on the two outer sides by four set screws *H*. In the center of the die a solid block *I* is fastened with three screws and two dowel pins. This block is hardened and ground all over to the shape of the templet. The ejecting or stripping device *J* for the die is made of a solid tool steel piece to the same shape as the templet, but is a very free fit, amounting to a few thousandths of an inch on the sides. This part is left soft and is located a few thousandths inch more than the thickness of the punching below the top of the die. When the die is sharpened, the stripper is ground off the same amount. No springs are used with the stripper, it being actuated by two ¼-inch studs fastened with screws on the stripper. These studs pass through the die and holder, and are actuated by a bar fastened to the gate of the press, thereby forcing out the punchings from the die. The six punches *N*, Fig. 3, are upset, as shown, at the end where they are inserted in the holder, while the other end is hardened, straightened, and lapped to size. The holes for the punches are located after the die is finished and assembled.

The cast iron punch holder *K*, shown in Fig. 2, is planed on top and bottom and across the four bosses. The four sub-press pins *D* are of tool steel, hardened as far as the head, ground to a light driving fit on the head end, and ground to a sliding fit in the die holder on the other end. The holes for these pins were located so that they are strictly in line with each other, and at the same time square with the punch and die. When the punch and die parts were hardened, they were placed together with two parallels placed between the castings, the punch placed inside the die,

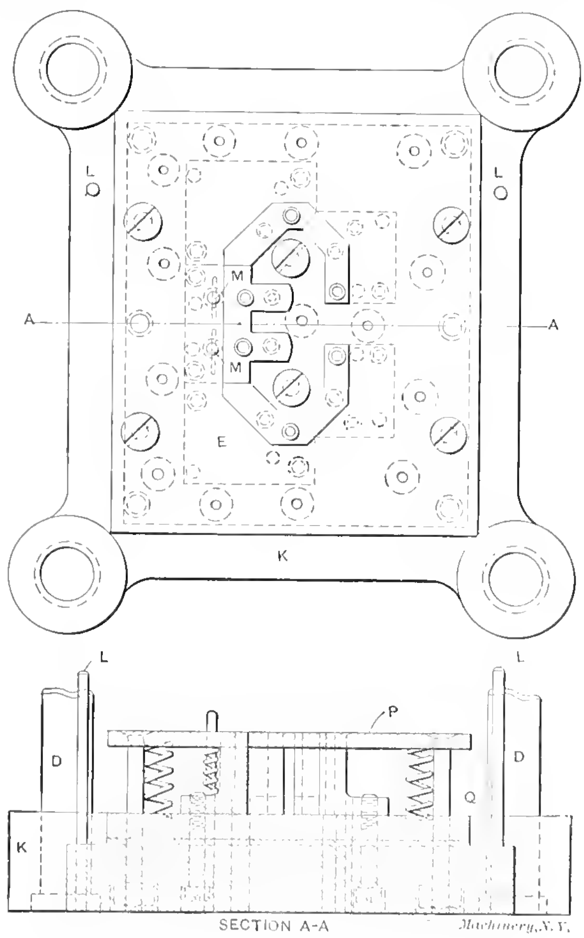

Fig. 2. Punch for Sub-press Die in Fig. 1

and the two clamped together with four C-clamps. In this way the holes, when bored, were bound to come in alignment.

The punch part which is shown at *E*, Fig. 3, is made precisely as the corresponding die section, only that in locating the positions for the piercing bushings *O*, it sometimes happens that the holes for the bushings are so many and so small that they cannot be conveniently bored. The holes are then transferred by a drill that runs through the die, and are of the same size as the piercing plug, the die being used as a drill jig. After drilling, the holes are counterbored to

the right size for driving fit for the bushings. The latter are hardened and ground all over, and the holes in them taper one-half degree. A straight pin, driven in so as to be located halfway in the bushing, and halfway in the section E, holds the bushing in position while in operation. A stripper plate P is placed over the punch sections with a free fit on both inside and outside. It is held by flat head screws which are adjusted with nuts from the bottom of the holder.

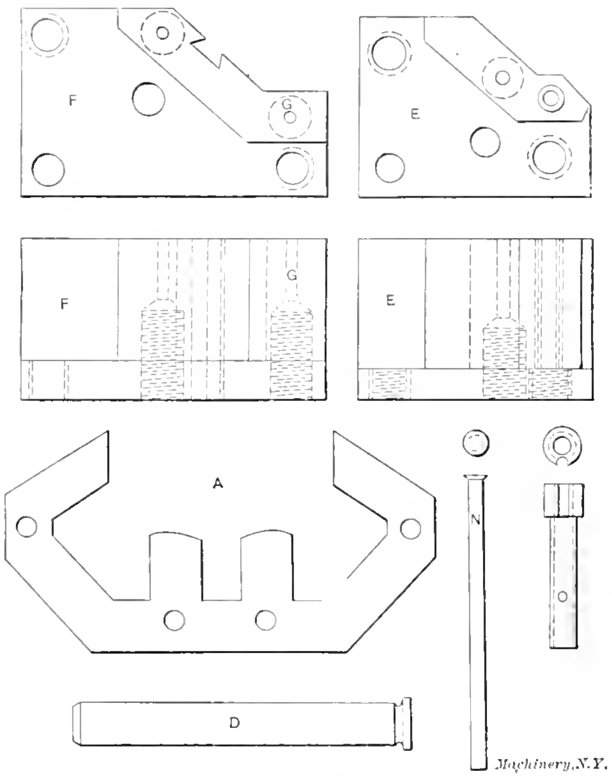

Fig. 3. Details of Sub-press Die.

Between the stripper and the punch-shoe Q, which is made of tool steel and hardened, sixteen spiral springs are placed to strip the metal. The punch-shoes themselves are secured with six screws to the cast iron holder K.

Two guide pins L, Fig. 2, are driven into the top of the cast iron holder K, and two gage pins M are located 1/16 inch from the cutting edge. A small wire is driven through the gage pins, below the stripper, having a spiral spring underneath, seated on the punch-shoe. When the die comes down, forcing down the stripper plate, the gage pins follow, coming up again on the upward stroke.

L. A. DORMAN.

ADDITION AND SUBTRACTION ON THE SLIDE RULE.

It seems to be generally supposed that it is impossible to perform addition and subtraction on the slide rule. This, however, is not so, as it is really a simple matter, and a little practice will enable anyone familiar with the slide rule to perform both operations with speed and accuracy.

Rule for addition: Assume that the scales are numbered in the usual manner, A, B, C, and D, commencing at the top of the rule. If we now wish to add 372 and 284, set the glass indicator to 284 on the D scale, and move the slide until 372 on the C scale coincides with 284 on the D scale and read the quotient 1.31 on the C scale. Add 1 to 1.31, making the sum of 2.31, and multiply 284 by 2.31, the product being 656. Then check the right-hand figure in the sum by adding mentally the right-hand digit on each number, thus, $4 + 2 = 6$. The answer must then be 656, since we read it to be between 650 and 660. The decimal point in the first operation is located in the same manner as in ordinary slide rule operations. That the rule for addition on the slide rule, as given above, is correct is proven in the following manner. Suppose that E represents the larger number; F, the smaller; and G, the quotient of E divided by F. Then

$$\frac{E}{F} = G, \text{ and consequently } E = F G. \qquad (1)$$

In this equation add F to both sides. Thus

$$E + F = F G + F = F (G + 1) \qquad (2)$$

If in this equation we substitute the numbers 372 and 284 given in our example, we have

$$372 + 284 = 284 \ (1.31 + 1)$$

which, we see, agrees with the operations as we performed them.

Of course the figure 1.31 is not exact, but it is near enough to obtain the first two figures exact, and the third figure is obtained exact as has been explained before.

Rule for subtraction: Suppose that we want to subtract 284 from 372. Set the glass indicator to 284 on the D scale, and slide the runner until 372 on the C scale coincides with 284 on the D scale, which leaves the quotient 1.31 the same as in the case of addition. Subtract 1 from 1.31, leaving 0.31, and multiply 284 by $0.31 = 88$, which is the desired remainder. This rule is proven in a manner similar to that for addition. Assume that K is the larger number, and L, the smaller; then

$$\frac{K}{L} = M \text{ and consequently } K = L M. \qquad (1)$$

Subtract L from both sides of equation 1 and we get

$$K - L = L M - L = L \ (M - 1). \qquad (2)$$

If we substitute the numbers which we used in our example in this equation we have:

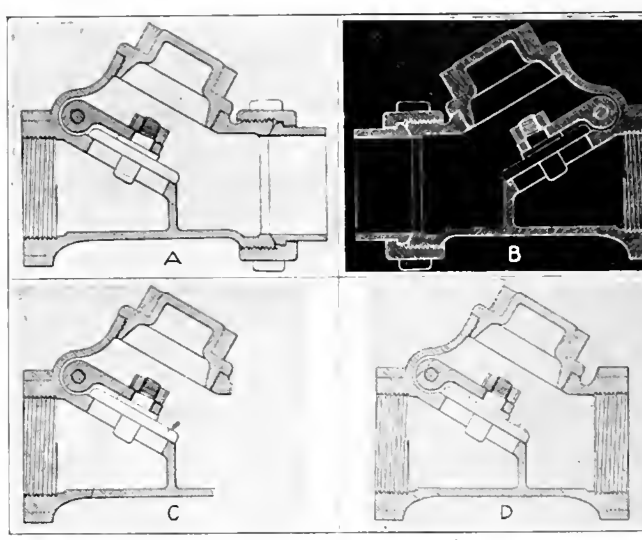
$$372 - 284 = 284 \ (1.31 - 1) = 88.$$

Claremont, N. H. WM. C. MICHAEL.

[The method explained above, while it is interesting as a demonstration of the mathematical principles on which the slide rule is founded, as well as the close connection between all mathematical operations, seems of course of little value for any pratical purpose, because the time taken to perform addition or subtraction on the slide rule in the manner explained will be several times the time necessary to perform this operation in the ordinary manner by adding the digits.—EDITOR.]

CHANGING DRAWINGS QUICKLY.

Occasionally a big change in a drawing is necessary, and a print is wanted at once, or a different style of machine is to be made, having the major portion exactly the same as shown on some previous drawing. The accompanying cut illustrates this case. A rapid method for changing the drawing is as follows: A tracing shown at A is on hand, but we wish a print showing this valve with a female pipe thread on both ends. From this tracing we then make a



Method of Changing Drawings Quickly.

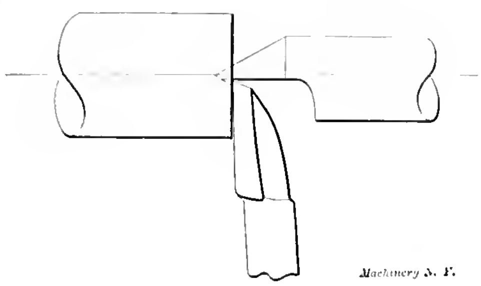
negative, shown at B, using a brown process paper. Now with a piece, or pieces, of brown opaque paper cover up all parts of this negative, B, that should not show on the required print. From this partially covered negative make a new print, C, again using brown process paper. On this new print, C, draw with india ink the special part of the new style valve and use the drawing D, thus obtained, as an ordinary tracing. The brown lines will print as well as the added lines in india ink. HOWARD D. YODER.

Wadsworth, Ohio.

NOTES ON CENTERING.

The letter by W. S. Leonard in the August issue of MACHINERY brings up one of the most important points in good lathe work, namely, properly preparing work for turning. The writer worked seven years at the business in engine shops, having the reputation of doing good work, before he saw a center reamer or learned that 60 degrees was the proper angle for a lathe center, and there are hundreds of mechanics in the country to-day who put in centers with a 90-degree center punch.

In centering a piece of work, the first thing to be done is to file or grind the end straight, if it is a rough forging, or grind off the teat, if it has been cut off in a machine. Then, if you have a centering machine, the work can be centered in that; if not, locate the center with a pair of



Half-center and Facing Tool.

dividers and prick-punch it lightly. Then drill and form the center with the two-lipped combination center drill and reamer, first introduced by J. T. Slocomb Co., and now made by several concerns. With this tool the cut is balanced, and the drill part steadies the reamer, insuring that the clearance hole is true with the angle, and that the centers are reasonably round. If you have not the above, the small hole should be drilled for clearance and lubrication about two-fifths the diameter and about twice as deep as you want the center. The drill is followed with the center reamer, care being taken to make the latter cut concentric with the small hole. A half round reamer is better than the ordinary three-fluted one, as the centers cut by it are always round.

After centering, both ends of the piece should be faced off true, so that, as the center wears, it will wear evenly and not get out of true. Mr. Leonard will find that in using a tool sharpened as he describes the point will not stand up, and if he succeeds in getting out more than one piece without a ridge around the center, and without re-grinding the tool, he will accomplish a miracle. The best method is to use a half-center for the foot-block as shown in the cut. This center has nearly half of the taper point cut away, leaving but little over a half circle to support the work, so that the end can be faced clean. ALLAN.

THE POSITION OF THE CHECK NUT.

Mr. Oskar Kylin's article on the position of the check nut in the August issue of MACHINERY is very interesting and instructive from a theoretical point of view, but under practical conditions it is far better to have the lock nut placed on the top of the regular nut. The reason for this is because the average workman in erecting machinery tightens up the first nut as tight as he considers necessary, which is generally as tight as he can; he next puts on the second nut, which he makes fairly tight, and then passes on to other work. Do you suppose he would hunt up the special lock nut spanner and hold back the lock nuts? No, sir; he wants to get the job finished in good time and monkey business like that "don't go." I know from actual experience with erecting gangs.

Let us see what the effect of this treatment is upon the theoretically correct position of the lock nut. Suppose we have a bolt on which a total strain of 1,000 pounds will be developed when both nuts are tightened up. The lock nut is placed upon the bolt first, according to blue-print, and drawn down to 1,400 pounds strain to make everything tight; then the regular nut is placed on top, tightened up to about 400 pounds, and let go at that. These conditions cause the lock nut to carry 1,000 pounds load and the regular nut only a 400-pound load, which is about the worst condition imaginable. Now let us take the "incorrect" way. The regular nut is put on first, drawn down to the 1,400 pounds strain, then the lock nut is placed on and drawn down to the 400 pounds, and the workman passes on, leaving conditions which, next to a correctly placed and carefully adjusted lock nut, are a very satisfactory distribution of strains, and the regular nut is to all practical purposes thoroughly locked just the same, unless the bolt actually moves forward enough to lift the bottom nut out of contact with the base, which is a rare and special case.

Here then is a point where actual practice is directly contrary to theoretical considerations; but we are dealing with actual conditions and must design our machinery to give satisfaction and results with the average workman's treatment, and must make our average blue-print show the lock nuts on top. By doing this we are sure to get best results, for the general workman will throw the greatest strain on the strongest nut. On all my designing requiring lock nuts I invariably show two regular nuts. The difference in cost is very slight and is offset by the saving in the stock room and avoidance of mix-ups in shipping. I know then also that, no matter how the workman may juggle up the method of locking, a regular full strength nut will always carry the majority of the load. GEO. P. PEARCE.

Williamsport, Pa.

[That practice in the above case is directly contrary to theoretical considerations, as our correspondent contends, is perhaps a rather daring statement to make. Whenever theory and practice seem to disagree, either the theory is wrong, that is, it simply has to be disproved, or the common accepted practice is wrong, in spite of being accepted. In the case in question, if the upper nut is not tightened down so as to place a greater stress on the bolt than that placed on the bolt by the lower nut, then both nuts will bear against the same side of the threads of the bolt, and there will be no real locking action. The check nut in that case does not really act as a check nut at all, but rather as an increase in length to the one nut already in place. When a check nut actually fills its purpose of locking the lower nut in place, it must place a greater stress on the bolt than does the lower nut alone, that is, the two nuts must bear against different sides of the thread in the bolt. This is the condition Mr. Kylin analyses, and that being the practical condition desired, his theory agrees with it.—EDITOR.]

SPRING CHUCKS.

Spring chucks are deservedly popular. They are of numerous designs, some good, some poor. Perhaps the most frequently met with of the poor designs is shown in Fig. 1. This chuck is simple enough, being composed of two parts only, the nut and the jaws or holder. The jaws are a part of the shank. In this case, however, simplicity does not

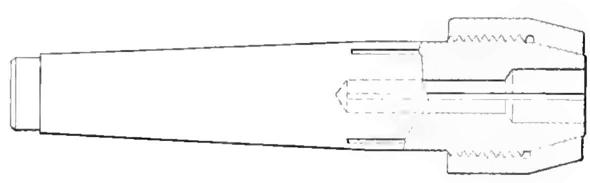


Fig. 1. Common, but objectionable, Form of Spring Chuck

stand for accuracy. The fault with this chuck is evident. By turning the nut, the jaws close, but at the same time the threaded portion of the shank reduces in diameter, becomes a bad fit, and is imperfectly round. The nut thus can assume a faulty position on the thread. Still, where no great accuracy is essential this chuck will answer the purposes for work which does not vary much in diameter.

There are two good designs in common use. One is the draw-in chuck, as found on tool-makers' lathes, and the other the push-out chuck, as found on turret lathes. These are good design, because the taper into which the jaws are forced is a solid ring—usually fixed to the machine spindle.

Even these chucks are true for but one exact diameter, though in practice they work well when the stock is slightly off size.

Sometimes it is difficult to arrive at a correct design for a particular condition. Fig. 2 shows a special design which will probably find appreciation. This chuck is used in an automatic gear cutter. The pinion which it holds is very small in diameter compared with the shaft of which it forms a part. Consequently, there is little room for any kind of holding device. When the gear cutting machine is indexing, the cutter is in the position shown in Fig. 2. Hence the chuck which holds end *A* of the pinion must not extend beyond a certain line.

The general design of this chuck is as follows: The chuck has three spring jaws *J*, produced by slotting the body in three places, part way, leaving the end *S* solid. These jaws are fitted into the taper end of a chuck closer *T*, solid with

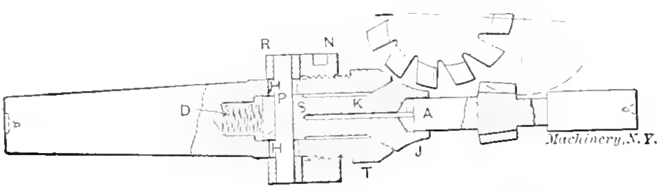

Fig. 2. A Special Spring Chuck for a Difficult Case.

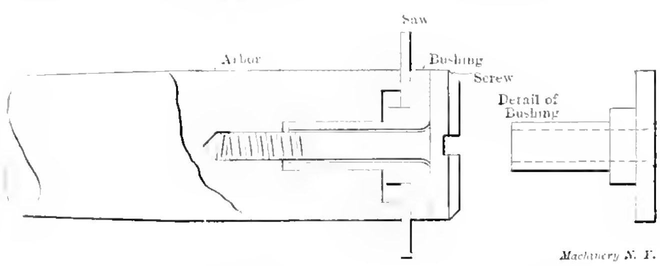
the shank. A nut *N* turns on the threaded portion of the closer or shank. This nut moves a ring *R* which is joined by a stiff pin *P* to the end *S* of the spring jaws. The pin *P* passes through slotted holes *H* in the shank. Hence if the nut is turned in the right direction it draws the spring jaws in on the taper and closes them.

In making this chuck certain points must be observed: The shank must be bored true with the taper; the spring jaws must fit perfectly on the taper, and at the end *S*; the nut must be faced true with the thread; and finally, the spring jaws should be heavy enough at *K* to resist the bending strain which is caused by the grip being beyond the taper, which closes the jaws. An auxiliary spring is shown at *D*. This can be used if it is found that the jaws fail to release when the nut is loosened. A chuck of this design, without the spring *D*, is in actual operation and gives perfect satisfaction. It fits the indexing spindle of the machine on which it is mounted. HARRY A. S. HOWARTH.

New Haven, Conn.

SAW ARBORS.

In reply to the inquiry by "Artebe" in the August issue of MACHINERY, in reference to the best type of saw arbor, would say that in my opinion none of the four arbors shown give the satisfaction and capacity for saws that is desired for gen-



Saw Arbor, permitting Greatest Interchangeability of Saws

eral work. No. 1 arbor will only hold saws of one bore and, rightly, only one thickness with one washer; it is also soft and will soon wear out of true. No. 2 has the same defects, except that the hardened bushing gives it much greater durability. No. 3 depends for its accuracy upon the concentricity of the plain portion of the screw with the thread, which is a poor design because of the difficulty of tapping with accuracy concentric with the hole; should the screw run eccentric, the result will be that the plain portion, or shoulder, will bind on one side of the hole and in a short time cut or wear the counterbored portion oval. No. 4 is also open to the same objections. I would advise the saw arbor shown in the accompanying cut as one that is fairly cheap to manufacture, and yet fills all the requirements satisfactorily. The hardened bushings which are comparatively cheap to manufacture can be changed to suit saws with various sized holes, and variations in thickness of saw require no changes at all. PENNSYLVANIA.

A BLACKSMITH'S DRILL JIG.

In the two accompanying half-tones and the line-cut is shown a special kind of drill jigs, specially designed for small parts which have to be produced in large quantities, and at the same time must be accurate. This jig I term a tong jig. It is forged, but it could be made of cast iron. If it is made out of cast iron, the handles should be made from small gas pipe, and either threaded or pinned to the jig. Making it from a forging, however, gives the advantage that the handles can be drawn down to a taper, giving to the jig the necessary elasticity for holding the work in place when the link *A*, Fig. 1, is slipped into place. This kind of a jig must be hinged at *B*. The lower and larger part *U* is machined for holding the pieces to be drilled, the top piece *D* containing the bushings. For castings or parts which are shaped to a circular segment this jig is very handy, as the

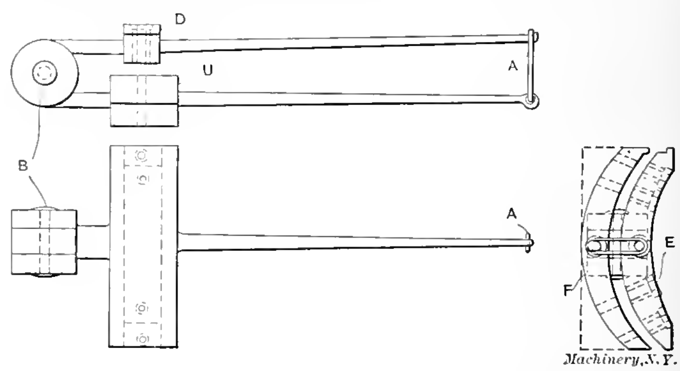


Fig. 1. A Blacksmith's Drill Jig.

operator can, by holding the handles, turn the jig to any angle desired. This jig requires no blocking up or clamping. The jig shown schematically in Fig. 1, is intended for work of a segment shape, but for straight work the bottom *F* should be straight, as indicated by the dotted line. The half-tones, Figs. 2 and 3, show another application of the

Fig. 2. The Jig Open, and the Work to be Drilled.

same principle in jig making. Fig. 2 shows the jig open, together with the piece to be drilled, before putting it in place. Fig. 3 shows the jig closed with a piece in place and the link over the handle. This jig differs from the one shown in Fig. 1 therein that the part holding the work to be drilled runs lengthwise of the handles. Of course, the various jigs will have to be made to accommodate the construction of the parts to be drilled. The angle casting for which the jigs in Figs. 2 and 3 is used is about 3½ inches long, with a small boss on the inside of the angle. Since this jig was put in use, not one part in a thousand has been scrapped.

As will be seen, this jig registers from the proper point, *viz.*, the outside corner, and if any chips are in the jig, the operator cannot put in another piece. Consequently he has to keep the jig free from chips and dirt in order to close the handles before drilling. The tool is very simple to operate. There is no bother with a number of screws and

clamps, two or three different sizes of wrenches, etc., as is usually the case with a box jig, which takes much longer to handle for putting in and taking out the pieces than it does to drill the holes. Another advantage with this tong jig is that, after the part that holds the work to be drilled has been properly machined, the operator cannot drill a piece until it is placed properly where it belongs, as he cannot

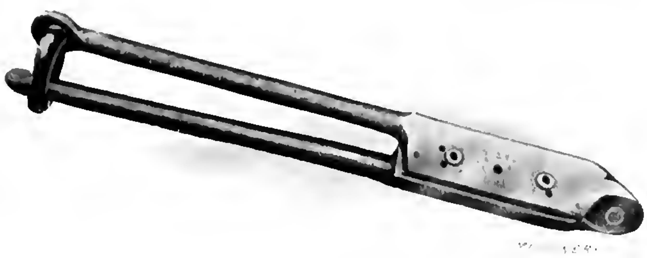

Fig. 3. Jig Closed, Ready to be Used.

close the handle. The writer has known of parts being put in box jigs, bottom side up, and the mistake has been discovered first when the holes have been drilled. Since the introduction of the first of these jigs in this shop, they have been coming rapidly to the front in this factory, and are driving the box jigs out of the business. J. F. SALLOWS.

Lansing, Mich.

CUTTING A SPECIAL CAM.

It often happens, even in well equipped shops, that odd jobs come up for which there are no tools, and which have to be produced in the old-fashioned way with the aid of common sense and a little rigging. Such was the case with the grooved cam, the form and development of which are shown in Fig. 1. It happened that in this case only the end positions of the roll were important, and all that was necessary with regard to the curved part of the path was a reasonably smooth action, the variation of the height of the roll due to the swinging of the lever on its fulcrum not being of enough importance to be taken into consideration.

We decided to cut it on a milling machine, and we first looked up a fixture, shown in Fig. 2, which had been used

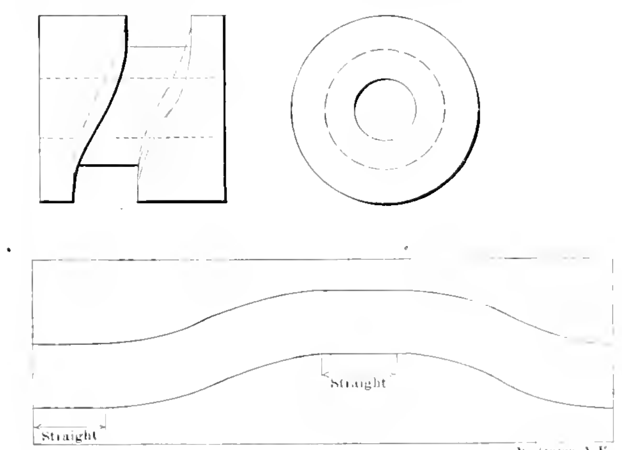

Fig. 1. Cam to be Cut, and its Development

some years before for a similar job, and by good luck had not been scrapped. As will be readily seen, this fixture has provision for clamping on the milling machine column, and a small adjustable slide at the top carrying a pin to follow the former. In addition we had to make the arbor and former, shown in Fig. 3. In making the former, a blank was first made; then the development of the cam was cut out as accurately as possible from a thin piece of tin and transferred to the former by wrapping the tin about it and scratching the outline. The former was then placed on an arbor in the milling machine, and an end mill of the same diameter as the roll was placed in the spindle, the center lines of the mill and roll being exactly in the same plane. The outline was now worked out as close as possible, feeding by hand. The last operation was to smooth up the curves with a file, and we were ready for making our cam.

The fixture was fitted on the milling machine column with the pin in the slide in the same horizontal plane as the spindle of the machine. The table screw was removed, and a rope was attached to the end of the table and run over a

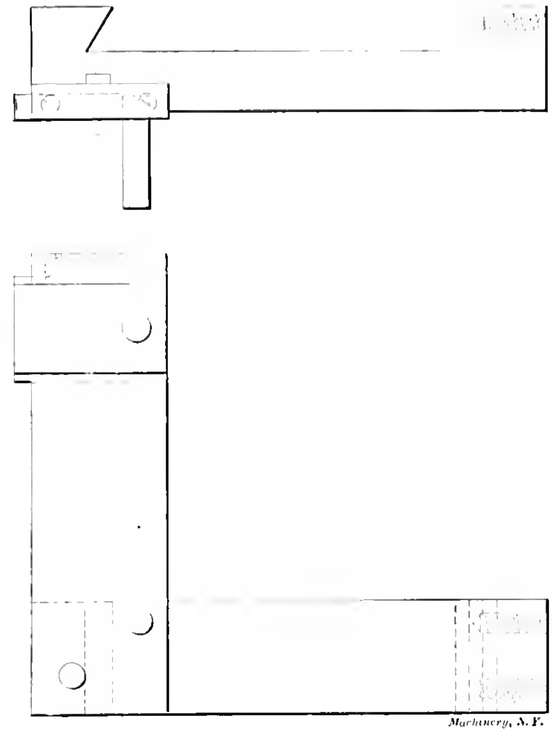

Fig. 2. Bracket to be secured to Milling Machine Column when Cutting Cam.

pulley in a wooden frame placed on the floor. A weight on the other end of the rope supplied the power necessary to hold the former against the pin. With the center line of the cam blank and former set at the same height as the axis of the milling machine spindle, and the blank and former assem-

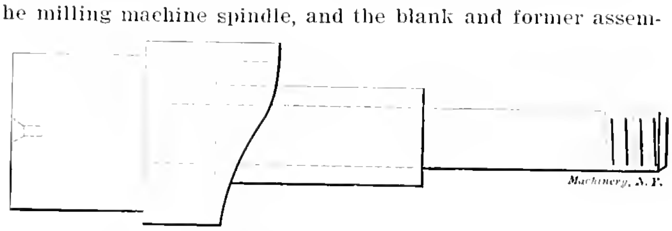

Fig. 3. Arbor and Former.

bled on an arbor, the arrangement was as shown in Fig. 4. The slide carrying the former-pin was adjusted to bring the end mill central with the position desired for the slot, and locked. On account of the spring in the parts, the slot was first roughed out, full depth, with a mill 1/16 inch under-size,

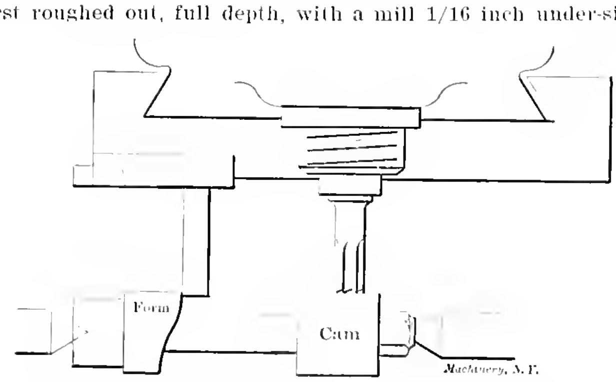

Fig. 4. The Machine as Fitted Up for Cutting Cam

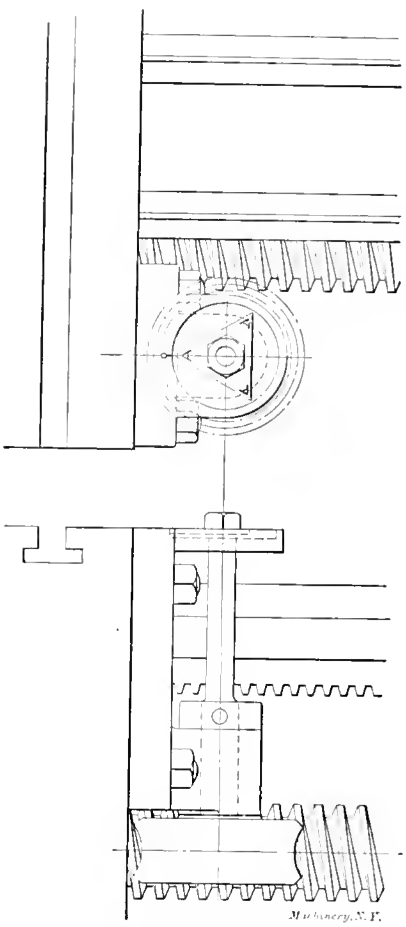
and afterwards finished with a mill the full size of the cam roll. The former-pin must be the same size as the finishing mill. The cams made in this way required very little fixing up in the curved part, and the straight portion came exactly as desired. ALLAN.

INDICATOR FOR THREAD CUTTING.

When cutting a thread in a lathe, if the number of threads to the inch being cut is a multiple of the number of threads to the inch on the lead-screw, the split nut may be

thrown into mesh with the lead-screw at any time, and the tool will follow the first cut. This is not the case, however, when the number of threads to the inch being cut is not a multiple of the number of threads to the inch on the lead-screw. Because of this, lathes are generally equipped with a backing belt, which is thrown in when the tool has made the desired cut, and the carriage is brought back to the starting point without having been disengaged from the lead-screw, which, of course, necessarily brings the tool into the right relation with the work. This is a good arrangement for short threads, say two or three inches in length, but when they are longer, and especially when they are large in diameter (which means slower speed) the backing belt is not a very economical contrivance, because considerable time is wasted while the carriage is being moved by the lead-screw from the end of the cut, back to the starting point. The accompanying illustration shows a simple device which may be attached to any lathe, and used to a good advantage when cutting threads. It can be fastened to the carriage as shown in the cut, and preferably on the side next to the tail-stock, as very often there is not enough thread on the lead-screw to permit its being put on the opposite side. This indicator is used in the following manner: Start the lathe, and when one of the three points marked *A* of the triangular pointer (see plan view), is opposite the zero mark, throw the split nut into mesh with the lead-screw. After the tool has reached the end of its cut, bring the carriage back by hand to the starting point. Wait until either of the points marked *A* is again opposite the zero mark, then throw the split nut into mesh with the lead-screw as before. If this is done with each successive cut, the tool will always come right with the thread. When the pointer is a triangle as shown, the worm-wheel, which is in mesh with the lead-screw, should be so proportioned that its number of teeth is three times the threads per inch of the lead-screw. If, for example the lead-screw has eight threads per inch, then the worm-wheel should have twenty-four teeth. Then, when either of the points marked *A* is opposite the zero mark, the lead-screw and the lathe spindle would occupy the same relative positions. The device does not work for fractional threads.



Indicator for Thread Cutting.

John Bradford.

[This valuable device is not new, however. It is claimed to have been originated in this country thirty or thirty-five years ago by William Gleason, of Rochester, N. Y. In fact, however, it is much older than that, having, we believe, originally been invented in England. See Machinery, December, 1897, May, 1899, and February, 1901.—Editor.]

THE "MONEY-BACK" SYSTEM.

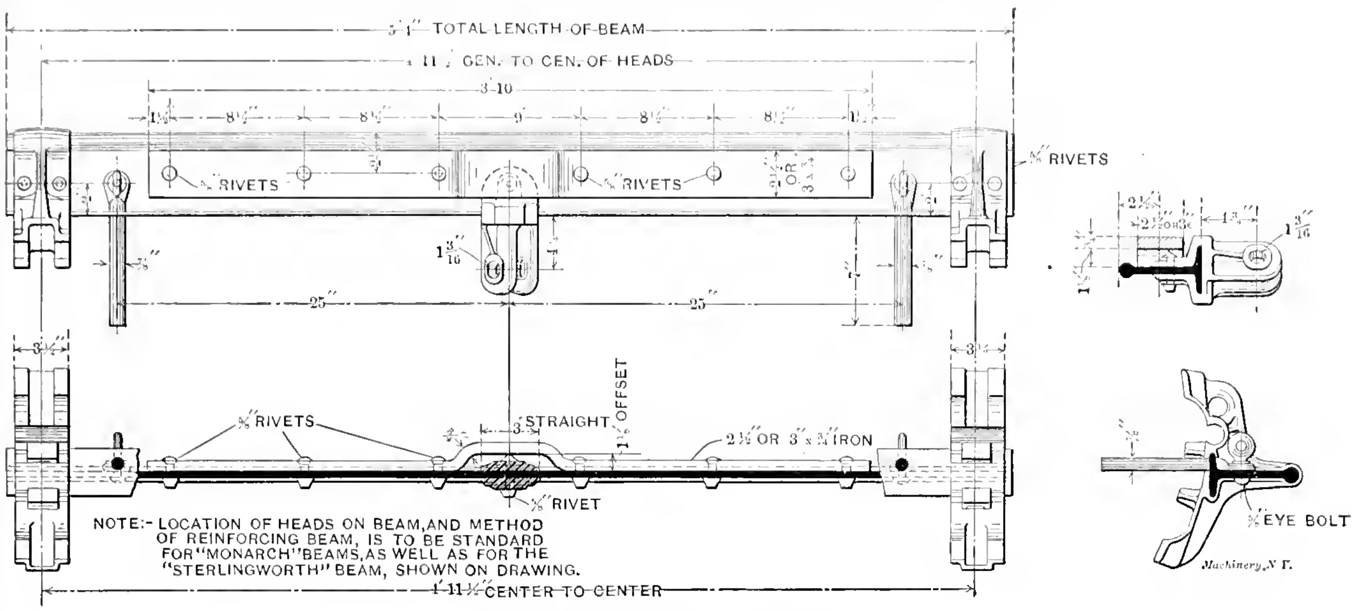
Lately we are seeing a good deal of what Elbert Hubbard calls the "money-back" system. This system simply means that if you don't like what you buy you can take it back and get your money back. Of course, you cannot really expect to use it a great while before you take it back; that is, you would not think you could, but a friend of mine had an experience that made him wonder where some people thought the limit was. He was asked to bid on two or three small machines of a slightly special character. He did so after finding out the requirements. He was asked if he would guarantee the machines to do the work, and he said he would, for in writing his bid he agreed to make the machines "satisfactory," in which he showed a laudable faith in his fellow men, and a lamentable absence of knowledge of law. The machines were delivered, certain defects were found in their working and certain improvements suggested and made, all of which was swallowed by the builder without comment.

About four months after the last alteration was made, the builder wrote and mentioned the fact that he could use some money to advantage, and would Mr. Purchaser kindly send a check? Mr. Purchaser did so for the full amount of the bill, and the builder forthwith spent the money and regarded the incident as closed. After another four months the builder was surprised to see a van back up to the door with two of the machines on it, and a few days later he received a bill for them from Mr. Purchaser. About four months later he found that his property had been attached by Mr. Purchaser and he had been sued for the value of the two machines and some more. Another four months and the case came to trial. Mr. Purchaser recovered about $50 damages for his bother about the machines while they were being altered in the first place, but had to take them back. Mr. Builder paid lawyers' fees, traveling and costs of court, about $150. Now he does not guarantee to satisfy any one. The money-back plan looks on the surface to be all right. It looks to be the only fair way, and it would be, if the man who buys was always as honest as the man who offers this plan. Suppose you build planers. You offer them on the money-back plan. Out of a thousand customers there will be one whose order you had better fill by going down to the freight office and writing your check for the amount of the freight, out and back, and presenting it to the railroad. They are the only ones that will make anything, any way, and you will save yourself a good lot of expense and worry. Then out of this thousand there will be nine who really want a good tool, but who are crafty and think that you will knock off quite a discount rather than take the tool back; then there will be about another hundred that will honestly think that some accident in the shop or carelessness of their workmen is not their fault, but yours. This will leave you with a hundred and ten planers, out of a thousand, second-hand on your hands and worth about 50 per cent less than your price for new ones. Then there are extra freight charges, etc., and you really must figure on about 10 per cent loss. To meet this, you must add about 11 per cent to your prices. Even then you are just as apt to find the whole hundred and ten returned machines in a single year's work, in which case you are bankrupt before you begin to get a show. If your goods are something that you can just take down off the shelves and send out, and that you can put back and sell again, you can do it on a very small margin of extra price, but when, as is apt to be the case, your machinery is saleable to only a few people, and it cannot be thoroughly tested without making it second-hand, then you must go slow. There are usually certain definite things that a customer needs to have a planer do. A guarantee that your planer will do it within a certain time and within certain limits of accuracy is something that we can all meet, and yet if the customer is not pleased with the color of the paint on the inside of the bed he cannot make you suffer.

The most satisfactory sale I ever made was of a gap lathe. The inquiry came for a lathe to do certain specified work, the most serious of which was a cut of a certain depth and feed on a certain diameter. The diameter called for a 36-inch lathe. We had a 24-inch gap lathe on the floor, so we rolled a motor up alongside, belted it up and put in a 36-inch pulley and found out whether it would take the cut, the same was as the Dutchman found out whether he could drink a keg of beer—by trying it. The result was that we sold a 24-inch gap lathe at a good profit, and our customer bought a lathe that would do just what he wanted at a low price compared with the 36-inch lathe that he expected to buy. Entropy.

RECLAIMING OLD METAL BRAKE-BEAMS.

The reclaiming of old bent and damaged metal brake-beams is no small item on a large railroad system, especially with our present heavy equipment putting them out of business regularly. One of the large systems (D. & R. G. Ry.) follows the plan shown in the accompanying cut, of using a ¾ x 2½-inch or a ¾ x 3-inch wrought iron strap as a reinforcing strip on all bulb or I-section beams that fail in service.



Method of Repairing Old Brake-beams.

When bent or damaged brake-beams of this class come into the scrap docks, they are piled to one side, and each month or so a gang of men is set at stripping them of the heads, fulcrums, etc. Then the bare beams are taken to the blacksmith shop to be straightened, after which they are ready to be drilled for the reinforcing strap rivets. They are then taken to an automatic riveter, where the heads, fulcrums, etc., together with the reinforcing strap, are applied. Beams of this type, fitted up in the manner described, give quite as satisfactory service as when they are new, and last much longer.

THE PROPER ADJUSTMENT OF SPARK COILS.

One of the most important adjustments about a spark coil is that of the vibrator spring. The tendency is to set this spring too tight in order to get a "good" spark. This is usually tested in the air, and when a big, heavy spark is obtained, the operator thinks that everything is all right, and starts the engine. The proper adjustment may be secured as follows: Draw the vibrator back until it does not touch the spring. Set the vibrator so that the iron head is from 1/16 inch to ⅛ inch from the core. Bring the spring up until it touches the vibrator lightly, and start your engine; if it skips, try adjusting the screw a little tighter, but leave the spring just as weak as you can, without the engine skipping. You will find that the battery will last very much longer. Sometimes the battery consumption is increased to three or four times the amount a coil should take by merely setting the spring stiff and getting a "big" spark. Of course, there is danger of setting it too weak, so that when the engine stops, the vibrator spring does not touch the contact screw, and the engine will not start.

We sometimes hear talk of waterproofing coils, but the best plan is to keep them in a dry place, not where they will be hot, but where they will not get damp, as the pressure of the jump spark is so high that it will run along a little streak of moisture almost as well as on a wire, and although the tendency is to dry up this moisture, in so doing it sometimes carbonizes the wood and makes another path for itself. Special care should be exercised on launches to have a good place for the coil and battery. Do not put more than six cells of dry battery or three cells of storage on the coil. If it does not work with this amount of battery in good condition, there is something the matter with it, increasing the voltage will not materially help the spark, and will only burn out the contact points. Secondary or plug wires should not be allowed to remain in contact with a hot pipe or cylinder. They are pretty sure to give trouble sooner or later. Place a piece of wood or fibre between wire and the heated metal. Oil should not be allowed to come in contact with rubber insulation, as oil rots rubber. Do not draw the spark out in the air to see how long it is; this strains the coil, and if there is any weakness, it will be sure to increase the trouble, even if it does not break down immediately.

Another puzzling trouble to find is a wire that is broken inside the insulation. This sometimes happens in the most unlooked for places, but usually where the wires are moved or bent most, as at the commutator, or where there is a great deal of vibration. The break can sometimes be located by bending and pulling, as the wire will be very much weaker and more limber in the broken spot. The spark plugs should be closely watched and kept in good condition. Much of the trouble attributed to the coil may be traced to the plug.

FACING WORK ON CENTERS.

In the August issue of Machinery the writer finds a kink on the subject of facing work on centers by W. S. Leonard. It astonishes some of his readers why he does not use the so-called half-center for such work. It appears as if Mr. Leonard were totally unacquainted with this appliance. Supposing it is wanted to cup the end of an arbor for holding work between centers, how would it be possible to do by using ordinary centers, unless by slacking the tail-center. For all such purposes the old style of center should be discarded, and the so-called half-center be used.

Beverly, Mass. Clarence E. Simonds.

STEAM WHISTLE OPERATED BY GAS.

In the August issue of Machinery, W. L. McL. suggests putting a steam whistle on the cylinder of a gasoline yacht engine. I would like to inform W. L. McL. that on an ordinary-sized yacht engine that is the best way he can find for spoiling his compression and the efficient running of his engine.

Arthur Knapp.

Ardmore, Pa.

[Mr. Knapp's objection, we suppose, is that screwing a pipe into a gas engine cylinder head will increase the clearance space an amount equal to the space in the pipe up to the valve. Of course it is possible to avoid this by decreasing the original clearance space an equivalent amount. In any case the valve should be close to the head.—Editor.]

* * *

In every work of genius we recognize our own rejected thoughts.—*Emerson.*

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

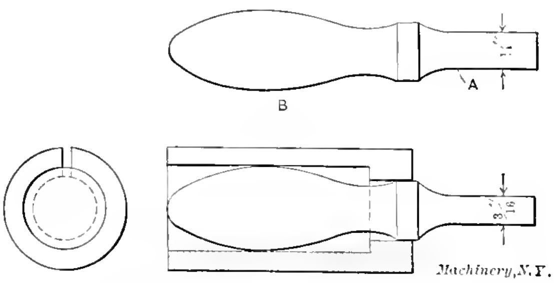
Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

BABBITTING KINK.

Another way than that mentioned in the August issue, of babbiting a solid box in a hurry and not have to scrape it, is to take a piece of paper, rub it with Albany grease, and wrap it around the babbitting mandrel. The grease will make the paper stick until the babbitt is poured, and will help it to run freely. After pouring, drive out your mandrel, clean out the paper, and the box is ready. ALLAN.

HOLDER FOR TURNING END OF HANDLES.

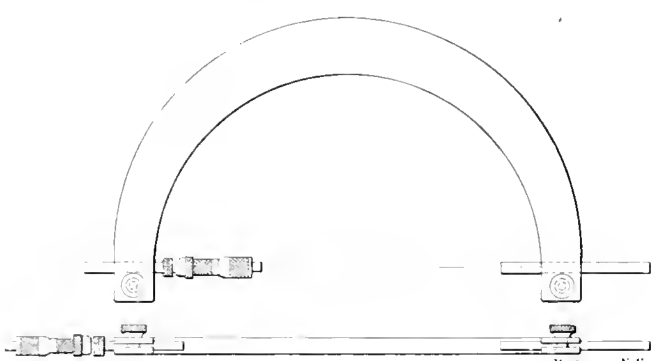
A job came up one day requiring a number of handles, as shown in the cut, to be turned down at *A* from a diameter of $\frac{1}{4}$ inch to 3-16 inch. I tried chucking them at *B*, but found



that it took considerable time to true them up, and very little pressure to knock them out of true again. Finally, I made a holder, as shown in the cut. This holder is simply a split bushing with a shoulder at one end. By this means I could grip the handles firmly, and hold them true for turning with very little trouble. ORIGINAL.

MICROMETER FRAME.

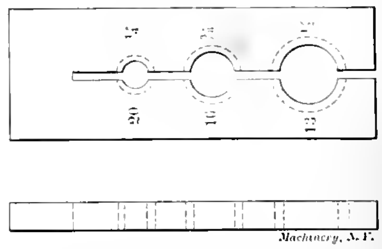
The accompanying cut shows a micrometer frame which I used some years ago at the Westinghouse works. The frame is an aluminum casting, and the anvil is simply a tool-steel pin, which fits well in the hole into which it is inserted, and can be clamped anywhere within the limits of its length. The



micrometer end of the frame is supplied with an inside micrometer head. The tool is adjusted to a gage, either to a standard pin gage, or to an inside micrometer gage. The capacities of three of these micrometers in a set were from about $3\frac{1}{2}$ to 7 inches, 6 to 11 inches, and 10 to 15 inches. When the head was turned outward, as shown in the lower view in the cut, the tool was very handy around a horizontal boring machine where a pin gage could not be used without removing the boring bar. SIRIUS.

A SCREW FILING JIG.

A clever little device for holding screws while filing the ends to shorten the length came to my notice a short time ago in a shop where many varying lengths of screws were needed. It was impracticable to buy all the various lengths, so a file was used. The screw, if held in a vise or hand clamp was sure to have the threads jammed, hence the jig shown was devised. The jig consists of a strip of brass, 3/16 inch thick. Three holes were drilled, tapped and marked. Then a saw cut was taken through the piece to the last hole. The screw can be put into the right hole, then the jig held in a hand clasp or a vise, and the file used without fear of bruising the threads. This works to perfection, and the plate can be tapped for a great number of sizes of screws, if desired. RAYMOND C. WILLIAMS.



Worcester, Mass.

BENCH VISE ANVIL.

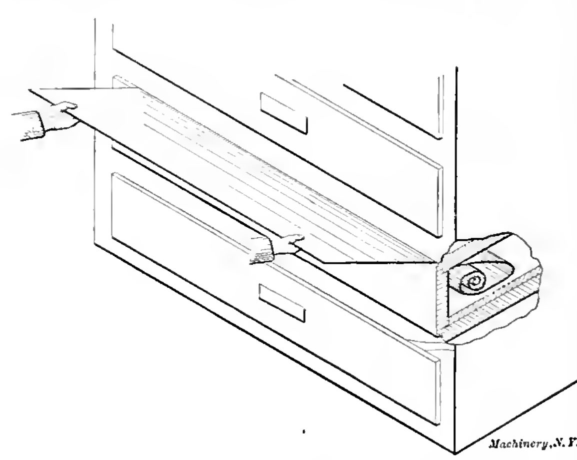
The accompanying cut shows a very handy bench vise anvil for the tool-room, model-maker, or amateur mechanic. The anvil is made from a piece of steel T-rail about 12 or 15 inches long, and as heavy as can be obtained, and the top, edges and ends are planed smooth, true and square. The web is cut out, as shown at *B*, so a clamp or swivel vise of about $1\frac{1}{2}$ or 2-inch length of jaw can be fastened to the end of the rail. There is a taper hole at *A* for different shaped stakes. The top and edges may be case-hardened if so desired. This makes an exceedingly handy outfit, as a great variety of work can be executed on it, and the vise can be brought in the best

position to see the work. The top is a good place for straightening work, and the edges for bending work. Pieces of suitable sized rails can be easily obtained from section foremen on almost any railroad. X. Y. Z.

[Perhaps *some* railway officials might object to X. Y. Z.'s naïve statement as to the ways and means of getting suitable sections of rail as an unwarranted incitement to breaking the eighth (seventh, Douay version) commandment.—EDITOR.]

SMOOTHING WRINKLED BLUE-PRINTS.

The cut shows our method of "ironing" soiled or wrinkled blue-prints after they are dry. The wrinkled print is laid in a cabinet drawer with just enough of it outside to conveniently hold in the hands, and the drawer is tightly closed. After being pulled out the print is perfectly smooth. The



angle of pull should be adjusted to the strength of the paper. Pulling through once will, of course, cause the print to roll up, when released; if this is not desirable, and the print is wanted to lie flat, reverse the print and pull through once more. HOWARD D. YODER.

Wadsworth, Ohio.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

In the July issue of MACHINERY, C. H. A. asks if there is any sure way of plating by dipping in copper sulphate so as to obtain a good plating, and also asks what is the correct solution. The best results are obtained by using a solution of 3 pounds of sulphate of copper to 2 fluid ounces of sulphuric acid. The surfaces to be plated must be carefully cleaned, so as to be free from dirt and grease. With the above solution good results are certain, and any reasonable desired thickness of plating can be obtained.

Scottdale, Pa. M. B. STAUFFER.

DEPTH OF THREAD IN PIPE FITTINGS.

A. B.—Do manufacturers of pipe fitting follow or agree on a common standard in the depth of thread that shall be tapped in fittings supplied to the trade? Is there a published record of same?

A.—The Briggs standard of pipe thread gives practically all the data required. The taper of ¾ inch per foot makes no precise standard of depth necessary, but, of course, where test plugs are used for inspection, certain arbitrary standards are necessary. The extra data sheet No. 78, made ready this month, on pipe threads and gages, gives the tool-room practice of one large manufacturing company.

TO LOOSEN A PULLEY ON A SHAFT.

N. M.—I have a number of 48-inch pulleys rusted fast on 2 7/16-inch shafts. I have tried almost every mechanical means known, short of hydraulic pressure, to start them, and so far have failed. The pulleys appear to be "welded" to the shafts with a dry, hard rust. I have tried to soften the rust with kerosene, gasoline and alcohol, but none of these apparently does any good. What would you advise?

A.—We would advise heating the hubs and lightly hammering them, and the continued use of solvents such as kerosene or alcohol, but probably heavy pressure will be required to start the pulleys loose. This, of course, is best supplied by a hydraulic press, but threaded rods may be rigged so as to obtain almost any pressure that is likely to be required in this case. The question is submitted to our readers.

DISTINCTION BETWEEN PITCH AND LEAD.

E. C. D.—Admitting that a screw and worm are essentially the same thing, why is the pitch of a screw known as the distance traversed during one revolution of the screw, and the pitch of a worm the distance from center to center of adjacent threads, regardless of multiple threads.

A.—This inquiry illustrates why a distinction should be made in the use of the terms "pitch" and "lead." Pitch should always be regarded as the distance from center to center of adjacent threads, irrespective of lead, while the lead should always be regarded as the axial distance traversed by one revolution of the screw without reference to the number of threads. In the case of single-thread screws or worms the pitch and lead are the same, but in the case of multiple-thread screws the pitch and lead are different, hence the desirability of always observing the distinction in meaning.

FEED MOTION GEAR TRAIN FOR BORING BAR.

W. H. S.—I wish to convert an old engine lathe into a boring lathe, using the boring bar shown in Fig. 1. The feed screw in the boring bar has four threads per inch, and is driven by the transmission gears A and B, having 14 and 32 teeth, respectively. The feed motion is to be transmitted to the center gear B by a square end bar C, shown in Fig. 2, which works through the hollow spindle, and is connected to the spindle through the back gear by a suitable train. The pinion D is connected to the feed bar by friction disks, which are released to stop the feed. The feed is reversed by the shifting spool-gear E. The pinion on the back gear shaft has 15 teeth and the spindle gear 73 teeth. What numbers of teeth will be required in the gear train to give the required feed in either direction?

A.—Since the feed screw has ¼ inch lead, and the gears are 14 and 32 teeth, a feed of 3/64 inch per revolution will require a differential movement of the feed bar C of $3/64 \div (\frac{1}{4} \times 32/14) = 21/256$. That is, the feed bar must run 21/256 turn slower or faster than the boring bar to give a feed of 3/64 per revolution. Expressed in another way, the feed bar must make 235 turns for 256 turns of the boring bar to feed the head to the left and 277 turns for 256 turns of the boring bar to feed the head to the right. Aside from the method of finding the proportions of the spool-gears E and E_1, perhaps, there is nothing different from the common trial-and-error operations followed in proportioning feed

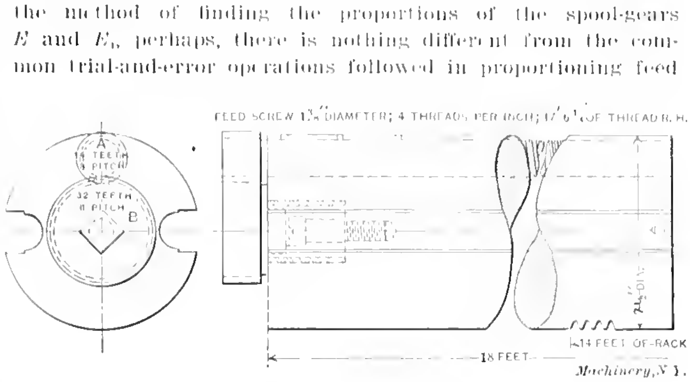


Fig. 1. Boring Bar Used.

gear trains, with which all machine designers are more or less familiar. If we make the two-spool gears with the same respective numbers of teeth, the squares of the tooth numbers must be in the ratio of 235 to 277 in order to preserve the required rate of feed in either direction. The numbers of teeth should be less than 100—preferably from 40 to 60. Hence we will multiply 235 and 277 by some factor which will yield products whose square roots will be numbers between 40 and 60. By a series of trials we find that the near multiples 2209 and 2601 yield roots 47 and 51, which

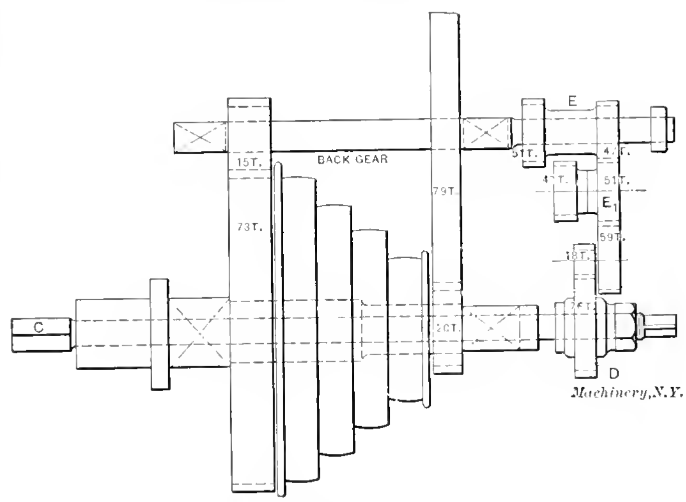

Fig. 2. Diagram o Gearing

are satisfactory. The numbers of teeth in the remainder of the train are given in Fig. 2. The proof for the differential motion of the feed bar for left-hand feed is

$$\frac{73 \times 47 \times 18}{15 \times 59 \times 76} = \frac{10293}{11210} = \frac{235}{256}, \text{ nearly,}$$

and for right-hand feed it is

$$\frac{73 \times 51 \times 51 \times 18}{15 \times 47 \times 59 \times 76} = \frac{569619}{526870} = \frac{277}{256}, \text{ nearly.}$$

* * *

In the August issue a description was published of the Besly disk grinder, having 26-inch steel disks, with the intimation that it was the largest disk grinder ever built. In this we were mistaken. C. W. Burton, Griffiths & Co., London, inform us that they build a 40-inch disk grinder, and that one was exhibited at the Engineering and Machinery exhibit held at Olympia Exposition, London, 1906. This large machine is built either with motor or belt drive. The work tables are about 18 x 27 inches and are carried on ball bearings. They are provided with T-slots and are traversed by rack and pinion. Adjustment in and out from the disks is effected by a micrometer feed screw. The approximate weight is 6,700 pounds, or over three times the weight of the grinder illustrated in the August issue.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

GRANT-LEES GEAR GENERATING MACHINE.

Any one who has followed the trend of development in machine tools in the past few years, must have noted the growing tendency toward the use of generating processes for the cutting of gear teeth. In the past two or three years, especially, much time and thought has been given to the process of generating gear teeth with a hob, whose normal outline has the form of the rack tooth of the interchangeable

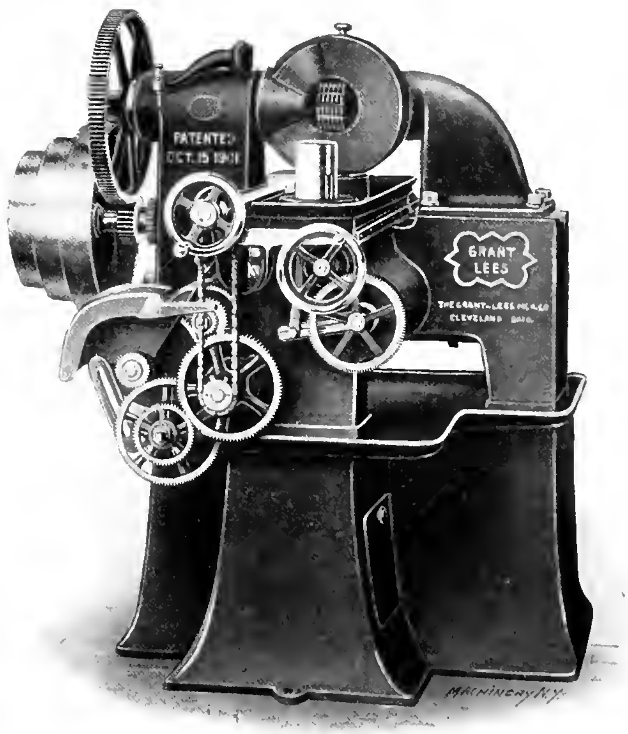

Fig. 1. Grant-Lees Gear Generating Machine. Front View.

set to which the gear belongs. The machine illustrated in the accompanying cuts, and described in the following paragraphs, is the latest product of this kind which has been brought to our attention. So far as we know, it is the first machine working on the hobbing principle for cutting spur gears that has been regularly built for the market in the United States. It is radically different in its constructional features from the European machines which have preceded it in this field, and contains a number of improvements which make a study of its details well worth while.

The general requirements of a hobbing machine for gear cutting are as follows: Means must be provided for driving the hob powerfully and smoothly at any angle with the axis of the work, so that spiral gears as well as spur gears may be cut. A work spindle, stiffly supported, must be provided, driven by a worm-wheel connected to the cutter spindle through change gears, so that the proper relation between the work and the cutter may be established to give the required number of teeth. Either the work spindle or the cutter spindle must be mounted on a slide, so that the center distance between the work arbor and the cutter arbor may be adjusted to give the proper depth of tooth. Either the work must be moved past the hob, or the hob past the work for the feeding motion, suitable means being provided to vary this rate of travel in accordance with the depth of cut and the hardness of the materials used. In addition to this, the feed of the work must be connected with the work-revolving mechanism by change gears, to give the proper movement for cutting spiral gears independently of the rotation of the work with the hob. These various movements and adjustments must be obtained in a way which will still allow the machine to have great rigidity, to prevent the deflections and inaccuracies which must otherwise result from the heavy cutting strain which the process involves. The solutions of these problems offered in the Grant-Lees machine will be understood from the cuts and the description.

As will be seen, the machine has the general appearance of the Lincoln type of miller, which is used so largely for heavy form cutter milling in repetition work. The power is transmitted from the cone pulley through reducing spur gearing to a bevel pinion meshing with the main driving bevel gear. This latter has a wide face, and engages, at the inner ends of its teeth, in addition to the driving pinion, with a second beveled pinion, keyed to the cutter spindle of the machine. The whole arrangement is shown quite plainly in Figs. 1, 3, and 5. The main driving bevel gear is in the form of a ring, revolving on a hub on the cross rail of the machine. The bracket carrying the cutter spindle has a long shank which passes through a hole in the center of this hub, and carries on its back end a graduated dial with suitable handles for setting it at the angle required for the work, and means for locking it in the desired adjustment. These arrangements are plainly shown in the rear view of the machine, Fig. 2.

The work is set on a hardened and ground tool steel arbor on a spindle having a vertical movement for the feed. The power for rotating the work spindle in unison with the hob (necessary in this machine, as we have just seen) is taken from the cone pulley shaft through change gears on the right side of the machine in Fig. 2, to the worm meshing with the index wheel on the spindle. The feed is obtained by a mechanism which raises the spindle as the cut progresses, the feed variation being obtained by change gears at the front of the machine as shown in Fig. 1. When the work has been fed in to depth, by adjusting horizontally the slide which car-

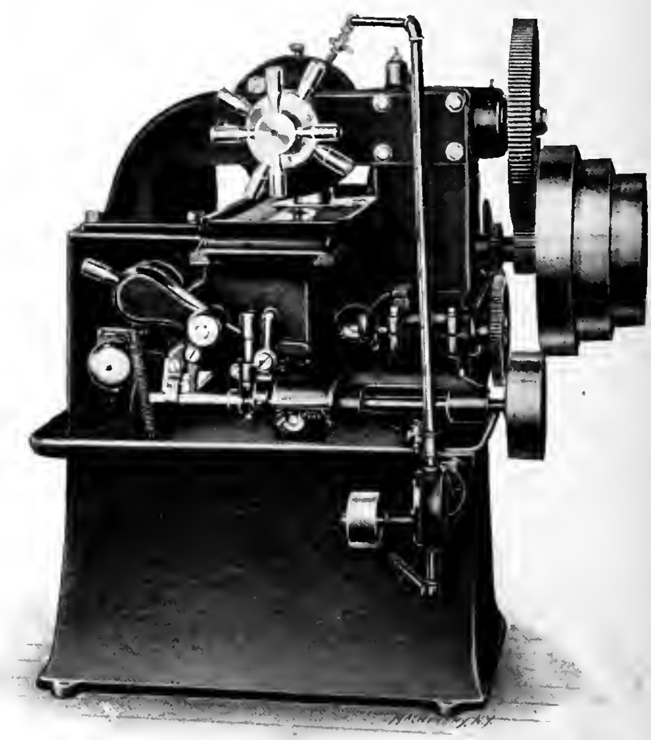

Fig. 2. Rear View of Gear Generating Machine, showing Feed Mechanism.

ries the work spindle, to figures read on the dial of the handwheel governing this movement, the cut may be started, and the work will be fed up past the revolving hob until the full width of face has been cut, whereupon feed will be stopped, the work withdrawn and returned to its previous position, and a gong will be struck to announce the completion of the work. The machine is, to this extent, automatic.

Figs. 1 and 2 show the front and rear views respectively of the machine, giving clear ideas of the general construction, and of the ingenious way in which the driving motion is conveyed to the hob, giving it a powerful drive and still allowing it to be swiveled at any angle. Ordinarily the driving

gear is covered by a case or cover, as shown in Fig. 1. Fig. 3 shows the machine cutting spur gears. The hob used, shown in Fig. 4, has teeth with a normal outline of the shape of the rack tooth, as explained.

Fig. 5 shows the machine cutting spiral gears. This is done as readily as the cutting of spur gears, it merely being

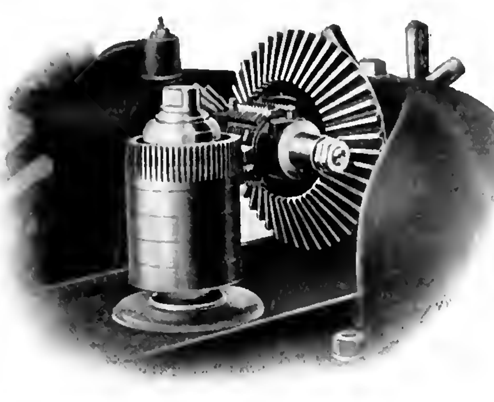

Fig. 3. Cutting a Stack of Spur Gears.

a matter of setting the hob at a proper angle and using the proper change gears for the spiral rotation of the work with the feed. The change gears for this motion are also located at the front of the machine. The connection with the index worm and wheel is presumably through some form of differential or "jack-in-the-box" gearing, so that the rotation of the work for the spiral, in connection with the feed motion, is superimposed on, and independent of, that due to its connection with the hob.

Fig. 4. The Hob Used in Generating Gears.

Fig. 6 shows a worm-gear being hobbed. For this operation the hob spindle is placed in a horizontal position, and the work is fed directly in toward the hob at the proper rate, and stopped at the proper depth, no previous nicking of the blank being required. The feeding motion for this, so far as can be judged from Fig. 1, is of the ratchet type, being adjusted by varying the position of the crank-pin in a slotted link.

Fig. 7 shows an ingenious steady rest, used for work of large diameter. Since the entire work spindle and the work

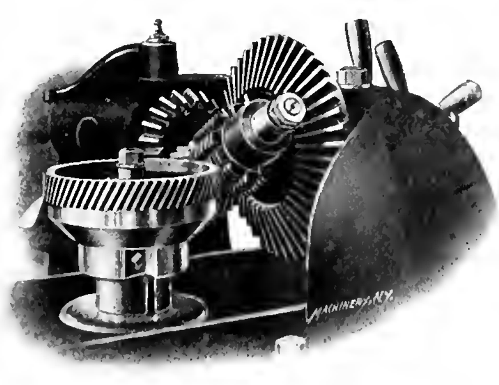

Fig. 5. Cutting a Spiral Gear.

it holds are raised to feed them past the hob, it is necessary also to raise any form of steady rest which might be used at the same rate as the work. The rest takes the form of a threaded post, raised by a nut geared through the worm and chain gearing shown to the vertical feed gearing at the front of the machine. The raising of the work and of the steady rest thus takes place simultaneously, and at the same rate. The attachment is shown in place in Fig. 1.

There are several advantages at once evident in this system of generating gear teeth. One cutter only is needed for each pitch, cutting all the gears from the smallest to the largest number of teeth. The fact that all the gears for a given pitch are cut by one correct hob, eliminates the errors arising from using one cutter for a considerable range of numbers of teeth in the old system. Another consideration which tends toward accuracy is the fact that the heat is uniformly distributed, owing to the fact that the work is continuously rotated. Since each tooth of the hob passes over each of the teeth of the gear, it is impossible for a gear cut on this machine to have thick or thin teeth, since all are cut under exactly the same conditions.

Another advantage of the system is its universality. The same machine is fitted to the cutting of spur, spiral and worm

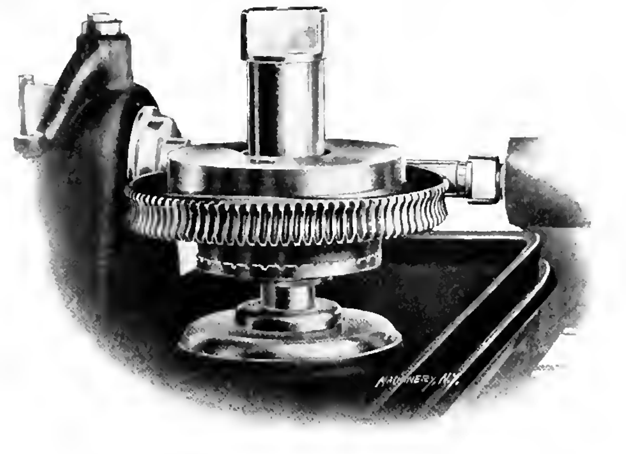

Fig. 6. Hobbing a Worm-wheel.

gears without requiring extraneous attachments, all the movements being provided for in the design of the machine. There is a great gain in simplicity as well, in this process, over the automatic gear cutter of the usual type, which is required to be provided with mechanism for feeding the cutter, returning it at high speed, indexing the work, and repeating the operations with rapidity and precision. Especially does the advantage of the generating machine appear when it is contrasted with a machine of this type adapted to the cut-

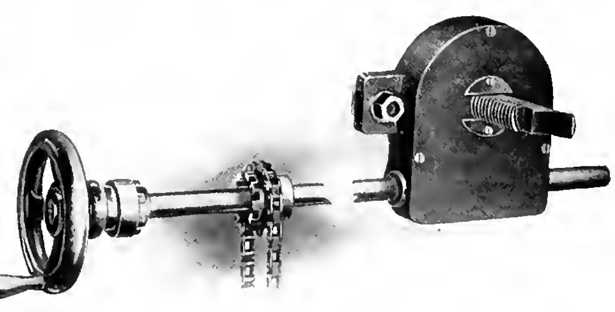

Fig. 7. Automatic Steady Rest, shown in Place in Fig. 1.

ting of spiral gears. It is difficult to escape the conclusion that there are great possibilities in store for the hobbing process of generating spur and spiral gears.

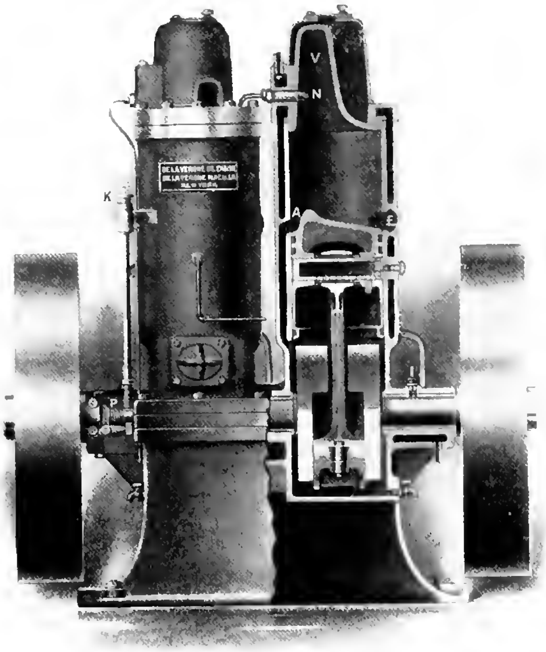
This machine is the result of the combined efforts of Mr. H. J. Lees and Mr. John J. Grant, the former well known as a pioneer in the development of the heavy multiple spindle milling machine, and the latter recognized as one of the most original and ingenious machine tool designers in the country. The Grant-Lees Machine Co. of Cleveland is building the machine and placing it on the market.

DE LA VERGNE TWO-CYCLE VERTICAL OIL ENGINE.

For the past twelve years, the De La Vergne Machine Co., New York, has built the Hornsby-Akroyd oil engine in sizes up to 250 H.P. With the valuable experience gained in the design and construction of this engine to guide it, the company has developed a two-cycle two-cylinder vertical oil engine designed for small powers. At present it is built in two sizes only—

7½ and 15 horse-power. The new engine uses ordinary kerosene or fuel oil. Kerosene is available everywhere, and in most sections can be purchased for about one-half the cost of gasoline. With kerosene at 10 cents a gallon and gasoline at 17 cents a gallon it is calculated that power developed from kerosene costs less than one-half as much as power developed by gasoline. The two-cycle engine has the advantage over the four-cycle type that the piston receives an impulse every revolution, and in a two-cylinder two-cycle engine the crankshaft receives two impulses every revolution the same as that of a single-cylinder double-acting steam engine.

Referring to the sectional part of the cut, air is admitted to the cylinder from the crank case through the port *A*, which is uncovered by the piston near the end of the downward stroke. The beginning of the upward stroke closes the fresh air port *A* and the exhaust port *E*. The air thus trapped is compressed into the vaporizer *V* at the head of the cylinder. A spray nozzle *N* projects into the vaporizer, and through



De La Vergne Two-cylinder Oil Engine.

this a charge of atomized oil is sprayed against the hot walls of the vaporizer. The spray is forced into the vaporizer by the plunger pump *P*, which is driven by a cam on the crankshaft.

The vaporizer is similar in construction to that used on the Hornsby-Akroyd oil engine, being a cast iron bulb on the cylinder head and forming an extension to same. No sparking device or hot tube is used. The walls of the vaporizer retain sufficient heat to vaporize each successive charge of oil, and ignition is effected by the heat of the vaporizer walls together with the heat of compression. Slightly before the end of the downward stroke the exhaust port *E* is uncovered, permitting the escape of burned gases, and on the upward stroke fresh air is drawn into the crank chamber through an automatic poppet valve. On the downward stroke this air is slightly compressed, and when the air port *A* is uncovered the fresh air rushes into the cylinder.

It is evident from the above that the construction is essentially that of the typical two-cycle engine; the design has been modified and improved with the view of obtaining all the advantages of the two-cycle type and of avoiding its defects. The fuel consumption is about one pint of kerosene or fuel oil per brake horse-power hour, and fuel consumption not to exceed one pound per brake horse-power hour is guaranteed when running at three-fourths to full load.

THE BURKE TAPPING MACHINE.

The half-tone shows a tapping machine made by the Burke Machinery Co. of Cleveland, Ohio. The spindle carries a chuck for holding the taps. Mounted on it are two pulleys, one of which is driven by a straight and the other by a cross belt. The spindle may be connected with the forward moving pulley by shoving it inward, or may be disconnected from this and connected with the reversing pulley by drawing it downward. These connections are effected by two expanding ring clutches, one in each pulley, operated by the end motion of the spindle. The work is held by the hand against the plate, shown attached to the bar passing through the base of the head-stock. This foot-stock bar slides freely in its bearings, and is provided with an adjustable stop for limiting its

Burke Horizontal Tapping Machine.

inward motion. When the work held against the plate by the hand is pressed against the tap, this pressure connects the spindle with the pulley which gives the forward movement. When the hole has been tapped to depth, as determined by the adjustable stop, the continued rotation of the tap draws out the spindle and so disconnects it from the forward motion, whereupon the withdrawal of the work puts the reversing pulley in connection with the spindle, and the tap is backed out.

The foot-stock bar has a movement of 3½ inches. The machine has a capacity for tapping holes up to ¾ inch in diameter. Unless otherwise ordered, it is furnished with a 5/16-inch chuck, without extra charge. The spindle will be tapered to fit a No. 2 Almond chuck, if the purchaser desires. The pulleys are 6½ inches in diameter for 1¾-inch belt, and are intended to run at about 100 revolutions per minute. The net weight of the machine is 40 pounds.

CHAPMAN DOUBLE BALL BEARING.

The ball bearing made by the Chapman Double Ball Bearing Co., 40 Bristol St., Boston, Mass., has, as the special feature of its design, an arrangement by which friction between neighboring balls is eliminated. A lot of balls running together in a bearing under pressure have a tendency to crowd together, and it is the belief of the makers of this bearing that a large

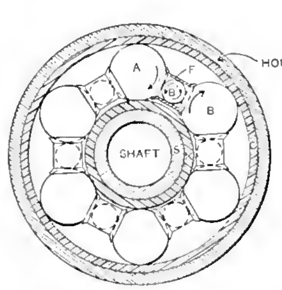


Fig. 1. Use of Intermediate Ball in the Chapman Bearings.

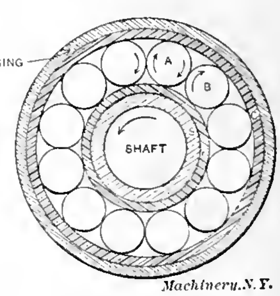

Fig. 2. The Cause of the Friction in Ordinary Bearings.

share of the loss of power, and the larger part of the wear to which the balls and races are subjected, can be traced to this crowding tendency, and the consequent friction of the balls on each other. The means taken to prevent this will be understood by referring to Figs. 1 and 2. In Fig. 2, which shows the ordinary bearing, balls *A* and *B* rotate in the same direction, as shown, when the bearing is in action. This, it will be seen, makes the two balls rub against each other at the point of contact, since the surfaces are moving in opposite directions at this point.

Fig. 1 shows the method of obviating this difficulty. A small ball *B'* is inserted between *A* and *B* on the line of cen-

ters between them, so there is no tendency for it to move out of position. It is held here by a light spool or bushing F, which is beveled at the ends to rest lightly against the large balls A and B, and has a central hole just large enough to allow the small ball B' to rotate freely. It will thus be seen that, barring the entirely negligible weight of the spool F, there is nothing except rolling friction to be considered in the whole bearing. The makers consider that this method of separating the balls is much preferable to the use of a cage, in which case the friction is merely transferred to the sides of the container instead of taking place between the balls themselves, as in the ordinary old-style bearing.

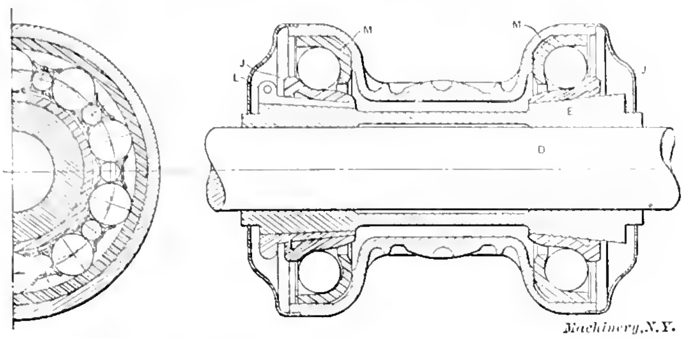

Fig. 3. The Chapman Ball Bearing for Shaft Hangers.

The application of this arrangement to hangers and other shafting bearings will be perhaps as interesting to the readers of MACHINERY as any of the numerous uses to which it has been put. A hanger equipped with a Chapman bearing is shown in Fig. 4, while Fig. 3 is a cross section explaining the construction followed. D is the shafting to be supported, and E is the sleeve on which the inner ball races are mounted. Races J and J are mounted on the sleeve, one at the right-hand, and the other at the left over an adjusting collar L. This may be moved in or out to adjust the bearing to the proper degree of play. It will be noted that the inner races J and the outer races M are both unsupported directly behind the line of thrust. A slight elasticity is thus allowed which permits the bearing to take care of minute irregularities due to temperature changes, etc., while still leaving the parts rigid enough to support any weight which may be put upon

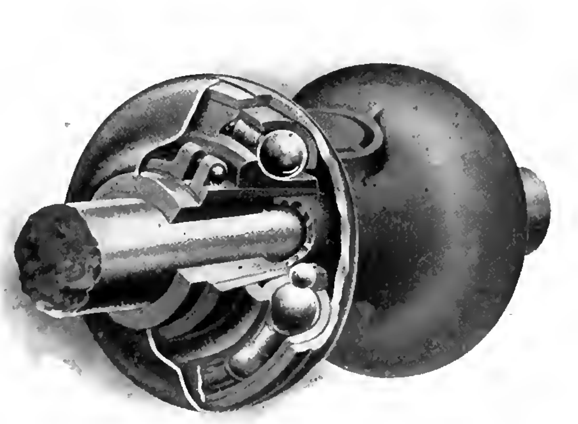

Fig. 4. Sectional View of the Hanger Bearing.

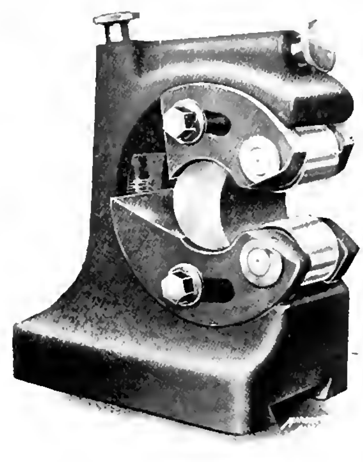
them. In addition to this, the complete bearing is free to swivel in the hanger to adjust itself to the axis of rotation of the shaft.

A number of tests have been made by a competent engineer comparing the efficiency of the Chapman bearing, the ordinary ball bearing, and the plain journal, the workmanship in each case being of the same quality. These tests were made in various ways. One of the simplest of them was carried out with an apparatus consisting of three exactly similar cast iron pulleys, perfectly balanced and weighing 105 pounds each, mounted on a central axle The first of these ran on a Chapman double ball bearing, the second on an ordinary three-point ball bearing of similar design, and the third on a plain journal of hardened and ground steel, running in a cast iron hub. A 7-pound weight was hung by a small cord from the periphery of each pulley in turn, at a height of 10 inches from the floor. Then the weight was released, and the number of revolutions that each pulley made before it came to a stop, as well as the duration of the spin, was noted. The Chapman bearing rotated for 16 minutes and 35 seconds, the ordinary ball bearing, 5 minutes 8 seconds, and the plain journal, 20 seconds.

LODGE & SHIPLEY ROLLER FOLLOWER REST.

The tendency of work carried on centers to spring away from the tool under the pressure of the cut is more pronounced with the high speed attainable with modern tool steels than was the case under former conditions. At the same time, the use of the follow rest to counteract this tendency has been made less satisfactory, owing to the coarser chip, higher speed and rougher surface left by the new steels. The jaws are rapidly worn away, and rubbing friction is a fruitful source of lost power. The half-tone shown herewith illustrates a follow rest in which these difficulties have been overcome.

The body of the follow rest is clamped to the dove-tail slide of the bridge of the carriage. The two jaws can be separated or brought together by a circular motion, effected by two screws meshing with teeth in these jaws; the screws are operated by the knobs shown at the top of the device. The jaws carry hardened steel rollers, and are so located as to give, with the point of the tool, a three-point support to the work. When once set, the device is adapted for a variety of diameters by simply moving the entire rest backward or forward by its connection with a screw which telescopes through the regular cross feed screw, and is operated by the hand-wheel controlling the tool rest. When approaching a shoulder, the position of the rolls is such that they support the shaft on the smaller diameter until the cutting tool has turned a portion of the larger diameter, when the rollers may be quickly brought to bear upon it. Ample provision is made for oiling. Sensitive adjustment is provided for, without the aid of the wrench, and the jaws, once set, can be locked in position.



Follower Rest for High-speed Turning.

This follow rest is made by the Lodge & Shipley Machine Tool Co., Cincinnati, Ohio.

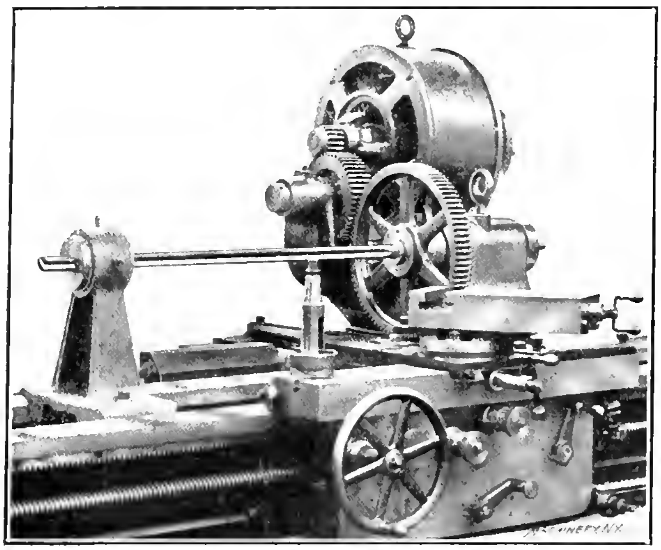
DEEP DRILLING ATTACHMENT FOR THE LATHE.

An attachment is shown in the accompanying half-tone for performing deep drilling rapidly and economically on the engine lathe. It consists essentially of a drill spindle, mounted on the cross slide in place of the usual tool-post, in combination with an electric motor and suitable gearing for rotating the spindle. A support is provided for holding the outer end of the work, the other end of which is clamped by the chuck or face-plate of the lathe. Provision is also made for forcing a copious supply of lubricant to the point of the drill used. The purpose of the attachment is to make it possible to drill a hole true with the center line by the usual method of rotating the work, and at the same time give the high cutting speed of which high-speed tools are capable, without necessitating a high rate of revolution for the heavy spindle and gearing of the lathe.

The drill spindle bearing, with the bracket on which the motor is mounted, is cast as one piece with the bed plate. This plate is bolted to the wings or arms of the carriage. The 3-horse-power 2 to 1 variable speed motor shown, is connected to the drill spindle through an intermediate raw-hide

gear. The spindle is bored to supply lubrication to the drill; it has a large bearing, and is ring oiled. The drill shank is fitted to the hole in the spindle by reducing bushings. The outer end of the drill is carried in a free bushing, revolving in a support bolted to the lathe bed. The drill used is of the special construction known as the "Chard" deep drill. A flat blade of high-speed steel is held in position at the end of a steel shank by a tapered pin; it is so ground as to break up the chips and thus facilitate their removal. Lubrication under pressure sufficient to clear the chips and cool the cutting edge is supplied by a pump, attached to the lathe at the rear of the head-stock, and driven from the lathe countershaft. Flexible tubing connects this pump with the hollow spindle through a nipple at the rear. Two copper tubes, flush with the surface of the drill, carry the lubricant to the cutting edge. This type of drill has been in use for some time on lathe spindles, back gear sleeves and pulley sleeves. Under favorable conditions a 2-inch drill has been advanced at the rate of 2¼ inches per minute. The drill in the cut is 1 inch in diameter.

This whole attachment may be easily removed from the carriage by the use of an over-head crane, suitable I-bolts



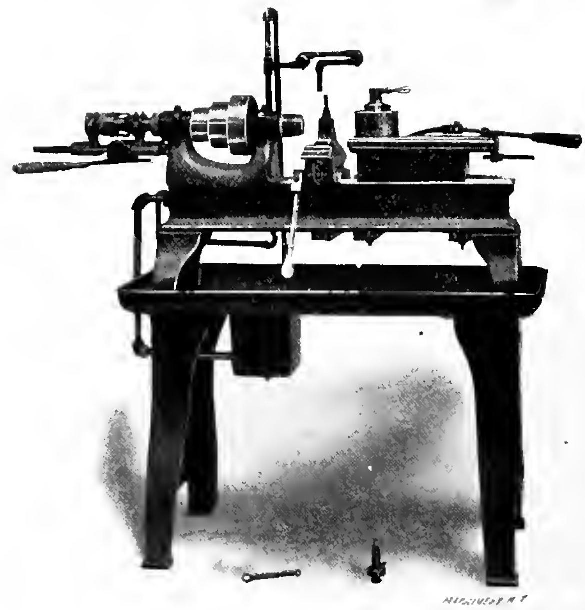
Motor-driven Attachment for Deep Drilling in the Lathe.

being provided for this purpose. Only a few minutes time is required to change the machine over to engine lathe work. The particular machine illustrated is used regularly for drilling central holes in locomotive driving axles, the hole being 1 inch in diameter and 44 inches deep. It was built by the Lodge & Shipley Machine Tool Co., Cincinnati, Ohio.

WELLS SCREW MACHINE.

This is a small machine of inexpensive design and construction, intended to be used for a large range of work originally done on more elaborate machinery. The machine is stiffly made, as may be seen from the cut, the head-stock being cast solid with the bed. The other parts, such as the turret slide, cross slide, etc., are provided with ample bearing surfaces and plenty of metal to resist the strains imposed on them when taking cuts with high speed tools. The spindle is fitted with an automatic chuck operated by a lever. The wire feed used is not of the ordinary chain actuated type, but instead follows the plan generally used in automatic machines, an inside tube and collet or finger being used to grip the stock, and feed it forward against the stop in the turret. This is operated by the same lever that works the chuck. This reduces the capacity of the wire feed, but has the advantage that the bar is under the control of the feed until it is entirely used up. For larger work the inside tube and collet can be taken out at any time, and hand feed used with the automatic chuck. The spindle is so designed that the cap may be taken off and any lathe chuck up to 8 inches in diameter used for holding large work, such as castings, etc.

This machine will be furnished with either a 4-hole hand operated turret, or a 4 or 6-hole automatic turret, with or without the wire feed just described. The equipment regularly furnished includes one automatic chuck and feeding collet for ½-inch wire, the turret slide and cross slide shown, oil pump and piping, and a friction clutch reversing counter-shaft. The machine swings 11 inches over the bed and has a 1⅛-inch hole through the spindle. The automatic chuck has a



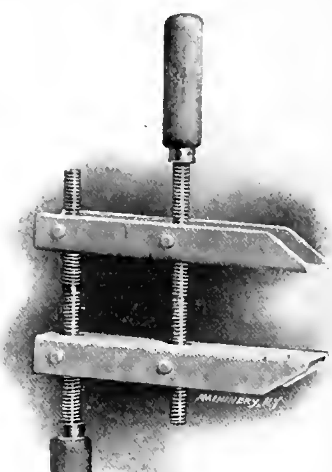
Wells Screw Machine.

capacity up to ⅞-inch and the wire feed up to ⅝-inch. Four and one-half inches is the greatest length that can be turned by the turret tools. The holes in the turret are 1-inch in diameter. The net weight of this machine is 675 pounds. F. E. Wells & Son Company of Greenfield, Mass., are the builders.

THOMPSON PATENT CLAMP.

The clamp shown in the accompanying half-tone is our old friend the wooden "hand screw" in a new guise. As shown, the jaws are made of steel in channel form, each of them carrying two swivel nuts, through which the wooden handled screws pass. Each of these screws is threaded right- and left-hand, the threads meeting at the center. Both screw spindles and swivel nuts are made of the best steel.

The clamp is opened and closed rapidly by grasping the handles in the two hands and rotating the clamp like a reel, the same as with its wooden progenitor. It has the added advantage, however, of allowing either screw to be adjusted without moving the other, so that the jaws may be set to incline toward each other, or away from each other, as well as in a parallel position. This is allowed by the use of the swivel nuts.



Metal Clamp on the Lines of the Wooden "Hand Screw."

The following advantages are claimed for the construction. The jaws being made in the form of a channel and of a good quality of steel, makes the clamp much stronger than any other. Owing to the rigidity of the design, this strength is obtained without sacrificing lightness. The jaws and screws being of metal, glue will not adhere to them. The jaws can be adjusted to any angle. It is twice as fast in operation as the old style, on account of the use of right and left thread

on the spindles. Owing to the use of metal screws and nuts, a stronger hold is obtained with less power. The jaws, which are polished, may be made to over-lap. The Erie Stamping and Mfg. Co., Erie, Pa., manufactures the clamp.

BULLARD RAPID PRODUCTION VERTICAL TURRET LATHE.

The Bullard rapid production vertical turret lathe is built by the Bullard Machine Tool Company, 531 Broad Street, Bridgeport, Conn. The steps by which this machine has arrived at its present form, as shown in the accompanying cuts, are typical of the process of development that machine tool design has gone through in the past few years, showing both the growth of the requirements which the builder has to meet, and the line of development which the machine has had to pass through to meet these requirements.

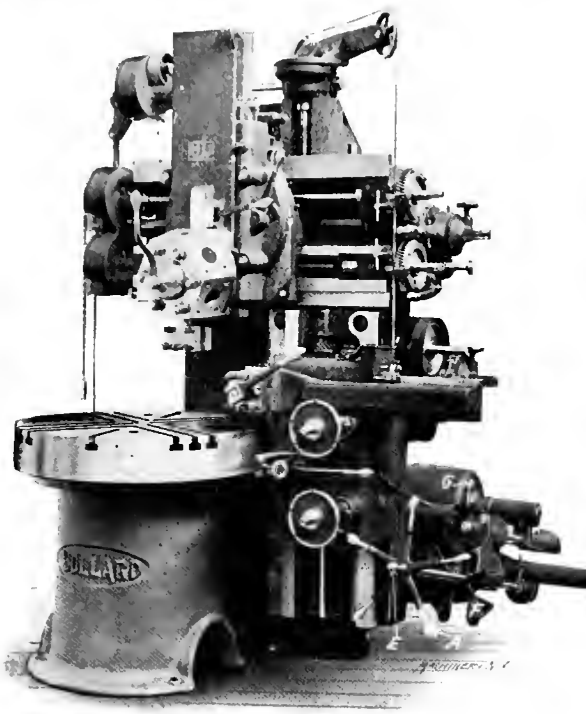


Fig. 1. Bullard Rapid Production Vertical Turret Lathe.

The boring mill is essentially a lathe, set on end for convenience in handling work of large diameter and comparatively short length. Being a lathe, the turret was naturally applied to it at about the time the turret lathe began to approach its present state of development. In larger mills, the use of two turrets was naturally suggested, owing to the room available on the cross rail, and the desirability of having as many tools cutting at once as possible. In the boring mills of smaller sizes, however, the carrying out of this idea was found to be impracticable, since in many cases the use of two heads required the second one to be swiveled to an excessive degree and extended from its supporting saddle to a point where the two tools could be used in close proximity. This extension of the tools beyond their supports resulted in a reduction in the feeds and speeds possible, owing to the lack of rigidity in the support, so that very little gain was found in the use of two turrets over that of the single tool.

A few years ago Mr. E. P. Bullard, Jr., of the Bullard Machine Tool Company, conceived the idea of placing one of the turrets on the vertical slide at the side of the column. This combination of vertical and horizontal rails and turret slides permitted the tools to be set for simultaneous cuts on any part of the work without interfering with each other. A machine was built to try out this idea, and later a number of them were installed in various plants, although they were not publicly put on sale. From time to time improvements and elaborations have been made until the machine has developed into its present form, which has been very properly called a "vertical turret lathe." It will be seen that the arrangement of the slides and tool-holders fits it for filling very nearly the field occupied by the heavy horizontal turret lathe, particularly in the matter of finishing castings and large diameter forgings.

The machine consists essentially of a rotating face-plate, mounted on a bed which has a vertical column carrying a horizontal turret slide at its right-hand side, and a cross rail with a vertical turret slide above the work. The ram or tool slide in the carriage on the vertical slide has a four-sided turret for holding turning and facing tools. The cross rail turret slide has a heavy hexagonal turret for boring, reaming, facing and turning tools. These two sets of tool-holders are provided with suitable feeds and handling devices as will be described.

The table is driven from an internal gear of nearly the outside diameter of the table. It is naturally self-centering, due to the large angular thrust bearing with which it is provided. The side strains are taken by straight vertical bearings of large proportions. The weight of the table spindle and work tends to preserve rather than destroy the alignment. The spindle journals are carefully scraped to fit, and are entirely immersed in oil.

A feature of the spindle drive mechanism is the fact that no step-up in the speeds is involved in the gearing, a constant reduction being maintained at all speeds, all the way from the driving pulley to the table.

The table has 15 changes of speed, obtained by a positive geared mechanism from a single speed pulley or electric motor. The controlling mechanism for these changes is planned on what the builders call the "automobile" principle, described in connection with their 56-inch "rapid production" boring mill in the December, 1905, issue of MACHINERY. The handle *G* may be given three positions corresponding to three changes of speed obtained by positive clutches in the headstock *B*. Pilot wheel *A* has five positions corresponding to

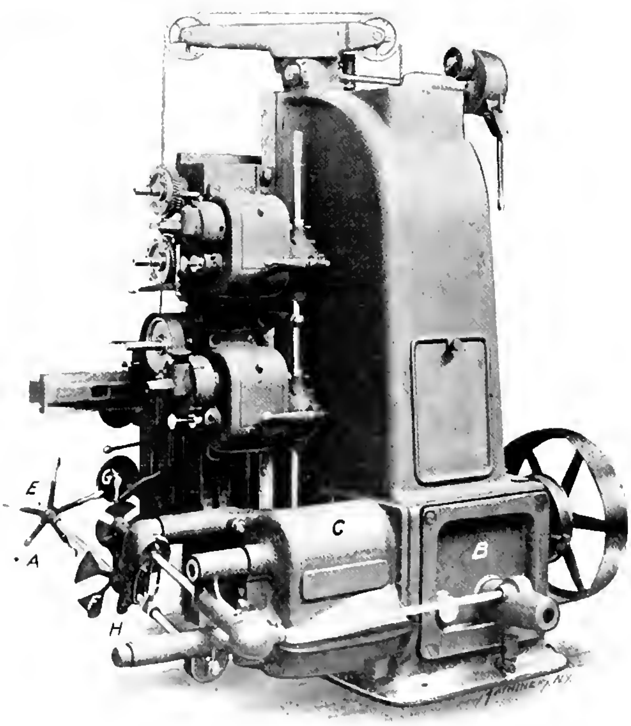

Fig. 2. Rear View of Vertical Turret Lathe, showing Spindle Speed Changing Device.

the five changes obtained in speed box *C* by a cone of gears and friction clutches. The raising of the shaft on which the pilot wheel is mounted, by handle *E*, throws a brake into action, for stopping the table at any desired point. The movements of *E*, *A* and *G* are interlocked by the locking disk *F*, the link *H* and the attached parts, in such a way that it is impossible for the workman to make an error in handling the controlling mechanism. The brake handle *E* cannot be raised until the pilot wheel *A* is placed in a neutral position, so that the power is cut off; and handle *G*, controlling the positive clutches, cannot be shifted until the mechanism is disconnected from the power and the brake applied. This

arrangment gives a "selective" control, making it possible to change from any speed to any other without going through the intermediate positions. The number of table revolutions per minute may be instantly ascertained from the direct reading indicator incorporated in the interlocking mechanism. The arrangement of the pilot wheel and its attached parts, the selective control, and the concentration of all operating levers within easy reach of the operator, account for the likeness to the mechanism of the automobile to which the builders refer.

The same facility for rapid changes is furnished for the various feeds, as has been described for the spindle speeds.

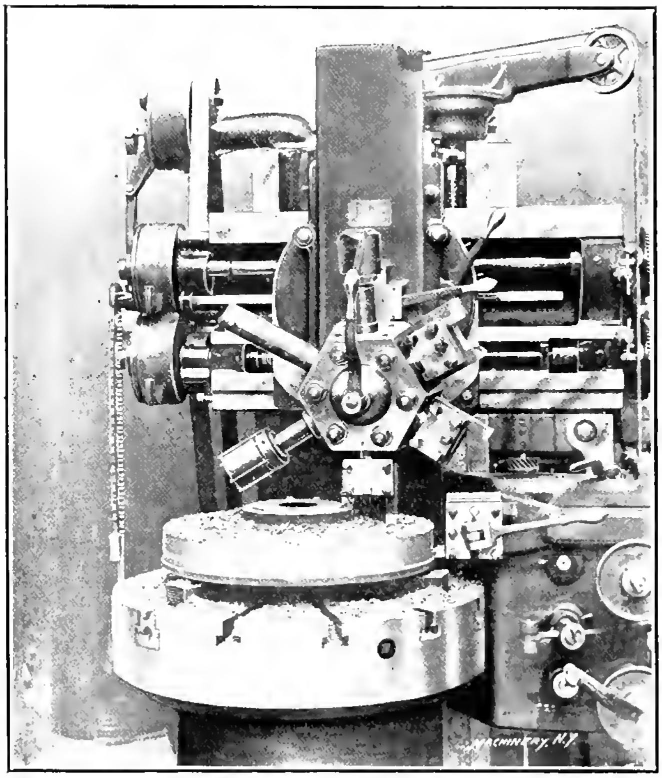

Fig. 3. Machine in Operation, Finishing Gear Blanks.

Each slide is provided with its own rapid feed change mechanism, handled by its own separate levers. The eight changes are obtained in two series of four by cones of gears constantly in mesh. Handles on each feed box are provided for shifting the position of the "diving" keys, to match the gears they are required to engage. It will be noted that there are no pull gears used in changing from cross to vertical feeds and vice versa. In the case of the cross rail, a drop worm is used which may be connected to the worm-wheel on either the cross feed or vertical feed shafts. In the case of the movements for the side head on the vertical slide, the change from cross to vertical feed is made by the lever shown between the two square-ended operating shafts. This lever controls friction clutches for throwing in either of the two feeds desired. The operating shafts on this side head are provided with disks having graduations for reading the movements in both directions, and similar graduations are provided on the worm-wheels operating the movements of the cross slide turret. Clips numbered to correspond with the holes in the two turrets are used at these two points. These clips may be set in any desired position, and used instead of stops for the various movements, obviating the necessity for all calipering and measuring except in the case of the first piece made. They have the advantage of greater accuracy, and are not subjected to some of the mechanical difficulties involved in the use of automatic throw-outs or positive stops.

Positive stops are provided for setting the turret slide accurately in a vertical position and for centering it for boring, drilling, reaming, etc.

A rapid power handling mechanism, operated from the driving shaft by a belt running to the small pulley and gearing shown at the extreme upper left hand corner of Fig. 1, may be used to operate all the movements of the main turret, or for raising and lowering the cross and vertical slides and all their attached mechanism. The cross and vertical slides move together as a unit. The two cross handles shown just at the left of the worm gears on the cross rail control the rapid power movements for that mechanism. A friction slip, set up strong enough to carry the heaviest feeds that are met with, but having the tension adjusted well within the limit of strength of the mechanism, is provided for each of the various feed movements, so that no damage to the machine will result from the attempt to run the slides beyond the limit of their travel, or from running them together so that they strike. The quick acting mechanism, being driven from the first speed shaft, has a constant rate, and has no relation to the speed of the table.

Fig. 4 shows the construction of the various friction clutches used throughout the machine. A bent lever, as shown, is arranged to expand an internal ring against the inner rim of the driving gear. The long end of this lever bears on the top of a plunger, which passes through the supporting sleeve to the hole in its center. Through this central hole passes a rod, flatted on one side, and carrying a wedge adapted to raise the plunger and throw in the clutch when it comes opposite to it. A series of clutches with their levers and plungers may be mounted on the sleeve, and this wedge brought to act on any one of them. Owing to the fact that the clutch lever has some degree of flexibility, the clutch is practically self-adjusting; but if, after long usage, it should be necessary to take up the friction on account of the wear it has suffered, the small wedge shown at the fulcrum point may be set up. Provision is made in the speed box construction whereby the adjusting points may be brought in line with a removable cap, so that it is unnecessary to take the machine apart for this purpose.

Fig. 3 shows the machine set up for a turning and facing operation on a gear blank. Its likeness to the horizontal turret lathe is at once evident, the shape of the tool-holders and the arrangement of the main turret being identical, although the vertical form of the machine renders necessary a general change in the outward appearance of the machine. This vertical turret lathe has, in fact, at least one advantage over its horizontal competitor, in the simplicity of the tool equipment required, owing to the fact that the main turret head on the cross rail has a full universal movement, both

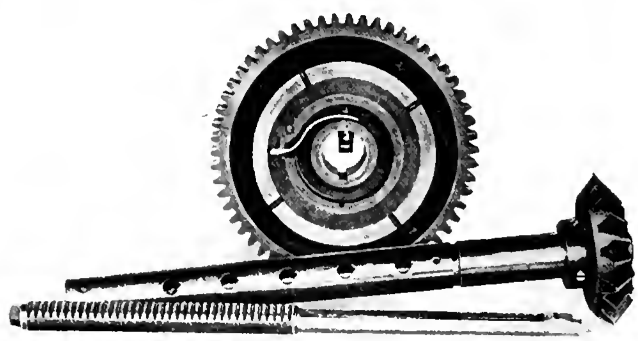

Fig. 4 Construction of Friction Clutch, generally used throughout the Machine.

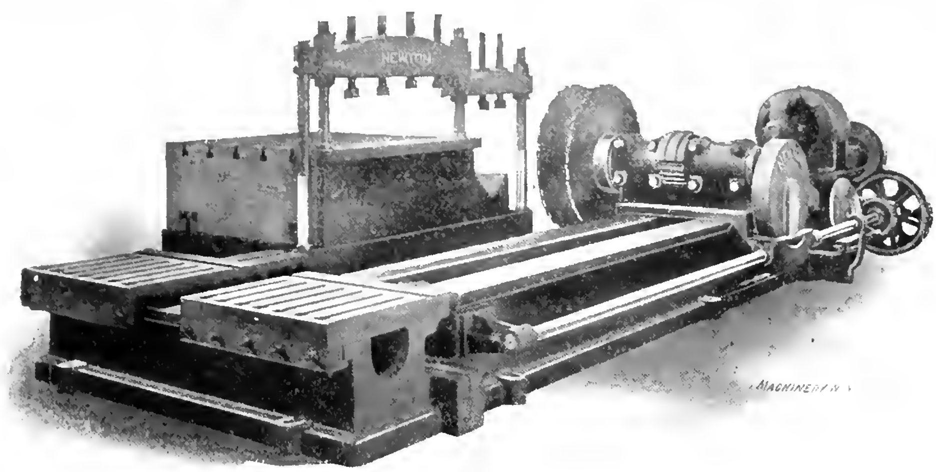
vertical and horizontal, throughout the entire range of the machine, so that expensive overhanging cutters are unnecessary. This advantage is well illustrated in Fig. 3.

The machine has a capacity for work 36 inches in diameter and 24 inches in height. The face-plate, which is 34 inches in diameter, may be built plain with four independent jaws fitted to it; or, if desired, may be given the form of a three-jaw combination chuck or a four-jaw independent chuck. The main turret will face work 36 inches in diameter, and has a vertical movement of 26 inches. It may be swiveled to any angle up to 45 degrees, either side of the center. The turret is 12 inches in diameter, and bored for tool shanks $2\frac{1}{2}$ inches in diameter. The side head has a vertical movement of 28 inches, and a horizontal movement of 15 inches. $1 \times 1\frac{1}{4}$-inch tool steel may be used in the four-sided tool-holder. A thread cutting attachment for threads from 2 to 14 per inch may be furnished extra if desired, and can be applied at any time subsequent to the purchase of the machine. The net weight of the machine is about 11,300 pounds.

NEWTON DOUBLE COLD SAW CUTTING OFF MACHINE.

This tool, built by the Newton Machine Tool Works, Inc., Philadelphia, Pa., is adapted to a wide range of work, owing to the construction of the work-holding tables and the provision made for carrying two saw blades when required. It was built for the Pennsylvania Railroad Co. for general locomotive work. In this service it may be used in cutting off round stock up to 11½ inches in diameter, for sawing off oblong sections up to 11½ x 38 inches long, or, with the double saws, for cutting out crank-shafts, connecting-rod ends, etc., to a depth of 11½ inches. Round stock is held in the V block shown at the further end of the work table. General cutting-off work may be done on the supplementary table, shown with the clamping device attached. When using the two saws for cutting out rectangular openings, the adjustable tables at the front end of the machine are used for holding the work. These may be set as close together as the width of the opening required will allow, so that the work is supported close up to the saws.



Cold Saw with Double Blades for Cutting Out Connecting-rod Ends, Etc.

The saw spindle is driven by spur gearing, from a phosphor bronze worm-wheel and a hardened steel worm of steep lead, enclosed and run in oil, and geared to a 15-horse-power motor mounted on the end of the base. The saw carriage has an automatic feed movement with power quick return, the feed variation being obtained from friction disks running at high speed.

In a test carried out in the shops of the builders, cuts to a depth of 12 inches were made in locomotive rod ends with the blades set 5¾ inches apart. The rods were 5 inches thick, and the time taken for each cut was 17 minutes. This record the customers have been able to maintain, resulting in a saving of about 50 per cent over the time required by former methods of working out the open ends.

DRILL SPEED AND FEED AND DECIMAL EQUIVALENT INDICATOR.

The Cleveland Twist Drill Co., Cleveland, Ohio, has designed the neat drill speed and feed, and decimal equivalent indicator

Fig. 1. Decimal Equivalent Indicator (one-half size).

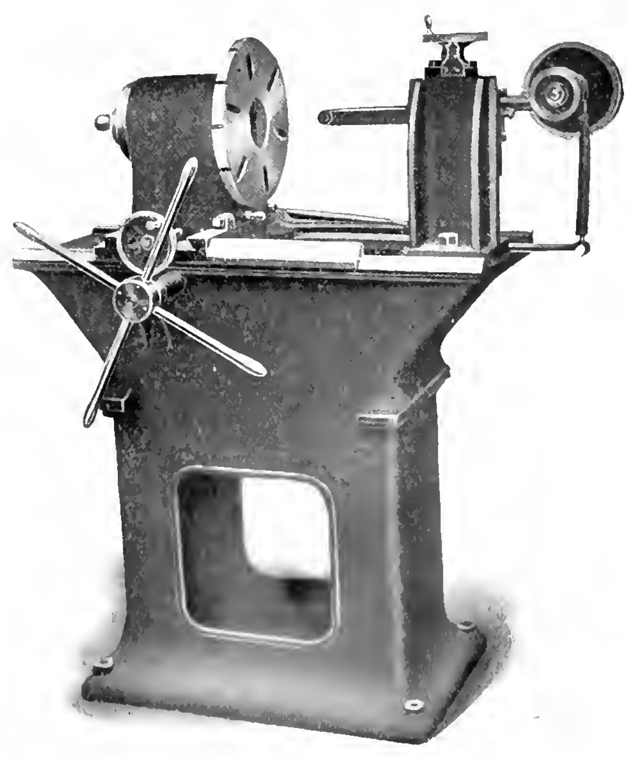
Fig. 2. Drill Speed and Feed Indicator (one-half size).

shown below. It consists of two celluloid disks pivoted on opposite sides of a third and larger celluloid disk. The outer disks are notched and the middle disk has concentric rows of numbers, as shown in the cuts. In the case of the drill speed and feed indicator, Fig. 2, the outer concentric row of numbers is the diameters of the drills. The second row, one number of which shows through the notch, is the proper speed in revolution per minute for carbon steel drills, and the inner row shows the revolutions per minute permissible with high-speed drills. Thus for a 2⅝-inch drill 43.7 revolutions per minute are indicated for carbon steel drills and 72.8 for high-speed steel drills. Good feed practice is stated in the paragraph on the face of the rotatable disk. The decimal equivalent indicator on the opposite side, Fig. 1, works on the same principle, the outer row of numbers being common fractions up to 1, varying by sixty-fourths, and the inner row the equivalents, to five places of decimals. The company will send these disks to all interested.

IMPROVED SQUARE HOLE GRINDING MACHINE.

In the February, 1907, issue of MACHINERY we published a description of a machine built by C. W. Burton, Griffiths & Co., Ludgate Square, Ludgate Hill, London, for grinding square, hexagonal and other flat-sided holes, such as are found in automobile work and other machinery. Ordinarily such holes are finished on the slotter or are broached. In automobile work, where parts subject to wear are generally hardened, the accuracy required necessitates finishing the surfaces of such small holes after hardening. The machine mentioned was designed to perform this difficult operation. The half-tone shows an improved design recently developed by the manufacturers, intended for general manufacturing.

The machine consists of a strong bed, provided with ways on which the work carrying carriage traverses by means of a rack and pinion operated by a hand-wheel. On cross ways on this carriage is mounted the work carrying head, which may thus be adjusted toward or



Machine for Grinding Internal Flat Surfaces

away from the center of the machine. The head is provided with a large hollow spindle for holding the work, and an index plate for setting the spindle for square, hexagonal and other shaped holes.

The grinding wheel is of the cup form, and is carried on a bar which projects from a vertically adjustable slide on the knee, shown at the right of the bed. It is driven by an endless round belt running along the bar, connecting the wheel with the small speed multiplying counter-shaft attached to the vertical slide. This counter-shaft is supported by a hinged arm with spring tension, so as to prevent the vibration in the driving belt from affecting the bar carrying the emery wheel —a condition which would impair the accuracy of the work if not allowed for. The vertical slide is elevated by a screw, having a hand-wheel graduated to read in thousandths of an inch. This movement provides for broad surfacing by raising and lowering the emery wheel, in addition to the traversing movement of the carriage, given by the pilot wheel. The feed movements are operated by hand.

WHITCOMB-BLAISDELL 20-INCH LATHE.

The Whitcomb-Blaisdell Machine Tool Company, Worcester, Mass., has recently placed on the market the 20-inch lathe shown in the accompanying half-tones. This lathe is intended to possess the required driving power at high speeds

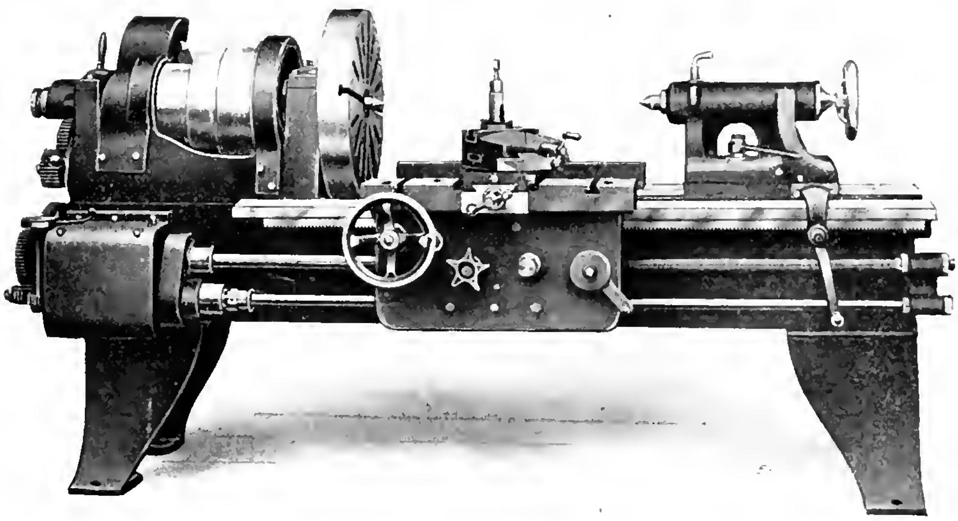


Fig. 1. Whitcomb-Blaisdell 20-inch Lathe.

for using modern tool steels, and at the same time to be easily handled in all its movements, so as to reduce to a minimum the time between cuts.

The bed of the lathe is substantial and well proportioned, being stiffly ribbed and of the box pattern type, with a broad top carrying ways of generous proportions. Fig. 3 shows the head-stock with the gear guards removed. A 3-step cone of large diameter and wide face is used. This, in conjunction with

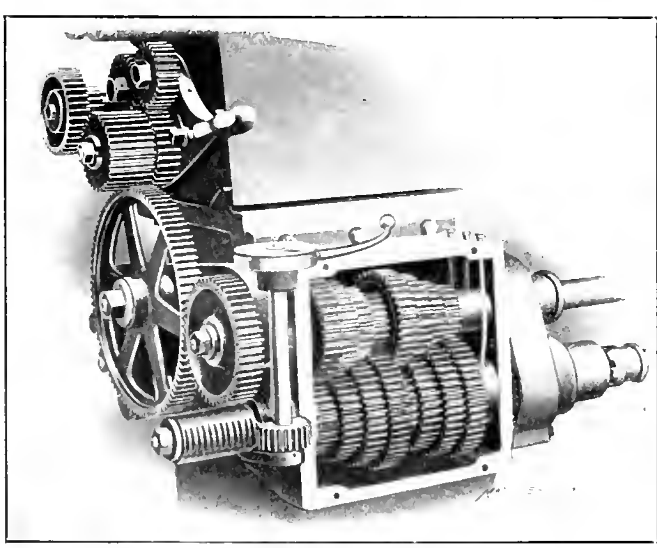

Fig. 2. Quick Change Gear Casing, with Mechanism Exposed, showing Pinion and Rack for Shifting the Key.

double back gearing, gives the lathe great power and wide range. Nine changes of speed are obtained, and the effective power developed at the different speeds is much more nearly equal than is the case when the same range is obtained with single back gearing and a cone having four or five steps.

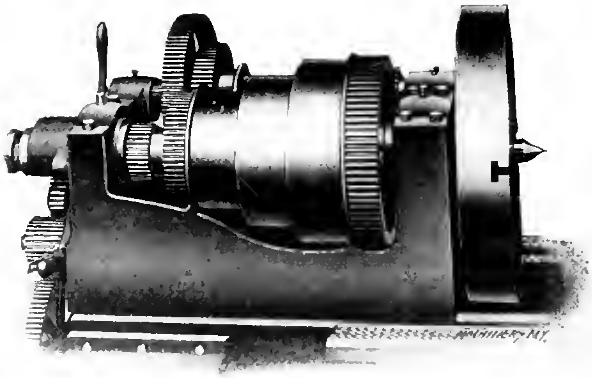

Fig. 3. Head-stock, with Guard Removed, showing Gearing.

The smallest diameter of the cone of this lathe is so proportioned as to give ample belt contact and speed. The spindle is of high carbon crucible steel with generous journals, running in bronze boxes.

A quick change device for feeds has been applied. This is best shown in Fig. 2. It is simple and durable in design, and well made. It consists, as shown, of two parallel shafts carrying eight gears each, meshing with each other. The gears on the lower shaft run freely on it, but may be connected to it by a sliding key, operated by the handle through the rack and pinion shown. This gives the operator command of eight geared feeds, or eight of the commonly used screw pitches. Then, by bringing into use a small compound gear permanently placed at the end of the head-stock, eight more feeds and screw pitches are obtained. All this is done without the removal of a gear. Three extra changes are provided, however, one of them solely for the purpose of permitting 11½ threads per inch to be cut, and the other two to double the range of both the feed and the screw pitch numbers.

The apron of this lathe is of substantial design and carries a feed mechanism of great strength and durability. The gears

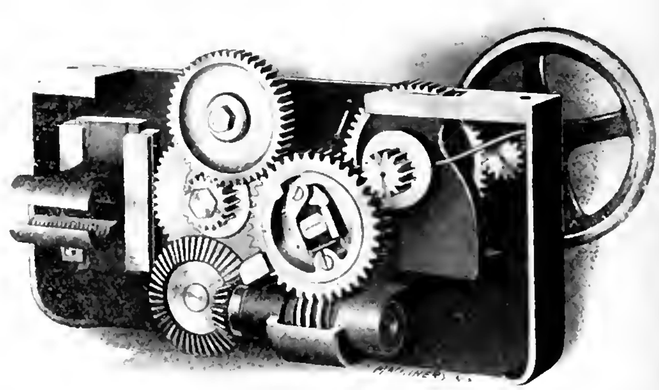

Fig. 4. Apron Mechanism of the Whitcomb-Blaisdell Lathe.

used have coarse pitch and wide face, and are strongly supported in the apron. The operating friction is powerful and simple, and may be adjusted from the outside of the apron to give a light or heavy carrying power, by simply turning a small exposed nut. Friction counter-shaft, large and small face-plates and the necessary wrenches are furnished with each lathe.

PEASE BLUE-PRINT CUTTING, TRIMMING AND SIZING TABLE.

The apparatus shown in the accompanying cut is made and sold by C. F. Pease Blue-print Machinery & Supply Company of 22 Fifth Avenue, Chicago. It is designed to facilitate the cutting to size of blue-prints, or of unexposed blue-print paper. The cutting or trimming table is constructed of hard wood with metal trimmings, and is so arranged as to be easily knocked down for shipment. The top of this table is covered with a sizing diagram, which gives at a glance the dimensions of the tracing or print being trimmed or cut, and the area in square feet, no calculation being necessary. The top of the table is 4 feet wide by 6 feet long. The cutting

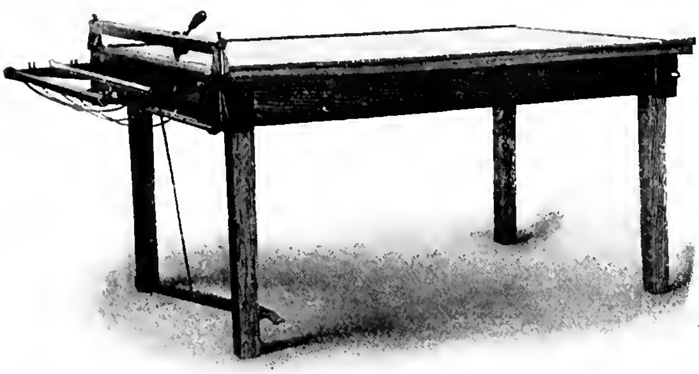

Table with Attachment for Sizing and Trimming Blue-prints.

and trimming device at the end is provided with a parallel clamp, operated by the treadle shown, which holds the paper or print securely while the knife is being used. The cutting knife is of the revolving type, rotating positively by mechanical means, not depending on the friction caused by the blade on the paper. Owing to this construction it will cut a narrow strip of the thinnest paper with rapidity and precision. The apparatus was designed especially for cutting up blue-prints exposed on the builders' continuous printing machine. It will cut accurately to a line, trimming the print perfectly at the same time it is cut from the roll.

* * *

It is reported that the White Star Line proposes to equip a passenger steamer on their Dominion Line with a combination of turbines and reciprocating engines. This steamer is to be built by Harland & Wolff. This combination has been advocated by Mr. Parsons for some time in the case of vessels of moderate or slow speed, from the point of fuel economy. It is proposed to use the turbines for the low-pressure expansion. A considerable gain in economy is expected with this arrangement, since the turbines are able to carry the expansion of steam economically to a degree far beyond that obtainable in the cylinder of the reciprocating engine. It will be necessary to provide for the use of condensers permitting a high vacuum. A gain of from 10 to 12 per cent is claimed in consequence. The proposal of Messrs. Harland & Wolff is to use two sets of quadruple expansion engines, each driving a screw propeller and placed in about the position they would occupy in a twin-screw steamer. Associated with them on a central shaft, a single turbine is to be used, driving a third propeller of a smaller diameter than the wing screws driven by reciprocating engines. This is only one of two or three arrangements which have been proposed, the problem being a more or less uncertain one as yet.

* * *

The machinists who hire out to go to the Panama Canal are required to provide the following extensive (?) list of tools: One pair each 8-inch inside and outside calipers; one 2-foot rule; 1 combination square; and one 4-inch or 6-inch steel scale. Car borers and axle turners are required to have one pair 8-inch inside calipers; one pair 8-inch outside calipers, and one 2-foot rule. Surely the eminent Isthmian Canal Commission should have included in the latter case that essential little tool required for making infallible press fits—the prick-punch.

INDUSTRIAL NOTES FROM EUROPE.

BRITISH TRADE CONDITIONS.

Steady business seems to be the characteristic feature of British trade in general, the amounts and values dealt with in the returns tending to increase. For the month of July the value of British exports increased by $35,000,000 or 20 per cent as compared with the same period in 1906, and the imports increased by $16,500,000. For the seven months ending July, the increased value of exports was $163,665,000, and the imports $157,140,000. The total values of the exports and imports for the same period were $1,528,536,735 and $1,900,000,000, respectively. Simultaneously with these developments the prices obtainable for bonds and railway stocks of the best descriptions have steadily depreciated, a feature not confined to this country. The much better rate of interest now obtainable from many industrial investments is advanced as one reason for the decline, but the situation has not yet been convincingly accounted for.

Labor Conditions and Supply.

In labor matters a noticeable feature has been the number of minor strikes of comparatively isolated character and dealing with local issues. A local strike of shipbuilders at Newcastle, in which the men left work in an irregular manner, has resulted in the Employers' Federation taking advantage of the incident to threaten a lock-out on a large scale, until machinery has been set up to allow of negotiation proceeding in every case of dispute, without stoppages being occasioned. In Belfast, however, a strike of carters and dockyard laborers for an increase of wages with reduction of hours, and also for the recognition of the union officials as responsible negotiators on the men's behalf, developed in a serious manner. Disturbances and riots principally participated in, with no definite object, by outsiders, culminated in armed force having to be resorted to with some loss of life. Government action in the way of conciliation had to be undertaken and with the personal efforts of local priests and magistrates and prominent government officials, a provisional settlement was arrived at by which wages were increased and hours reduced but no present concessions granted as regards recognition of union officials. This latter point is, however, being brought into considerable prominence by railway employes who consider it of even more importance than immediate questions of wages and hours. Considerable pressure has recently been brought to bear, with some success, on non-unionists, particularly in the coal and cotton trades, to induce them to join the trade unions. Whether such action is inimical to general progress is open to discussion. In connection with the new Workmen's Compensation Act, recently brought into operation, which greatly increases the number of work people entitled to benefit in case of accident, the services of many elderly men have been dispensed with in view of their assumed greater liability to meet with accidents. It has been proposed to make the insuring of risks compulsory on the part of the employer, somewhat on lines now in vogue in Germany.

American concerns are often exercised as to the future supply of labor, but the offering of prizes at agricultural shows for the largest working families is a method most probably untried. Over here, in the almost purely agricultural county of Lincolnshire, the leading agricultural society annually offers prizes for the largest families who have been brought up and placed in agricultural service. The first prize this year was awarded for a family numbering nineteen children, of whom fourteen had been brought up and placed in work. The second prize went to a family which had numbered twenty-three, of whom seventeen had been brought up and twelve placed. President Roosevelt would scarcely recognize symptoms of race suicide in Lincolnshire.

New Discoveries of Coal and Iron.

Periodical scares arise as to the future supplies of coal and iron, pessimistic tendencies nearly always prevailing. However, at the present time new deposits of iron ore are reported in the north of Ireland, Staffordshire, Derbyshire, Cumberland, Lancashire, and Sussex. In the latter county

coal for smelting purposes is not at present available, the ore having to be shipped to the north for smelting, but boreholes are being sunk with some prospects of coal being found, and somewhat more optimistic views on the topic generally find expression.

Shipbuilding Developments.

Touching on shipbuilding matters, the trial performances of the *Lusitania* have evoked great interest, particularly the 48 hours run over a course of 300 miles under conditions representing average Atlantic conditions, when the contract speed of 24½ knots was exceeded by a margin of three-quarters of a knot. To the present time, its design, construction, launching and performances have been a continuous series of triumphs. In the naval section, the *Bellerophon*, recently launched at Portsmouth, less than eight mouths after the laying down of the keel, represents an increased displacement over the *Dreadnought* of about 700 tons. The length and beam of the new vessel are 496 feet and 82 feet, respectively. Turbine engines to develop 23,000 horse-power will be fitted, giving a speed of 20¾ knots. Her armament will include ten 12-inch guns, with four 7-inch guns for repelling torpedo attacks. The total cost will be about $10,000,000.

Harland & Wolff are understood to purpose utilizing a combination of reciprocating and turbine engines in a new Atlantic liner to be laid down, and the departure will be closely followed in view of the possibilities in the way of economies in steam consumption, increased maneuvering facilities and decreased first cost. In connection with the maintenance and deepening of the Mersey channel at Liverpool, three of the largest dredgers yet built are employed, but a still more powerful one is to be added, capable of lifting 1,000 tons of sand in 50 minutes from a maximum depth of 70 feet.

The proposal of the Canadian Government to construct a ship caual with a navigable depth of 24 feet, connecting the Great Lakes *via* the St. Lawrence and Montreal with Liverpool, and perhaps Manchester, by the establishment of a special line of steamers, will, if proceeded with, involve an expenditure of $100,000,000. The firm of C. H. Walker & Co., of London, who were the engineering contractors for the construction of the Manchester to Liverpool ship canal, is freely mentioned as likely to be instrumental in the carrying out of the work.

Olympia Machinery Exhibition.

The Engineering and Machine Tool Exhibition to be held at Olympia, London, during September and October is being participated in by a larger number of representative British tool makers than that of last year. One reason for the smaller representation then was the lack of tools to show, as deliveries were often many months behind. The leading tool merchants contrived to make a good show, Continental specialties being well in evidence, and generally the exhibition was so successful from a business standpoint that special efforts have this year been made to secure good locations and place the latest productions on view.

Machines for General Purposes in Demand.

Concurrently with the general appreciation and employment of special machine tools, particularly in the line of turret lathes and automatics, is to be noted a disposition to concede cheerful recognition of the possibilities of comparatively simple, but well made tools which combine ample power with some extra facilities for all-round work. This is particularly the case where, though a good aggregate of work is dealt with, the demand for any one article is somewhat irregular, and the ability to employ the machine regularly at a medium profit on any miscellaneous work is of greater importance than the possibilities of mass production, at very low labor costs, of an expensive machine which could only be intermittently employed. Of late years the Glasgow district has become more prominent in the line of machine tool manufacture.

For some time heavy machine tools have been produced in good quantity, chiefly in connection with shipbuilding and marine and locomotive engineering, but medium and light tools were not so systematically built and brought to the notice of users. The industry in these branches now seems likely to increase, the recent shortage of American tools having no doubt assisted in the upward movement.

Shanks & Co., Ltd., of Johnstone, in its more recent commercial literature enters more fully than is usually the case into the reasons for the distinctive features embodied in its designs.

Slotting and shaping machines appear to hold their own with increasing tenacity notwithstanding the competition of improved types of milling machines, and a statement of Messrs. Shanks on the rate of machining plane surfaces on a 20-inch stroke traverse head shaper is of interest, it being to the effect that 30 square inches per minute may be machined with heavy cuts.

New Grinding Machines.

Macdonald, Adamson, Swinburne & Co., Ltd., of Barrhead, near Glasgow, is one of the latest additions to British manufacturers of precision grinding machinery. Its universal machines are driven by motor or direct from the line shafts, no overhead gear being employed. The speeds of the headstocks, traverse, and emery wheel drives are all separately adjustable by the finest gradations, and controlled by individual lever in front of the machine. Another line taken up by the company is the manufacture of disk-grinding machines in a variety of designs and capacities. With regard to the employment of grinding machines in general, the necessity for frank collaboration between the builders and users of the machines and the makers of the abrading wheels, in the selection of suitable grades, etc., of wheels, and the methods adopted in their employment is much more generally assented to than formerly, an attitude conducive to even more striking and satisfactory results than has already attended this form of machining surfaces.

JAMES VOSE.

Manchester, England, August 24, 1907.

MISCELLANEOUS FOREIGN NOTES.

INTERNATIONAL EXHIBITION IN TOKIO.—The Japanese government has allowed $5,000,000 for an international exhibition to be held in Tokio next year. The total cost is estimated to be $10,000,000, half of which has already been subscribed for by private citizens. The exhibition will open on April 1 and will last until October 15, and it is intended to make it the greatest exhibit that has ever taken place outside of Europe and the United States.

ENCOURAGEMENT OF INDUSTRY IN MEXICO.—An agreement has been entered into between the Mexican government and some industrial promoters for the establishment within the territory of Mexico of a factory or factories for the manufacture of engines and motors. The capital invested in the business is to be exempt for a period of ten years from the date of the contract from all direct Federal taxes, with the exception of the stamp tax. All the necessary material and machinery may be imported free of duty.

SPECIALIZED GERMAN EXHIBITIONS.—We mentioned in our September issue the tendency in Germany to discourage world's fairs, and instead favor small exhibitions of certain branches of industries. A general exhibition of inventions for use in the minor industries has been in progress in Berlin this summer. It was held as a preliminary to a larger exhibition to be held later in the same city, and for the purpose of stimulating invention and "enlarging and multiplying the points of contact between inventor and capitalist, designer and manufacturer, producer and customer."

PROGRESS IN THE AUTOMOBILE BUSINESS IN GERMANY.—The automobile business in Germany seems to be not only in a flourishing state as far as production is concerned, but to be a well-paying business as well. The well-known German automobile firm, Benz & Co., reports for 1906 earnings amounting to nearly $300,000, and declares a dividend of 15 per cent. In 1905 the firm paid 7 per cent. In view of the recent failures of some American automobile concerns, these results are the more remarkable. It is likely, however, that the German firm has not capitalized "good will" at quite as high a figure as have some of our concerns.

MACHINERY.

November, 1907.

A RECORD-BREAKING ARMOR-PLATE VAULT.

PROBABLY most of our readers would be at a loss to guess, off hand, the purpose of the enormous steel plate structure shown in Fig. 1, were the caption of the cut not there to explain it. The building of armor-plate vaults is a comparatively new development, having sprung up in the past eight or nine years. The one whose making and construction we are to describe is so much larger than anything else of its kind, that an uninitiated mechanic would be justified in being perplexed to state the use to which it is to be put. This vault was built by the Bethlehem Steel Works, of Bethlehem, Pa., in whose shop the photographs from which the accompanying half-tones were made, were taken.

General Description of the Vault.

This armor-plate vault is a sort of glorified safe, to be filled with strong boxes which are to be rented to the customers of the Carnegie Safe Deposit Co., in the new United States Realty Building, corner of Cedar street and Broadway, New York City. The advantage claimed for the armor plate vault over all other types of construction is that it is fire, burglar, mob and earthquake proof. This one is built in two stories (as shown in the line cut Fig. 2), with a connecting passage between them carrying a stairway and a passenger elevator. The lower story is 9½ feet high, 106½ feet long, and 30½ feet wide. The whole structure weighs about 1,200 tons. It is provided with an "emergency door" in the right hand corner of the foreground of Fig. 1. The upper floor is 82 feet long, 9 feet high, and 19 feet wide, provided with two doors for regular service, one at either end.

The upper vault, in particular, is to be equipped on a scale of magnificence exceeding anything of the kind previously installed. The whole room is to be finished in solid bronze, with all the fittings of the same material. It will be seen in Figs. 1 and 2 that the vault is so large that it overflows the unobstructed floor of the sub-basement, and includes two rows of the columns of the building within its area. To take care of these, several openings, entirely cased in, are made through the vault from top to bottom.

Besides being remarkable in its general features, this vault is unusually interesting in its design and construction. As stated, it is intended to be fire, burglar, mob and earthquake proof. Danger from fire is obviated by the heavy 16-inch coating of concrete and fire-proofing material which surrounds the top, bottom and sides. The burglar's chances for success are small, as the walls of the vault are made of 4 inch Harveyized steel armor-plate, of the same kind as furnished the government for war vessels. Not only would the burglar have to perform the task of getting through this case-hardened surface, but to even reach the armor-plate he would have the reinforced concrete to reckon with. As may be seen from the cut, the vault is made of separate steel plates, with numerous joints; but these are all dove-tailed together and held in such a way as to make their separation impossible from the outside, and the fitting is so finely done that the joints are impervious to nitroglycerine.

Barring those for the doors, the armor plate walls are free from openings of any kind, which a burglar might use in be-

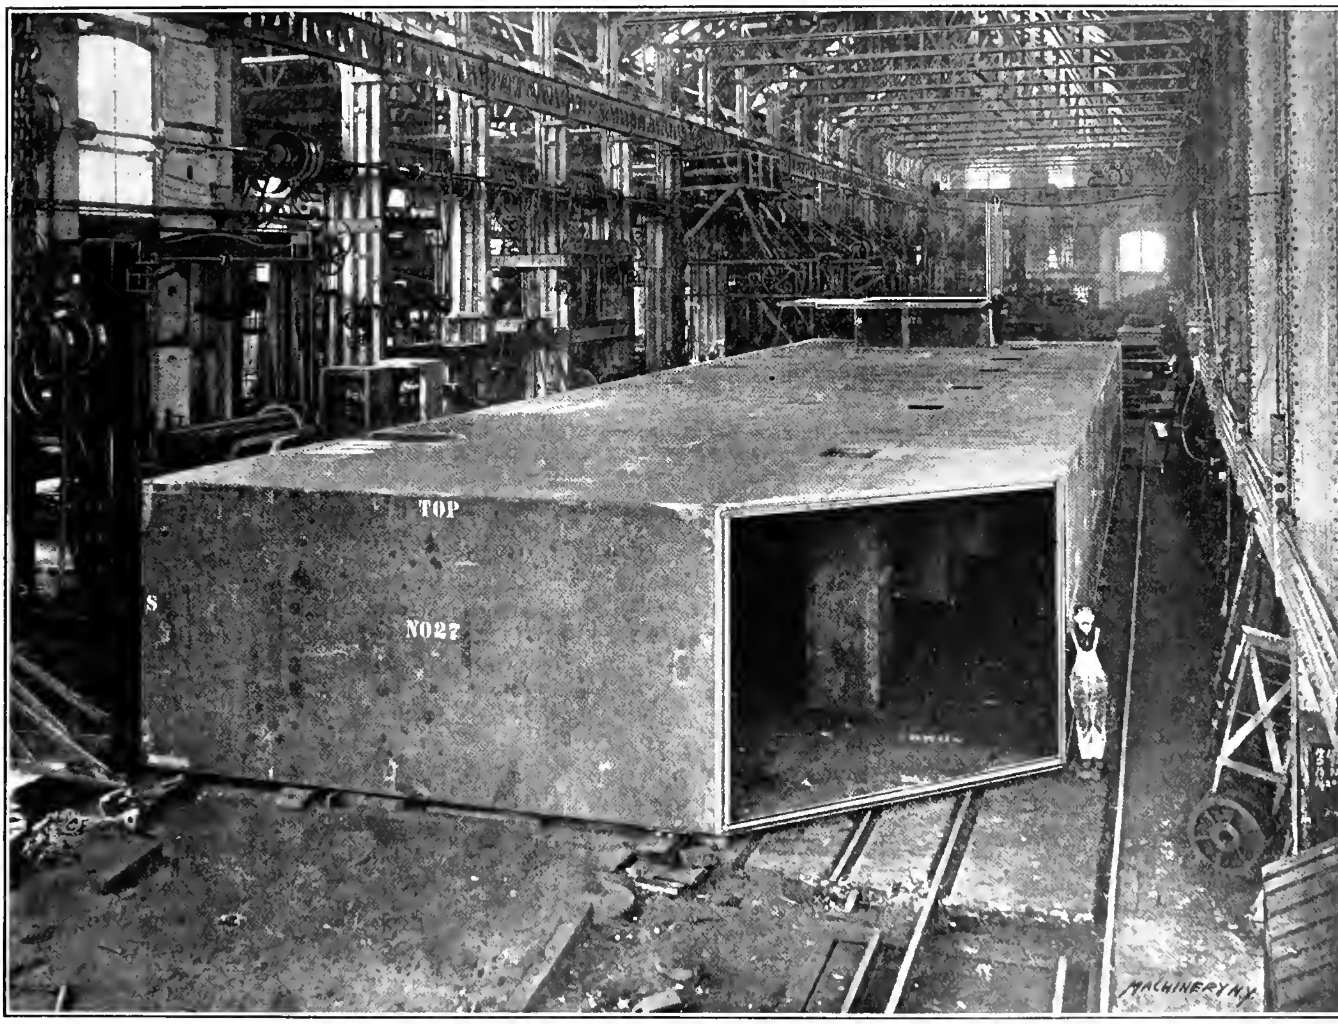

Fig. 1. Lower Story of Vault, on Erecting Floor of the Armor Plate Shop of the Bethlehem Steel Works

ginning his vault-breaking operation. There are no holes through the doors for the locking mechanism. The automatic time lock is the sole means of opening the vault, once it has been locked. For each of the three doors there are four clocks, making twelve in all. All twelve of these would have to fail simultaneously to make an accidental permanent locking possible. The clocks are set for the hour of opening on the next day, or any succeeding day, and the vault doors are closed. When the hour arrives, the clocks automatically throw the bolt-operating mechanism into action and the doors are released, so that they can be opened from the outside. No combination of any kind is used for these main doors.

As to the matter of protection against mobs (a contingency which seems almost too distant a thing to be reckoned with) the vault is safe from a 3-inch projectile, even without reckoning with the outer protection of reinforced concrete. It is not believed that a gun of a larger caliber than this could be handled by a mob. The vault is made strong and stiff enough to support the wreckage of the building, supposing the latter were thrown upon it by an earthquake or other disaster. In fact, it would seem as if valuables intrusted to this remarkable structure would be reasonably safe.

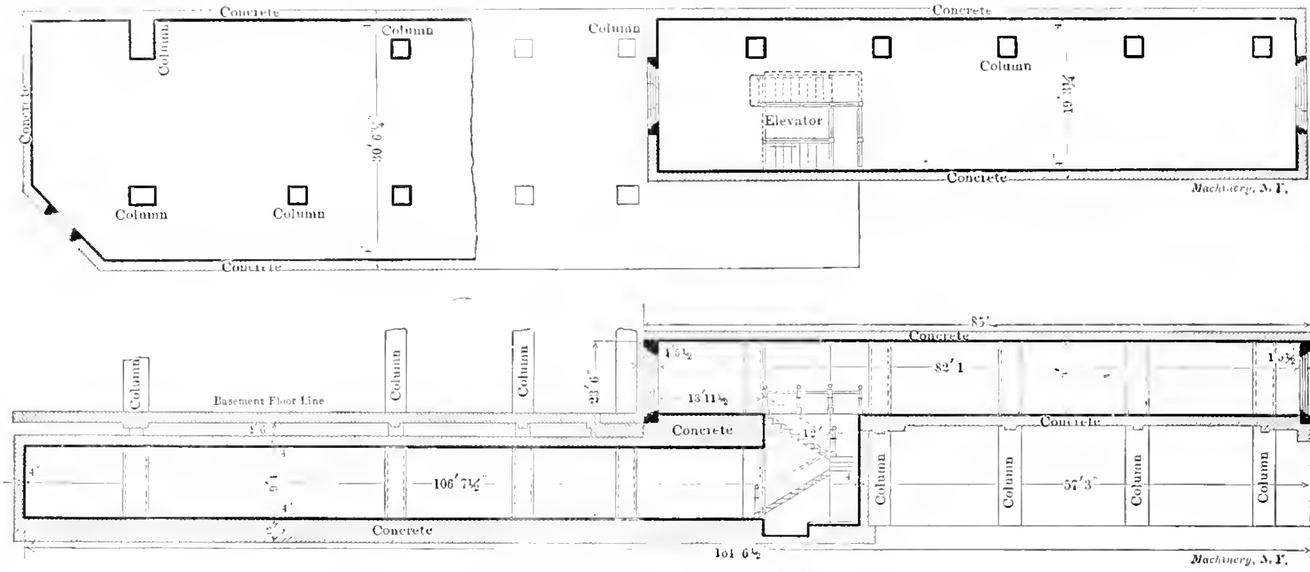

Fig. 2. Plan and Section of Vault, giving Dimensions.

Design and Construction.

It is in the mechanical design and construction of this vault, however, that we are principally interested. It is built in sections of Harveyized armor-plate, 4 inches thick, the sections being dove-tailed and wedged together from the inside in such a way as to be impregnable from the exterior. Details of the joints are shown in Fig. 3. As shown, the side plates have a dove-tail which fits into a groove in the edge of the bottom plates. A key, driven into this groove after the side plate is inserted, forces it tightly into position and makes its removal impossible without first removing the key. In a somewhat similar manner the side plates are dove-tailed and fitted into corresponding grooves in the top plate. Here, however, the keys are driven upward into the space made for them on the tapered side of the joint, and when in place are locked there by a filling piece, which is inserted and screwed into position. The top plates are joined to each other by rabbeted joints as shown, held together by bolts from the inside. These bolts are tapped into blind holes, so that there is comparatively little difficulty in doing the drilling and tapping needed for them from the inside, in the soft part of the metal. The side plates are similarly spliced together.

The fine work on this vault, so far as workmanship is concerned, is in the making of these numerous joints nitroglycerine tight. To accomplish this, the joints must fit within 0.001 inch or less. The vault must, of course, be erected on a firm foundation, allowing no deflection, to make this fine fitting possible. This was satisfactorily done on the erecting floor of the shop, and as that provided for it in its final resting place is of much more rigid and permanent construction, there will be no difficulty on this score. It is when one comes to think of the score of joints in the structure, and the large size of the parts of which it is built, that the problem of making these joints tight is seen to be a serious one. This is further complicated by the heat treatment of the plates by which their faces are hardened. This is essentially a case-hardening process, and being such, it involves the distortion consequent on all such operations. A few words explaining the procedure in machining and hardening these plates will serve to show how the difficulty is overcome.

Forging, Machining and Hardening the Plates.

As received from the forging department, the plates are formed to the desired thickness and area. Their edges are finished on heavy rotary planers to the required dimensions. The material is a nickel steel of great toughness and hardness, so that the cutting speeds by necessity must be very slow. The machinery used, however, is rugged enough so that heavy chips are taken. After the finishing of the edges, the plates have the dove-tail grooves and rabbets formed in them

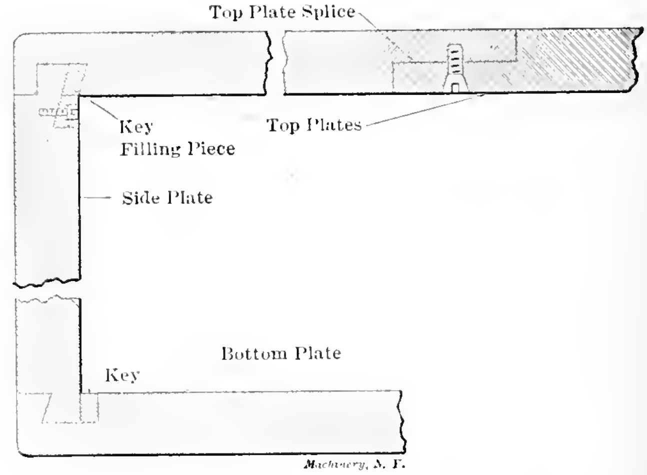

Fig. 3. Details of Joints used for Fastening the Sections Together.

on the planer. These surfaces forming the joints are not finished quite down to size, although every care is taken to have them square with each other, and of the proper dimensions. The plates are now taken to the hardening furnace. Owing to the great depth of hardening or "Harveyizing," the operation is a matter of many days, though it is very similar in principle to the shorter process used on small work.

After this heat treatment comes the straightening needed to return the finished surfaces to their original alignment. This is done under a heavy hydraulic press, the plate being slightly heated for this purpose, just enough to facilitate the bending without altering to the slightest degree the hardness

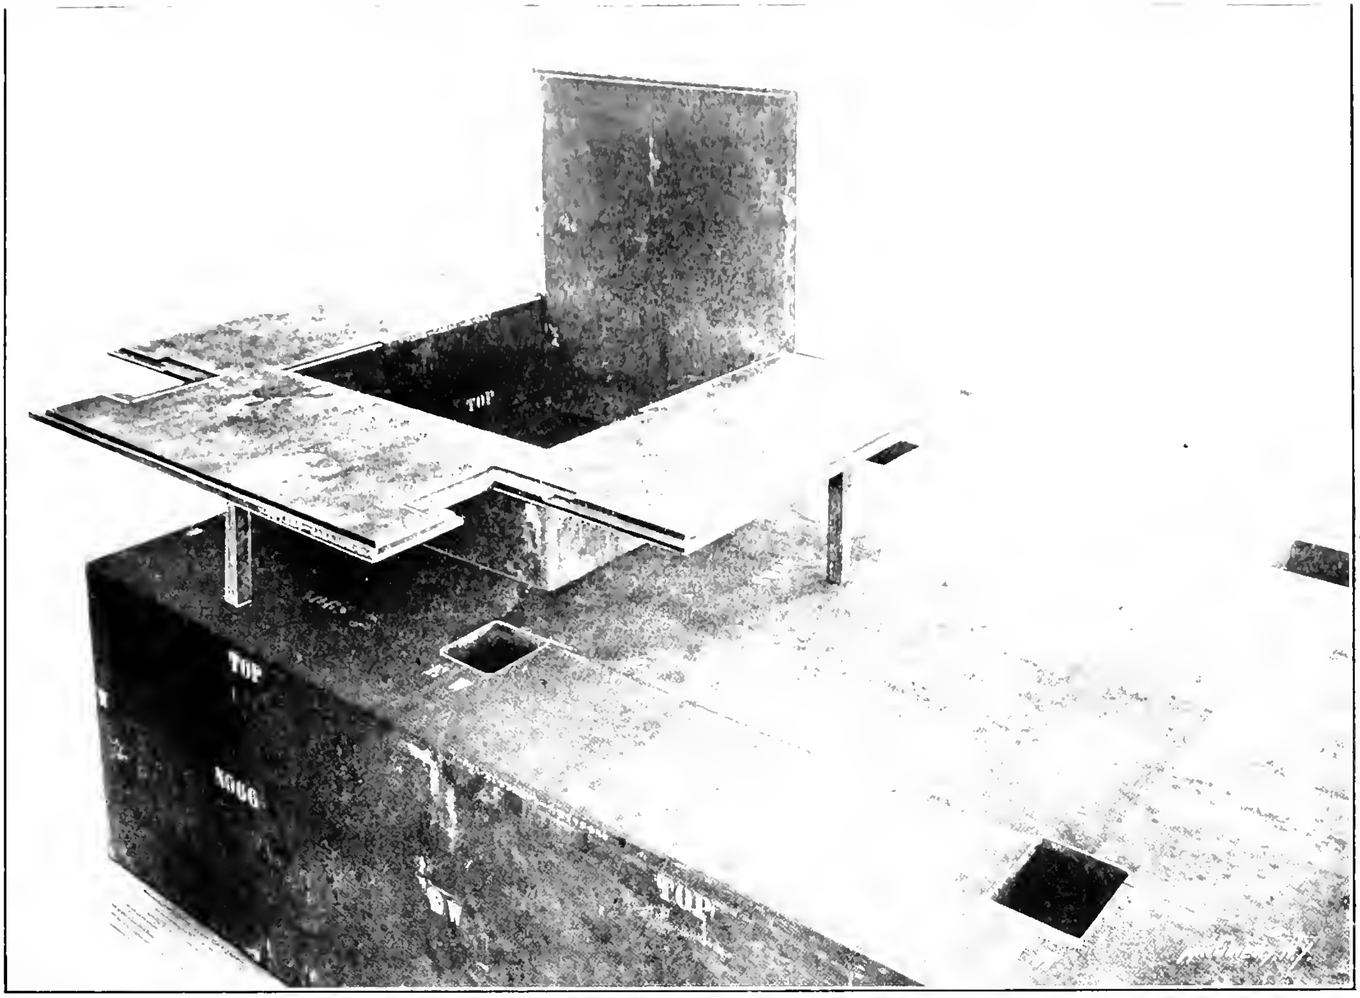

Fig. 4. Elevator and Stairway Well, Partly Assembled; note the Complicated Machine Work at the Joints.

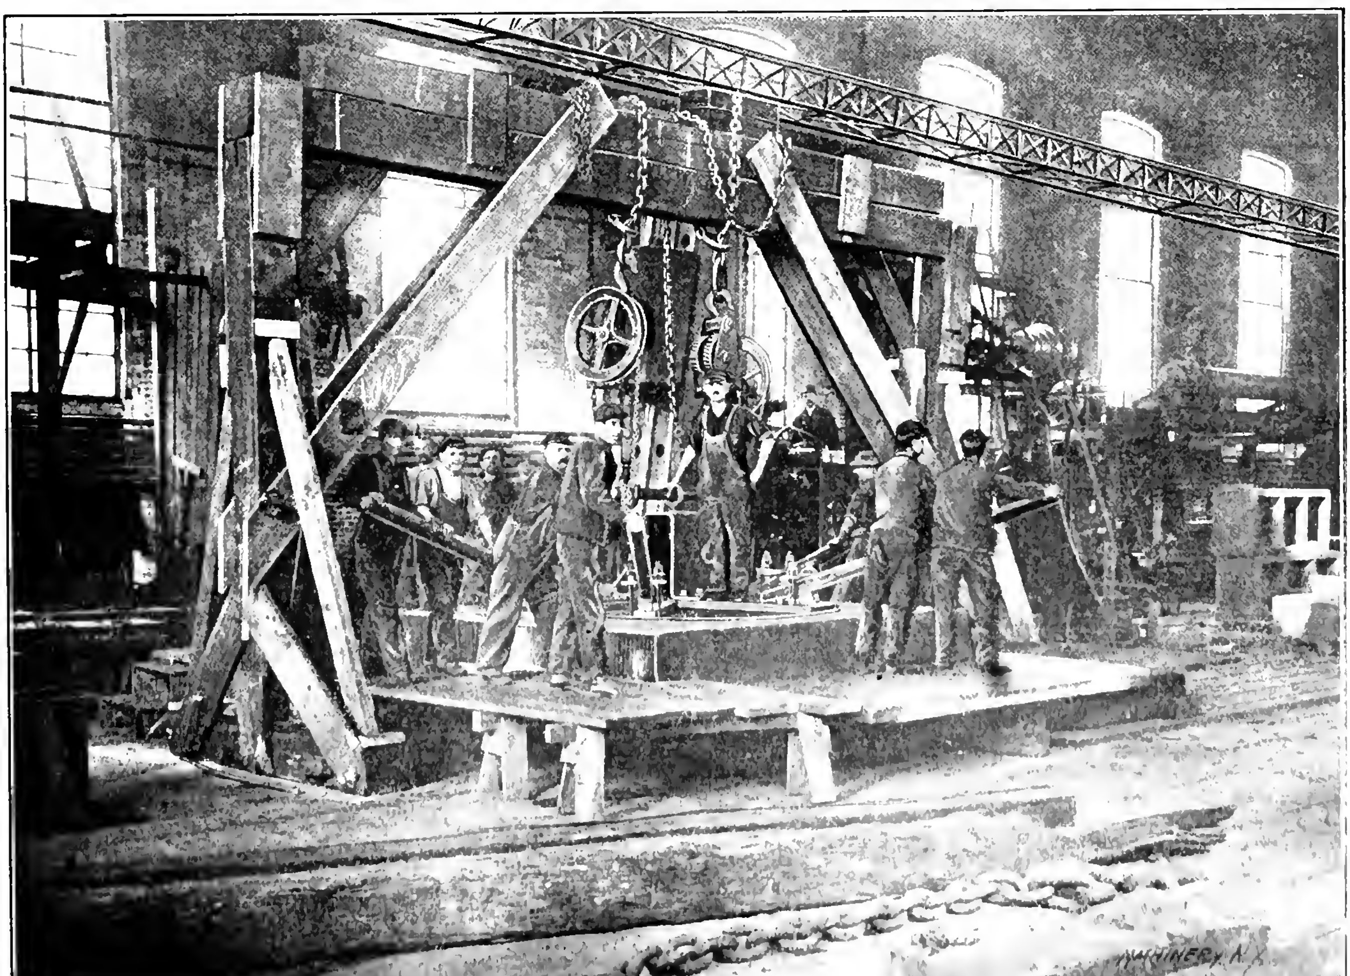

Fig. 5. Grinding in the Door into the Door Plate; a Case of Valve Grinding on a Large Scale.

which has been given to the face. The final operation on the finished surface is one of surface grinding, performed on the machine shown in Figs. 6 and 7. As shown, the spindle of this machine is carried by a traveling head and is driven by a flying belt arrangement. The plate is aligned on the supports provided for it, where it remains stationary, all the movements for traverse and feed required being given to the wheel. All of the surfaces forming the joint are thus finished. As to the matter of giving these joints the accurate

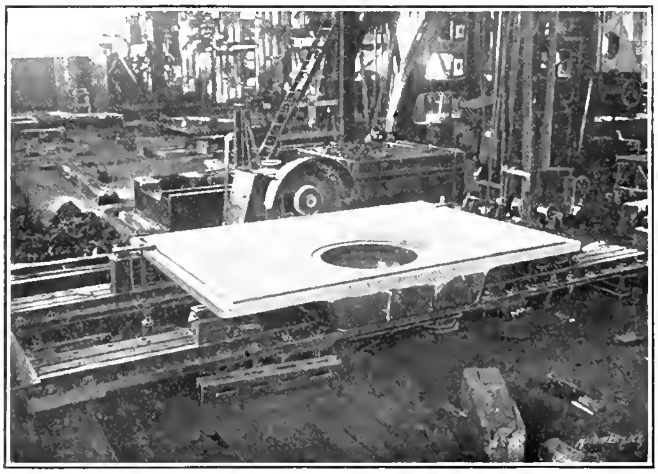

Fig. 6. Finishing Grinding the Joints after Hardening.

dimensions required for making the whole structure as tightly fitting as it has to be, no more can be said than that a high degree of skill is called for. The simplicity of this statement, however, does not detract from the unusualness of the feat. Nothing except the ordinary tools of the machinist for such work are needed or used.

Making the Door Plates and Doors.

The heaviest pieces in the vault are the sections in which the doors are formed. That for the emergency door, filling in the corner shown in Fig. 1, is in place on the grinding machine in Figs. 6 and 7. This small door is not used for regular service, but only in case the eight clocks of the two main doors fail to operate for some reason or other. The forgings of which these door plates are formed are unusual

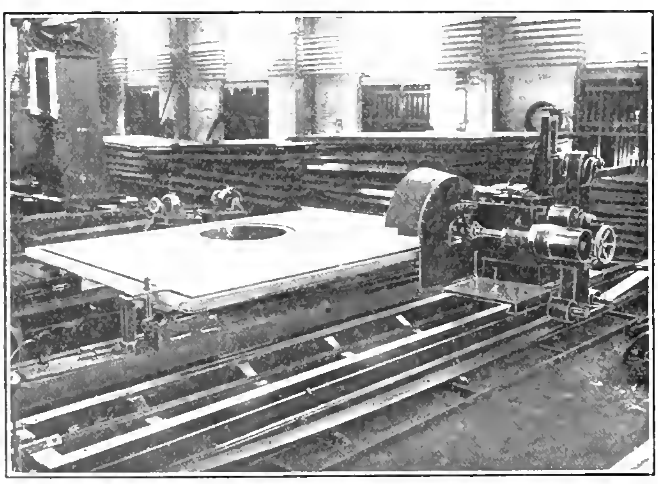

Fig. 7. Rear View of Grinder, showing Flying Belt Drive.

pieces of work, owing to their great size and somewhat complicated form. They are formed under the hydraulic press, no hammering operations being used. It might be mentioned that the joint by which this emergency door plate is fitted to the main structure is especially remarkable, being formed as it is of dove-tails on all four sides, and being on an angle cut out from the corner of the vault. Another splendid piece of dove-tailing was done in providing for one of the columns of the building which enters a recess in the further side of the vault near the front end, as shown in Figs. 1 and 2. This recess is seen directly over the word "Top" on the front plate, Fig. 1. This recess has all its joints dove-tailed, and it was something of a Chinese puzzle to design it so it could be removable at all, and still be secure from tampering from the outside.

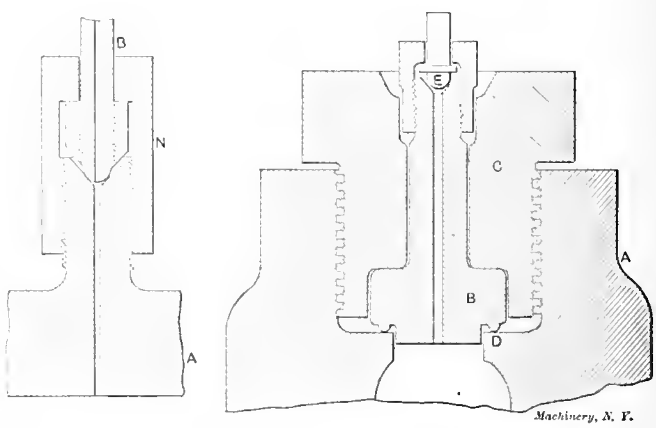
The forgings carrying the main doors are heavier than that of the emergency door. One of these is seen in Fig. 5, supported on blocking and having its door ground into it. This is a rather remarkable operation. It is essentially the operation of valve grinding, with which every automobile owner is familiar on a small scale. In this case, however, it requires twelve husky helpers to rotate the "valve," and even then it is only made possible by having the door suspended from the two chain blocks shown, so that only a portion of the weight bears on the seat. This work is done in the ordinary way with emery and water. The plate and its door were machined on the boring mill, then hardened, and finally finished by this grinding process. The door weighs about 18,000 pounds.

The operations involved in forming the armor-plate sections of which this vault is built, are interesting. They are essentially the same as those used in forming the plating used for warships. We hope to be able to describe something of this work in a forthcoming issue of MACHINERY.

* * *

CONNECTIONS FOR HIGH PRESSURES.

While the methods used in the design and construction of ordinary hydraulic machinery are well known to persons having to do with this kind of work, it may still be in place to refer to the common design used when encountering high pressures for relieving the threaded portions of a design from the direct pressure of the water. The cuts shown herewith are taken from an article in the July 26 issue of *Engineering*. These designs are particularly intended for pressures above 10,000 pounds per square inch. In Fig. 1 is shown a detail of a connection between a steel tube and



Figs. 1 and 2. Connections for High Pressures.

cylinder. The tube is solid drawn steel tubing, 1/16 inch bore and ½ inch outside diameter, and the actual joint is made directly between the tube and the fitting, as shown in the cut. In this cut *A* represents a portion of a high pressure cylinder, *B* is the steel tube mentioned, and *N* is the nut which presses down the spherical end of the steel tube against *A*, thus forming the joint. Steel tubes jointed in this way have been found to give satisfactory results at pressures up to 45,000 pounds per square inch. Small openings, say up to ¼ inch in diameter, may be closed up in the manner shown in Fig. 1, but for larger apertures, say up to 1½ inch in diameter, a steel plug of the form shown in Fig. 2 is used. This design is of a cover for closing up against pressures up to 40,000 pounds per square inch. In this *A* represents the body of the high pressure cylinder. The cover *B* carries a ring *D* which presses against the flat portion of *A*, thus making a tight joint. The central part of the cover *B* projects slightly beyond the ring *D*, thus protecting it from injury in handling. The screw *C* simply serves the purpose of holding down the cover *B* against the body *A*. At *E* is shown a joint of the same class as that shown in Fig. 1.

* * *

It is stated in *Revue Universelle des Mines* that in Germany 29 per cent of all the blast furnace gas is utilized for power purposes.

FAULTS OF IRON CASTINGS.—2.

POINTS FOR THE MACHINE DESIGNER.

FORREST E. CARDULLO.

Sponginess.

A second fault to which iron castings are subject is that of sponginess. Sponginess is due to the formation of gas bubbles in the iron, at the instant of solidification. In all ordinary cases this is due to an improper mixture of iron. However, if the casting is very thick at one place, and thin at most others, it will be impossible to obtain a mixture which will have satisfactory properties for general work, and not be spongy at points of extraordinary thickness. It is an excellent rule to allow no part of a casting to be at a greater distance from a sand surface than 2½ inches. In case this rule is strictly adhered to, and the castings are of fairly uniform thickness, no trouble will be experienced from sponginess, except from the use of poor iron. When, however, we are obliged to concentrate a considerable quantity of metal at one place, and give it a greater thickness than 5 or 6 inches, either we must take care that it will be at some point where the sponginess will do no harm, or else we must make provision to do away with it.

The only practical method for doing this is to place a riser immediately over the heavy spot. When the metal is poured, and the riser is full, a rod of wrought iron is inserted and worked up and down until the metal has almost solidified. By so doing, the bubbles have a better chance to escape, and the iron is left perfectly solid. Of course, it is not possible to use a riser effectively in this manner, unless it can be placed directly over the heavy spot. A riser at a point a few inches distant is useless. The use of a riser in this way, and for this purpose, is unnecessary when the part of the casting in which the heavy spot occurs is subject to no particular stress, or is not required to be tight under pressure, but nevertheless, a spongy spot is a defect in a casting, which should, if possible, be avoided.

Shrink-holes.

A third fault to which iron castings are subject is that of shrink-holes. A shrink-hole is a cavity in a casting, caused by the shrinking away of the metal in cooling. Like sponginess, this defect is especially likely to occur in those parts of a casting which are excessively thick. To avoid this fault, it is best to avoid sudden changes in the thickness of a section. If the part of a casting which is unusually thick does not have to be machined, the difficulty may be overcome by placing in the mold at that point a piece of iron, so that the casting will be caused to solidify at that point first, on account of the chilling effect of the cold iron. If, however, the heavy spot in the casting has to be machined, or if it is subject to heavy stress, this method of preventing shrink-holes is to be avoided, since the chilling of the iron makes it so hard as to be impossible to cut with a tool, and at the same time creates stresses within the metal which weaken it. In such a case, shrink-holes are best prevented in the same manner as has already been described for the prevention of sponginess, namely the use of a heavy riser, and the working of the iron with a rod when it is cooling.

The designer must therefore avoid heavy spots in castings, whenever possible, for the reason that they are likely to produce two serious faults, sponginess, and shrink-holes. He must avoid them especially in those parts of castings which are to be machined or which are subject to heavy stresses. If they cannot be avoided entirely, in such a case, they should be so arranged that risers may be placed immediately over them, so that a rod may be inserted into the riser, and into the heart of the spot where the metal is thickest.

Scabbiness.

A fourth fault often encountered in iron castings is that of scabbiness. Although iron in the molten condition does not permeate the sand of the mold, as water would if it were poured in, nevertheless, on account of the great weight of the fluid, it has a considerable erosive action on the materials of the mold. If, as it flows into the mold, the iron eats away fillets or partitions, or scours away patches of sand, it is obvious that the casting will not be of the proper form, but will have its angles partly filled up, and unsightly protuberances upon its surfaces. Such imperfections as these are known as scabs. The sand so washed from its proper place may float on the iron, and rise to the top of the mold, where it forms a dirty mixture, which, when cleaned away, leaves a rough depression in the surface of the casting, also known as a scab.

The remedy for this trouble is to avoid as far as possible sharp fillets, and thin tongues of sand, projecting into the mold, and to so gate the casting that the current of iron, as it enters the mold, will spread itself out, and not concentrate itself in any particular direction, for if it does, it will eat away the part against which it flows, just as quickly and surely as would a current of water. In general, proper gating is a

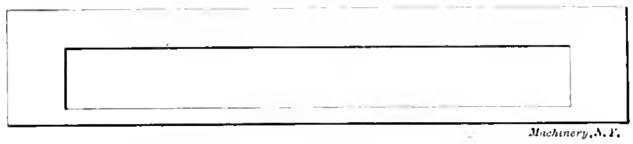


Fig. 1. Casting of such Shape as to be Subjected to Severe Internal Stresses.

matter which must be attended to by the molder, but if the designer has arranged things so that proper gating is inconvenient or impossible, the castings will almost surely be scabby.

Sand-holes.

The fifth fault to which iron castings are subject, namely sand-holes, is one which is almost invariably associated with that of scabbiness. If the sand which has been eroded by the entering current of iron does not rise immediately to the surface, the iron may partially solidify before it will float to the top. As a result, it will rise till it strikes a part of the iron which has so solidified, and will remain there, imprisoned within the body of the casting. Sand-holes generally occur in that part of a casting which lies near the top of the mold, and just a little ways under the skin. They may occasionally form large cavities which seriously impair the strength of the casting, but more often they form very small holes, which being full of sand, destroy the edge of any tool which may be used for the purpose of machining the casting, and leave the finished surface pitted and unsightly.

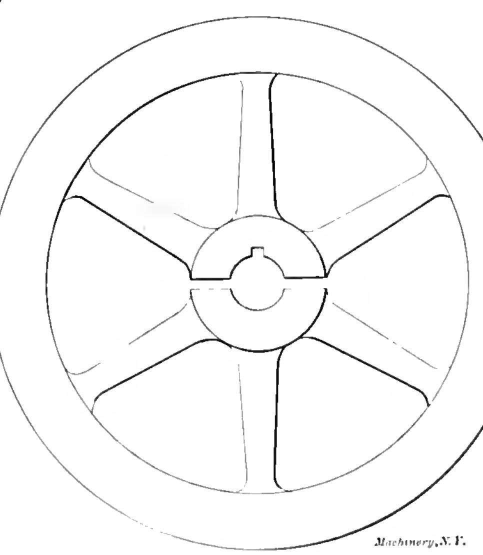

Fig. 2. Method of Obviating Shrinkage Strains in Large Wheels.

From this description of their origin, it must be apparent that the cure for sand-holes, as far as the designer's work is concerned, is the same as that for scabbiness. The fault may also be avoided by the use of a riser, so arranged that the current of iron will sweep the loose sand out of the mold and into the riser, where it will do no harm; but while this remedy avoids sand-holes, it does nothing to remedy scabbiness, which is generally the cause of sand-holes.

Floating Cores.

A sixth difficulty often encountered in the production of sound iron castings, is caused by floating cores. The buoyant

effect of the molten iron on a core is equal to about three times the weight of the core, if it is solid, and very much more than that in case the core is hollow. Large cores are generally built up about cast-iron skeletons known as core frames. These core frames are roughly of the same shape as the core, and serve to support it, and to bind it together. Were it not for these frames, heavy cores would fall to pieces by their own weight, and would be broken up in the process of casting, owing to the buoyant effect of the iron. A projecting piece of core having a volume of four cubic feet, for instance, will weigh approximately 500 pounds, and have a buoyant force of about 1,500 pounds thrusting it upward when the mold is poured. If the core frame is not amply strong and stiff, this force will bend the projection upward, or even break it off entirely. Hence the necessity of making large cored cavities of such form that the cores may be rigidly anchored and thoroughly secured. Nor is it sufficient that provision be made for securing the cores, but they must be of such shape, and so reinforced by the frames, that they will be stiff and strong, and not bend appreciably under the tremendous forces which will act on them when they are surrounded by the molten iron.

One of the most difficult things to cast properly is a long iron pipe having a small diameter and thin walls. If such a pipe be cast in the usual position, that is lying, horizontally, there will be an upward thrust along the whole length of the core, tending to bend it. On account of its slenderness, the central portions will be deflected upward, making the walls of the pipe thinner on one side, and thicker on the other. Often the deflection proves sufficient to thrust the core against the side of the mold, if it is long, or, in case the

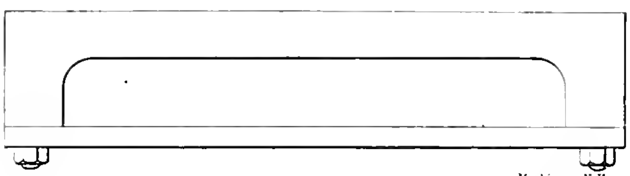

Fig. 3. Piece shown in Fig. 1, made in Two Parts.

thickness of the wall is great in proportion to the length of the core, to break it off entirely. On this account, pipes and hollow columns of cast iron are often cast on end, thus avoiding any deflection of the core. The same principle may be applied to many other pieces, by taking care to so design them that long and slender cores shall have a vertical position when the mold is poured. If they have such a vertical position, and are supported at both ends, they will have no tendency to deflect one way or another, and this source of trouble may be completely avoided.

Cold Shuts.

The seventh fault is known as a cold shut. A cold shut is caused by the imperfect uniting of two or more streams of molten iron, flowing together, which are too cold to coalesce. Such a fault often occurs on the upper side of a thin cylinder cast horizontally, when the iron is not sufficiently hot at the instant of pouring It there appears as a seam in the side of the cylinder, where it is very apparent that the metal has united imperfectly. It is not only a weak spot in the casting, along which it will readily split if called upon to sustain any great stress, but it is a spot which will surely leak under pressure, and which it is impossible to calk. The cause of the imperfection is generally improper gating, or else too great thinness of metal. If the iron is obliged to flow in thin streams for long distances, it will be cooled very much, and probably the advancing face will be partially solidified. Consequently, when it meets a similar advancing face of metal, which has been similarly cooled, there is small likelihood of their uniting properly.

The remedy is obviously to so design the casting that the metal will not have to flow in thin streams for long distances. The arrangement of gates and risers is often of great importance in minimizing cold shuts, and if the casting is large, and at the same time has thin walls, the designer must see that the gates may be so arranged that the iron may quickly fill up the mold. While the arrangement of the gating generally depends on the molder's fancy, he may often be limited by the shape of the casting, and obliged to place the gate at some point where the iron, in flowing in, must spread itself into a thin sheet, or pass for a considerable distance through a narrow passage. Under such circumstances, a cold shut is hardly to be avoided.

Shrinkage Strains.

The eighth and last fault to which I shall call attention is that of shrinkage strain. If we have two pieces of iron fastened end to end, as shown in Fig. 1, one piece being notably thinner than the other, the thinner piece will solidify first in the mold, and cool some hundreds of degrees below its freezing point, before the thicker part solidifies. As a result, the thicker part, when cooled to air temperature, will have, or rather tend to have, a less length than the thinner part, the reason being that at the instant of solidification of the thicker part, both pieces had the same length, although the thinner part was much the cooler. The thin part will then be in compression, while the thick part is in tension, and severe stresses will exist within the piece, which make it weaker than it would otherwise be in most cases.

Sometimes, however, we are enabled to utilize the shrinkage stresses to advantage. For instance when cast iron was the standard material for the manufacture of ordnance, guns were cast with cores through which water was circulated, so as to cool the surface of the bore before the outer parts solidified. When a gun is fired, it is known that the inner layers of metal are stretched more than the outer ones. By cooling the inner layers of metal first, shrinkage strains are produced in the walls of the gun, causing the outer layers of metal to compress the inner ones. The combined effect of the shrinkage stresses and the stresses produced by the explosion is to produce a uniform stress throughout the walls of the gun, and so reduce the chance of rupture.

It is not often, however, that we are able to take advantage of shrinkage strains in this way. More often they are troublesome, causing work to warp in the process of machining, or causing mysterious cracks to develop without apparent cause. Since these strains are due to unequal rates of cooling in the different parts of the casting, the best way to eliminate them is to so arrange the thickness of the various parts, that the entire casting shall solidify at the same time. The second best way is to so arrange the parts of the casting that the unequal contraction shall not produce dangerous stresses at any point. In order that the entire casting shall cool at a uniform rate, it is necessary that all parts of it shall be of approximately uniform thickness, and that there shall be no sudden changes of section. In order that unequal contraction shall not produce dangerous stresses in the metal, it is necessary that there shall be no sharp corners, and that the various parts shall be free to expand when necessary. For instance, a wheel or pulley with a solid rim is likely to have severe stresses set up within the arms by unequal cooling, but if the hub be divided as shown in Fig. 2, by means of a thin core, and then bolted subsequently, no shrinkage strains will occur, since the arms are free to expand or contract, independently of the rim.

Shrinkage strains often become so serious that it becomes necessary to make pieces in two or more parts, which it would be perfectly possible to make, at much less expense, in one piece. Large jacketed cylinders, for steam and gas engines, are good examples of this. When cast in one piece, the shrinkage stresses, together with the stresses set up by the varying temperatures incident to service, are often sufficient to crack them. Were the piece shown in Fig. 1 made in two parts, as shown in Fig. 3, there would be no shrinkage strains in either part, although the cost of machining the surfaces which are fitted together, and of putting in the bolts, would not always warrant the construction.

Relative Economy of Simple and Complicated Castings.

In conclusion, it may be well to state that the most of the faults enumerated will be more likely to occur in a part of a complicated casting, than in a similar part of a simpler casting. For instance, the cylinder of a gas engine will be more likely to have some imperfection if it is cast integral with the frame, than if it is cast separately. In the same

way, the frame will be more likely to have an imperfection of some kind, than if it were cast separately. Assuming that ten per cent of the cylinders or frames would be lost if they were cast separately, it is more than likely that fifteen per cent of the castings, having cylinder and frame cast together, would be rejected for faults in the frame, and fifteen per cent of the remainder would be rejected for faults in the cylinder. In other words twenty-eight per cent of these castings would be rejected, against ten per cent of the simpler forms. If more than eighteen per cent of the cost of the castings is saved in machining, or in other ways, by casting cylinder and frame together, it is well to do so, but if the saving is not more than sufficient to balance the loss, it is well to make several simple forms, instead of one complicated one.

* * *

COLLEGE AND APPRENTICE TRAINING.

The subject of the monthly meeting of the American Society of Mechanical Engineers, held October 8, was "College and Apprentice Training." A paper having this title was read by Prof. John P. Jackson of the State College of Pennsylvania, in which he pleaded for more co-operation between the present collegiate institutions and manufacturing industries. He was of the opinion that a great lack at the present time is a connecting link which will make the collegiate work of technical schools more practical and that will enable students to realize more quickly the benefits they should accrue from their technical work. The discussion was animated, and about as many diverse opinions were expressed as there were individuals taking part. One speaker (Mr. C. W. Cross, of the New York Central) intimated that a great fault with higher education is that in too many cases the wrong men were educated. He epigramatically remarked "there are no text-books on horse sense," the idea being, of course, that a man to be successful in engineering work must first of all have good common sense and an instinctive knowledge of the proper course to pursue without regard to what he has learned in schools. If he does not possess this natural instinct, no amount of education will make up for it. Mr. F. W. Taylor is a firm believer in the refining effect of work. He believes that the great need of the college graduate is to learn how to do dull, monotonous tasks day after day without feeling that he must be learning something. He said that a graduate is purely in an absorptive frame of mind; for four years he has been learning things without giving out ideas. When he comes into the shop he finds that his employers look to him to produce, and they are more interested in the ideas and suggestions that he can or will make, and in the work he can do, than in teaching him new things. Until he learns to do his work simply as a cog in the wheel of production he will not be a valuable man to his employers. He must become a trained and disciplined producer before he is really fitted to direct the production of others. It can hardly be said that anything startlingly new was contributed to the discussion, but it nevertheless may be profitable. The meeting betrays the deepest interest of educators and manufacturers in what is doubtless one of the most vital subjects affecting our manufacturing industries.

* * *

The curious fact that the useful life of frosted incandescent lamps is only a little more than half the life of the corresponding plain bulb lamp has long been recognized. One explanation advanced is that the temperature of the frosted lamp is higher, due to the increased absorption by the bulb. Mr. Edward P. Hyde of the Bureau of Standards, Washington, D. C., claims, however, that this explanation is not correct, but that the decreased efficiency of the frosted lamp depends upon the fact that although the filament in the frosted bulb emits the same total flux of light as that emitted by the filament in the plain bulb, the light is reflected through the glass of the frosted lamp several times, and the absorption of light by the carbon filament itself becomes so great in that case that the apparent intensity of the frosted lamp at any time during its life is less than that of the plain lamp, and the difference in intensity increases with the length of time a frosted lamp is used.

ECONOMY TESTS OF 7,500 K.W. WESTINGHOUSE-PARSONS STEAM TURBINE.

The following data comprises the principal results obtained during the eight-hour economy test on September 1, 1907, upon turbine No. 253 installed earlier in the year at Waterside Station No. 2 of the New York Edison Company. This test was conducted entirely by the New York Edison Company, under the direction of Mr. J. P. Sparrow, chief engineer.

The turbine unit tested is of standard Westinghouse construction throughout. [See MACHINERY, February, 1904, engineering edition.] It has a maximum rated capacity of 11,250 kilowatts, and was built to operate on 175 pounds steam pressure, 28 inches vacuum, and 100 degrees superheat. Under these conditions, the turbine unit was guaranteed to have a minimum steam consumption of 15.9 pounds per kilowatt hour at the generator terminals with a normal speed of 750 R.P.M. Incidentally, the electrical efficiency of the generator was guaranteed to be 97.8 per cent exclusive of friction and windage, at a load corresponding to that sustained during the test. The results of the tests, detailed below, show an economy about 7.5 per cent better than the guarantee.

Methods of Conducting the Tests.

Load.—During the test period, No. 2 Waterside Station sustained practically all of the 25-cycle load on the system, of which the unit under test carried practically 70 per cent, the remainder being carried by other turbine units. This load was maintained as constant as possible by remote control of the turbine governor by the switchboard operator. Between the first and the last hours of the test, the maximum variation in load was held within 4 per cent above and below mean. During the last hour, however, the load decreased somewhat. Previous to the test, this turbine unit had been running on a load of 7,000 kilowatts, which was increased to its test load ten minutes before the start.

Calibration.—Three-phase electrical load was measured by the two-wattmeter method, using two Weston indicating wattmeters of the standard laboratory type. These instruments were calibrated at the New York Electrical Testing Laboratories immediately before and after the test. The power factor was maintained substantially at unity, and all electrical readings were taken at one minute intervals.

Steam Consumption.—As a surface condenser was used in connection with this turbine unit, the water rate was determined by weighing the condensed steam delivered from the condenser hot well. This condensation was weighed in a tank mounted upon platform scales, with a reservoir above large enough to hold the condensation accumulating between each weighing. (See the accompanying cut, Fig. 2.) These weighings of 12,000 to 13,000 pounds each were made at intervals of five minutes.

Gland Leakage.—By the loop method of connecting the gland water supply, shown in the accompanying cut, the necessity for correcting condensation by an amount equivalent to the weight of the gland water used is avoided. It will be noted that a continuous gland water circuit is used entirely outside of the weighing apparatus, and that all overflow from the standpipe returns to the hot-well delivery.

Condenser Leakage.—As the circulating water is quite salt, any condenser leakage may immediately be detected by the salinity of the condensed steam, which should be pure distilled water. On this account, condenser leakage was determined entirely by chemical analysis, employing the silver-nitrate test with a suitable color indicator. This method proved extremely sensitive, and possessed a decided advantage over the ordinary method of weighing the leakage accumulating during a definite period when the condenser is idle and under full vacuum. As samples of circulating water and condensed steam could be taken at the same time, this method made it possible to discover any change in the rate of condenser leakage taking place during the test, while the method of weighing, above described, provides only an average result during the period.

Hot-Well Correction. In this condensing plant, the delivery of the hot-well pump is automatically controlled by a float valve in the interior of the hot-well. This maintains the

water level therein at a practically constant point, and hence no correction had to be made for difference in level of water in the hot-well before and after the test.

Steam Supply.—Steam pressures and temperatures were determined close to the turbine throttle. As usual, the degree of superheat was obtained by subtracting from the actual steam temperature the temperature of saturated steam at the corresponding pressure carried at the time. All gages and thermometers were calibrated previous to the test at the U. S. Testing Bureau. It will be noted that both pressure and superheat were somewhat below the guarantee.

Vacuum.—Vacuum was measured directly at the turbine exhaust by means of a mercury column with a barometer alongside for reducing to standard barometer—30 inches. This also obviated the necessity for temperature correction between the two mercury columns. During the test the vacuum was not maintained quite up to normal.

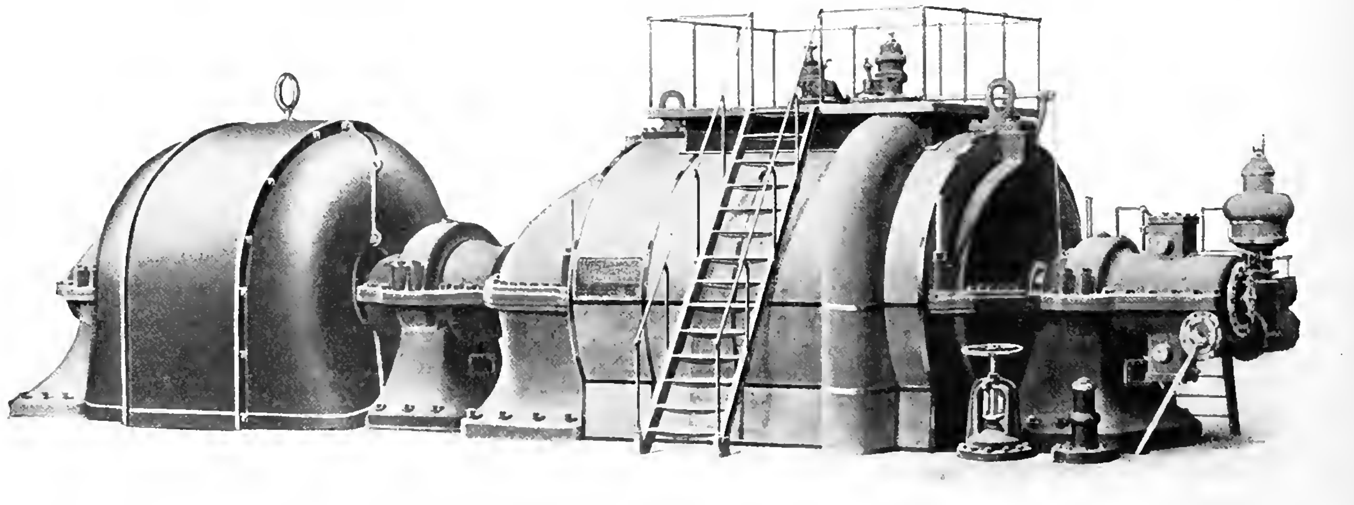

Fig. 1. Westinghouse-Parsons 7,500 K.W. Steam Turbine, Waterside Station No. 2, New York Edison Co.

Results of Tests.

The following data represents the results of the tests, calculated for the conditions as actually run, *i. e.*, for instrumental errors only:

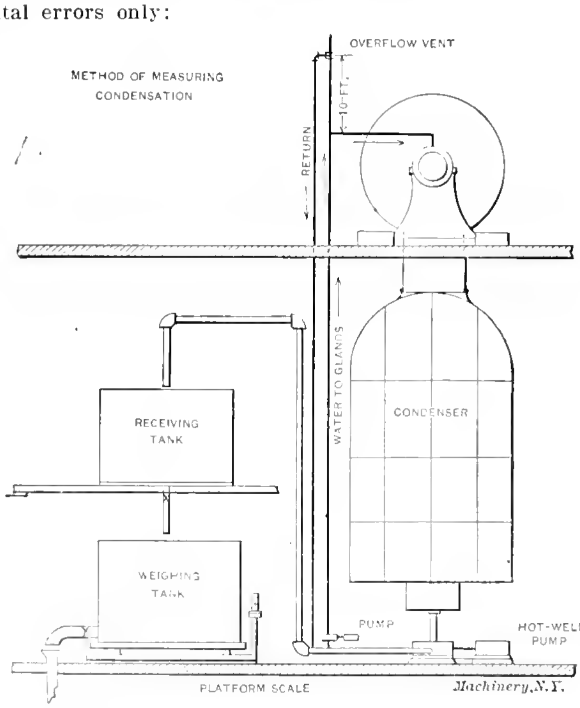

Fig. 2. Diagram of Water-weighing Apparatus, Etc.

Duration of test	9:30 a. m. to 5:30 p. m.
Average steam pressure at throttle, lbs. per sq. in. gage	177.5
Average superheat at throttle, degrees F.	95.74
Average vacuum (referred to 30-inch barom.) in. Hg.	27.31
Average load on generator, K. W.	9,830.48
Average steam consumption, as tested, lbs. per K.W. hr.	15.15

Test Correction.—Owing to the departure, during the test, from specific operating conditions upon which guarantees were based, it was necessary to correct the observed results by the following amounts:

Pressure (2.5 pounds high) correction, 0.25 per cent; vacuum (0.69-inch low) correction, 1.84 per cent; superheat (4.26 degrees low) correction, 0.29 per cent.

These corrections were mutually agreed upon previous to the test as representative of this type of turbine. When applied to the observed steam consumption given above, the following results, representing contract conditions, are obtained:

Average corrected water rate during 8-hour test	14.85 lbs. per K. W. hour
Guaranteed water rate	15.9 lbs. per K. W. hour

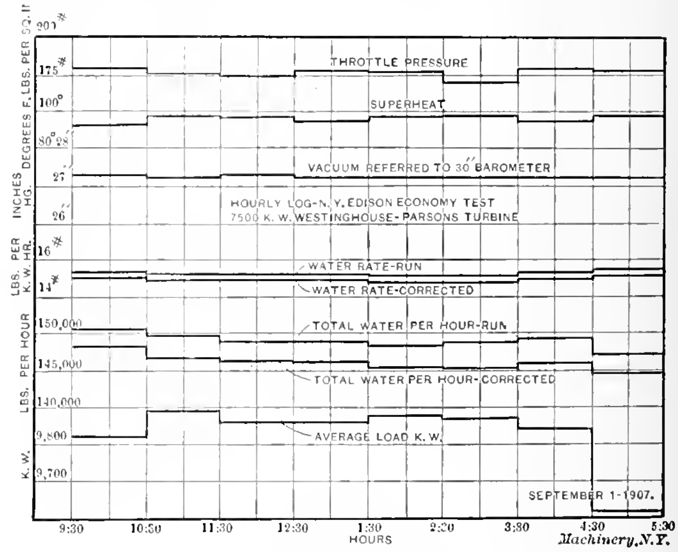

Fig. 3. Log of Test.

Log.—Referring now to the accompanying log, Fig. 3, it is interesting, as a check upon the average figures above presented, to observe the results segregated into hourly periods, as shown. Here it will be noted that the load was considerably lower during the first and last hour than during the main part of the test. Neglecting, therefore, these two hours and considering only the six-hour period from 10:30 a. m. to 4:30 p. m., the results are as follows:

Average corrected water rate, six hours	14.8 lbs. per K. W. hour
Equivalent water rate	10.65 lbs. per B.H.P. hour
Equivalent water rate	9.8 lbs. per I.H.P. hour

The two latter quantities are determined by applying conversion factors for generator efficiency and for internal losses.

A noteworthy agreement exists between the results here noted and those previously obtained from tests of machines similar in design installed in the Manhattan Station of the Interborough Rapid Transit Co., New York, and the Long Island City Station of the Pennsylvania R. R. At the same loads and with equivalent operating conditions, the performance of the machines is almost identical.

LAPPING FLAT WORK AND GAGE JAWS.*

F. E. SHAILOR†

The main essential points of the art of lapping can be described in an article, but, the same as with any other line of mechanical work, it is necessary that the workman shall do considerable lapping before he can become proficient. There are certain motions, touches, sounds, refinements, etc., which the skilled workman acquires by practice, that are impossible of enumeration and description, or of enumeration and description that would be intelligible to an inexperienced man. For instance, ask a carpenter how he knows that he is sawing a board straight, and he will be unable to tell you. Nevertheless, he has acquired a peculiar sense of touch, or such general acuteness of the senses, that he knows instantly when the saw starts to "run out." His mind and arm automatically, as it were, return the saw to a straight line without missing a stroke. It is the same way with a die-maker. He can file a die, looking only at the surface line, and can detect the instant when his file "rocks" from a straight line. He will tell you that he "feels" it, but is unable to define what the sensation is. Likewise I am unable to explain some of the finer points in the art of lapping, and I will simply point out those which are fundamental, and which must be acquired first by the workman unaccustomed to such operations. He must acquire the refinements by practice and experience.

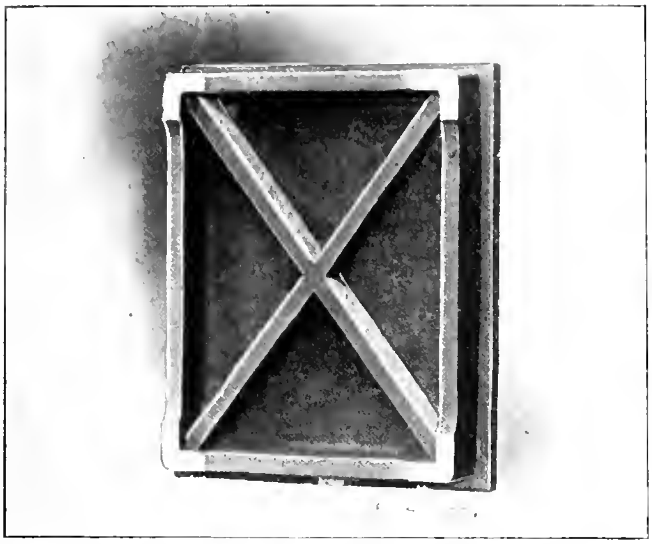

Fig. 1. Back of Standard Flat Lap, showing Ribbed Construction.

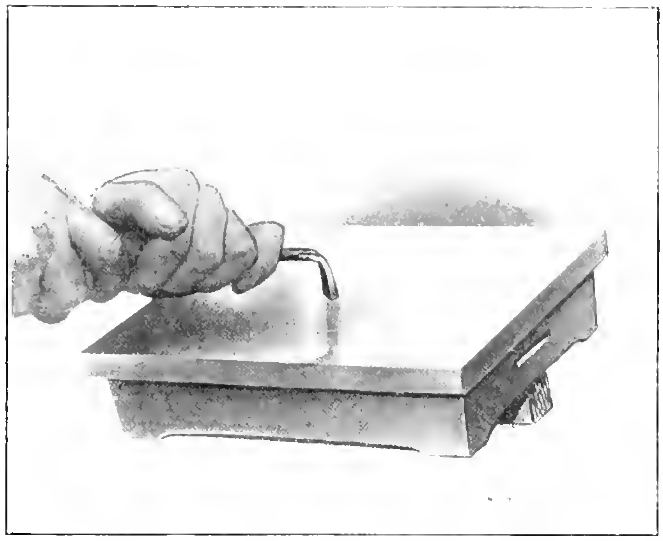

Fig. 2. Scraping Down the High Spots.

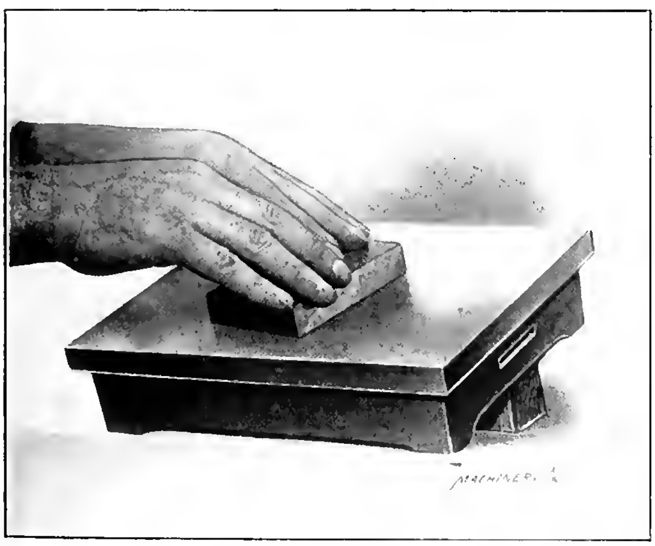

Fig. 3. Charging the Lap, using a Hardened Steel Block.

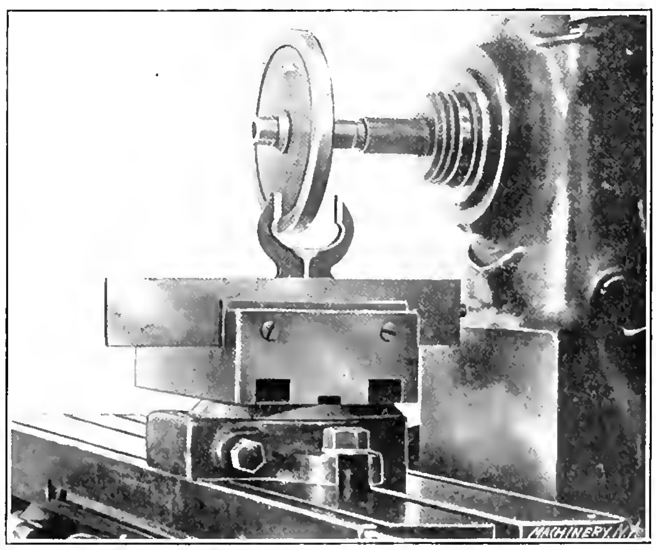

Fig. 4. Lapping a Gage.

A Perfect Lap Required for Perfect Lapping.

The first requisite of perfect lapping is a perfect lap, and right here is where the novice will make his first mistake, that is, in the preparation of the lap. To make a surface lap, it should be carefully planed, strains due to clamps being avoided, and then it should be carefully scraped to a standard surface plate. This is done by rubbing the face of the lap on the standard surface plate and scraping down the high spots until a perfect plane surface is obtained. If a standard surface plate is not at hand, a lap can be made level by using three laps that are nicely planed and used alternately as follows. We will number the laps Nos. 1, 2, and 3. Now, rub No. 1 and No. 2 together, and scrape the high spots until they fit. Then introduce No. 3 and scrape it down to fit No. 2, and then to fit No. 1, and so on. The third lap eliminates the error that might follow if only two laps were used. For example, it is possible to fit two plates accurately together without making them plane surfaces, one becoming concave and the other convex. The third lap absolutely prevents this and produces a perfect plane surface if time and patience hold out. It is a slow operation, but not so slow as trying to lap a piece true with a lap that is not true.

The Objection to Ground Laps.

The laps may be ground together instead of scraping, but the writer prefers the scraping process, as it is easy to see when the job is done. It is also better to scrape them, because it is quicker than attempting to grind them level with the fine grade of emery that is required for nice lapping, and it must be remembered that when ground together the laps *are already charged*. Hence, the necessity of using a fine grade of emery if they are ground together.

Using a Hand Surface Lap.

The writer prefers a cast iron lap, Fig. 1, thoroughly charged, and having all loose emery washed off with gasoline. When lapping, the surface is preferably kept moist with kerosene, although gasoline causes the lap to cut a trifle faster. It evaporates so rapidly, however, that the lap soon becomes

* See MACHINERY, May, 1904: A Few Suggestions in Tool-making.
† Address: Great Barrington, Mass.

dry, and the surface caked and glossy in spots. When in this condition, a lap will not produce true work. The lap should be employed so as to utilize every available part of its surface. Gently push the work all around on its surface, and try not to make two consecutive trips over the same place on the lap.

Do not add a fresh supply of loose emery to a lap, as is frequently done, because the work will roll around on these

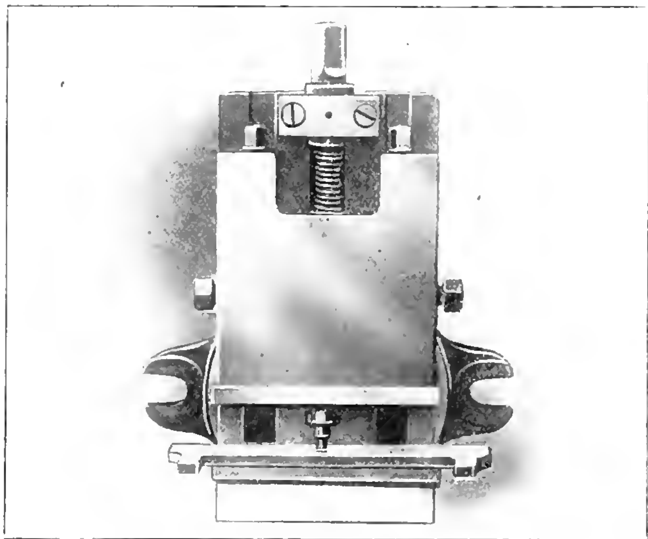

Fig. 5. View of Machine Vise, showing how a Gage is Clamped without Springing it.

small particles, which will keep it from good contact with the lap, causing poor results to follow. If a lap is thoroughly charged at the beginning, and is not crowded too hard, and is kept well moistened, it will carry all the abrasive that is required for a long time. This is evident, upon reflection, for if a lap is completely charged to begin with, no more emery can be forced into it. The pressure on the work should only be sufficient to insure constant contact. The lap can be made to cut only so fast, and if excessive pressure is applied, it will become "stripped" in places, which means that the emery which was imbedded in the lap has become dislodged, thus making an uneven surface on the lap.

Causes of Scratches—Grading Emery.

The causes for scratches are as follows: Loose emery on the lap; too much pressure on the work which dislodges the charged emery; and what is, perhaps, the greatest cause, poorly

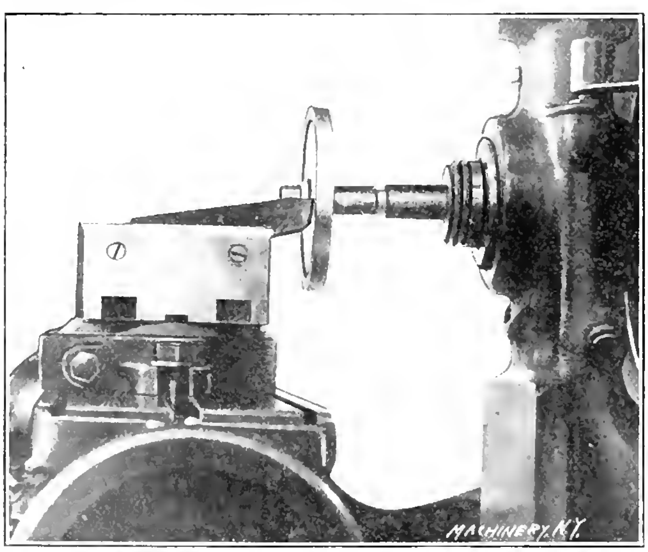

Fig. 6. Truing the Lap with a Tool held in the Vise.

graded emery. To produce a surface having a high polish free from scratches, the lap should be charged with emery or other abrasive that is very fine. The so-called "wash flour emery," sold commercially, is generally too uneven in grade. I would advise all those who have considerable high class lapping to do to grade their own emery in the following manner: A quantity of flour emery is placed in a heavy cloth bag, and the bag gently tapped. The finest emery will work through first, and should be caught on a piece of paper. When sufficient emery is thus obtained it is placed in a dish of lard or sperm oil. The largest particles of emery will rapidly sink to the bottom, and in about one hour the oil should be poured into another dish, care being exercised that the sediment at the bottom of the dish is not disturbed. The oil is now allowed to stand for several hours, say over night, and then is decanted again, and so on, until the desired grade of abrasive is obtained.

For the information of those not well acquainted with grading abrasives, it may be said that the grade of diamond dust known as "ungraded" is obtained in about five minutes, while it requires about three weeks to obtain the grade known as No. 5, which is very fine. But, even at the end of three weeks there still will be small particles in the oil that have not settled, due to the viscosity of the oil.

To lap true and free from scratches, one must have skill and be thoroughly conversant with the peculiar sounds, touches, and motions spoken of above. For a high polish on work, a rapid motion and slight pressure are necessary for success. It is also necessary that the lap is properly charged with properly graded abrasive.

Lapping Gage Jaws.

Fig. 4 shows the best method that has come to the writer's notice for lapping the jaws of gages. The lap is made of cast iron and is relieved as shown, leaving only a thin edge or

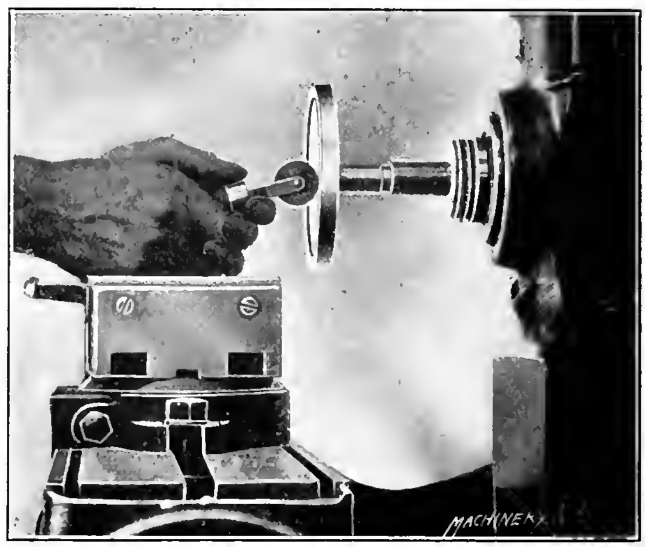

Fig. 7. Charging the Lap with a Roller.

flange on each side to bear against the jaws. As the machine table is worked back and forth, the lap passes over the entire surface of the jaw, grinding it down in the same manner as would be done with a cup emery wheel. Care must be taken to clamp the gage in the vise so as not to spring it. Fig. 5 illustrates an approved method for holding a gage so that the vise jaws will not deflect it. Should the gage be sprung, it is clamped at the center only, leaving the ends free. Snap gages are now mostly made of machinery steel and pack-hardened. Made in this way they do not change much, as the interior of the gage is left soft, and whatever change occurs can be easily remedied, but in any case the method illustrated is the safest one to follow, for it leaves no doubt as to the gage being held free from spring during the lapping operation.

A lap should be turned on the arbor on which it is to be used, for it is almost impossible to put a lap back on an arbor after it has been removed, and have it run true. Therefore, the lap should be recessed quite deeply, as shown, to allow for truing up each time the lap is placed on the arbor. Perhaps when the lap is mounted on an arbor in the milling machine, it will be found to run out not more than 0.001 inch, but that means that it is touching the work in only one spot, and the result can be hardly better than if a fly-cutter was used for a lap. Fig. 6 shows the operation of truing the lap. A keen cutting tool is clamped in the vise and in this way the lap can be trued as nicely as though it were done in the lathe. In fact, it is superior, for there is absolutely no change

in the alignment of the lap with the work spindle after it is turned, which might easily happen should it be turned in the lathe and then mounted in the milling machine spindle. With a perfectly true lap a perfect contact between the lap and gage is insured for its entire circumference. Both sides of the lap should be turned at the same setting on the arbor.

Fig. 7 shows the operation of charging a circular lap, using a roller mounted in a suitable handle for the purpose. The emery is rolled in under moderate pressure. It is good practice to make the roller of hardened steel, and after charging the lap, all the surface emery should be thoroughly washed off.

The next step is to square up the jaws of the gage. Do not depend on the zero marks of the vise. The jaws of the gage may have sprung a little in hardening, and if the zero marks of the vise are depended upon to square the work, there possibly will not be sufficient stock on the jaws to clean up. Be very careful to set the gage by the surface of the jaws and to clamp it in the vise as previously noted, so that it is under no pressure tending to spring it out of shape.

Importance of the Sound Magnifier in Machine Lapping.

When employing a power-actuated lap, the little instrument shown in Fig. 8 is useful in determining the instant when the lap touches the work. By placing the forked end on the work and the wooden part to the ear, the sound is greatly magnified, and it makes it much easier to determine the precise point of initial contact. If one depends upon the naked ear to tell when the lap touches the work, he is liable to crowd the lap too much, and scratch the work or strip the lap. With this instrument the mechanic will know the instant the lap just touches the work, and this is the position where its work should be done. In short, the lap should not work under any appreciable pressure, but should simply touch the work. Hence the desirability of some means of magnifying the sound and not depending on the naked ear.

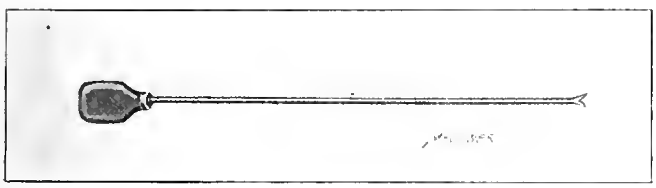

Fig. 8. Sound Magnifier.

The workman should avoid the custom of adding a fresh supply of abrasive to the lap, as it is not only injurious to the character of the product, but it naturally increases the time required for lapping. To illustrate the action, suppose that an arbor is to be ground in a grinding machine, and that it is belted so that it runs with a wheel at the same speed. The consequence will be that no grinding action could take place, as there would be no difference in motion. The condition is very similar when loose emery is placed on a surface lap. The emery simply rolls around between the work and the wheel, and occasionally a piece of emery is imbedded in the lap long enough to scratch the work. While it may look as though the lap was cutting much faster, the truth is that it cuts slower and produces poor work.

In lapping jaws, some workmen rough lap, and then finish by hand, but a better job will result when finished in the machine. I consider that it is poor practice to rough lap a gage, using a coarse grade of emery, and then wash the lap and smear it with fine emery. Of course the lap is already charged with a grade of emery last used, and the act of putting on a supply of fine emery on the lap will not produce as good a surface as if the gage were finished without the fresh supply of emery, though the latter is of a finer grade.

In the above remarks I have attempted to give some idea of the precautions that should be observed in lapping accurate work, but any practical tool-maker will know that I have left out many of the minor points which are necessary for the best work and which are properly regarded as refinements of the art. It is impracticable, however, to explain them in an article for the reasons enumerated in the beginning. Experience alone will give the workman the fine touches that are necessary for producing the highest grade of work.

HOT BEARINGS.*

THEIR CAUSES AND THE MEANS OF AVOIDING THEM.

E. KISTINGER.†

In our modern high speed steam and gas engines, turbines and the like, hot bearings are of more frequent occurrence than is generally supposed. Very often a new plant, just put into service, has to be shut down on this account. It not infrequently happens that the engine which has run "hot" is one of several, identical in design and construction, the bearings in the others having operated without trouble. Appar-

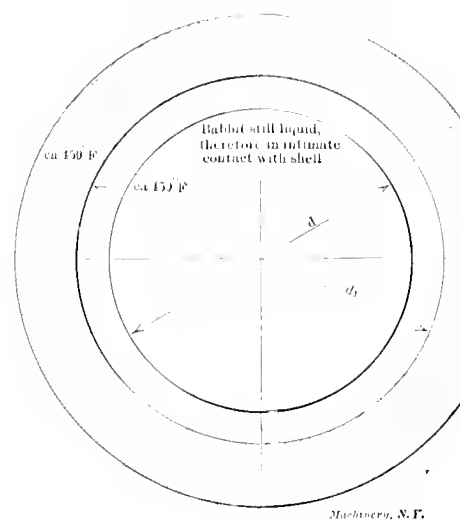

Fig. 1. One-piece Bearing; Babbitt just Poured. Both Shell and Babbitt at the Solidifying Temperature.

ently there is no cause for this particular engine to give trouble, but in order to remove the difficulty, various makes of babbitt metals and bronzes are tried, sometimes with good results, sometimes without. Again, it occurs that a machine or engine operates at the beginning with perfect satisfaction, but after a time one or more of the bearings begin to run "warm," and finally "hot," so that relining becomes necessary. As a general rule it is then simply accepted as a fact that the bearings "ran hot"; seldom does any one think it worth while

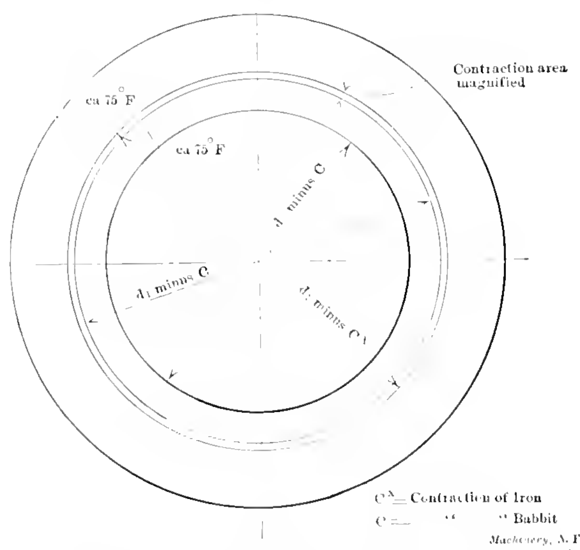

Fig. 2 Same Bearing as shown in Fig. 1 Cooled Down to Normal Temperature.

to seek out the fundamental causes for the trouble. That there is always the element of doubt, in regard to bearings, is evidenced by the fact that our modern engine builders usually deliver an extra set of bearings with the engine, so that, in the event of trouble, a new set is at hand. The following may be of some assistance towards discovering and eliminating, in a scientific manner, and along technical and metallurgical lines, the real causes of hot bearings.

*See MACHINERY, May, 1905, Oil Grooves and Bearings; December, 1906, January and February, 1907, The Design of Bearings.

† Mechanical Engineer, American Glyco Metal Co., Chicago, Ill. (Joseph T. Ryerson & Son, 22 Milwaukee Ave., Chicago, Ill., general distributors.)

investigation will show that the main reasons for hot bearings are:

1.—Shrinkage or contraction of the babbitt.

2.—Shrinkage strains set up in the babbitt metal liner by the unequal distribution of the babbitt metal over the shell.

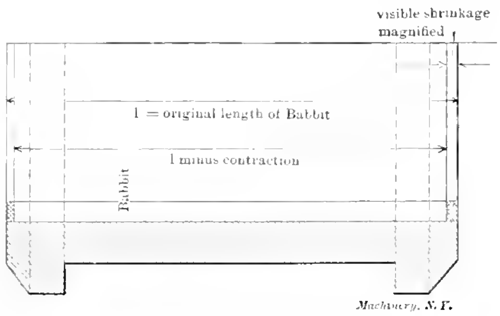

Fig. 3. Babbitt Bearing without Dove-tailed Grooves or other Retaining Device.

3.—A lack of contact between the babbitt metal liner and the cast iron or cast steel shell.

4.—The lubricant becomes partially deflected into the wrong place.

Shrinkage or Contraction of the Babbitt.

a. Shrinkage in a diametral direction As an illustration of this point, one may take the simple example of an iron ball and ring. If this ball, when cold, will just pass through an iron ring, it will not do so when somewhat heated and expanded. After cooling down, however, it will again pass through the ring. A similar action takes place in a bearing.

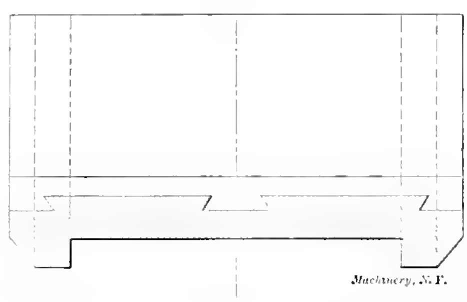

Fig. 4. Same Bearing as shown in Fig. 3, but with Dove-tailed Grooves. Visible Shrinkage Prevented, but Shrinkage Strains Produced

In Fig. 1, of the accompanying illustrations, the babbitt liner may be considered to have been jnst poured in, and the metal to be still liquid. At the exact solidifying point the babbitt will have filled all the interstices and be in good contact with the cast iron or cast steel shell, provided the babbitt itself has sufficient fluidity to enable it to penetrate the smallest spaces. From this solidifying point on, the babbitt will contract according to its coefficient of contraction. Now, if the coefficient of contraction of the babbitt were the same as that of the material out of which the shell is made (usually

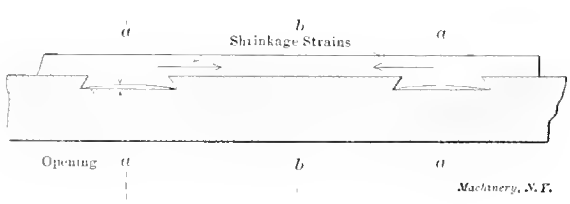

Fig. 5. Illustration of Shrinkage Strains produced by Unequal Distribution of Babbitt Metal.

cast iron or cast steel), and provided that the shell had acquired the same temperature as the babbitt, the shell and the babbitt liner would then contract equally, and a fairly good contact would result, and there would be nothing to set up counter strains during shrinkage. But, as the coefficient of contraction of almost all babbitt metals is approximately two to three times higher than that of cast iron or cast steel, a shrinkage or loosening of the babbitt liner from the shell must absolutely take place after the solidifying point of the babbitt is reached. Fig. 2 shows this contraction as it would appear if magnified. The fact that most bearings are "split" does not, of course, change this result. If the babbitt is secured in the shell by means of dove-tailed grooves, or other anchoring devices, so that the actnal visible contraction from the shell is lessened or minimized, then an unavoidable consequence of these grooves or other devices is *shrinkage strains*, set up while the babbitt cools down, as explained further on.

b. Shrinkage in an axial direction. With regard to shrinkage in the axial direction, it may be observed that the same results take place. Fig. 3 illustrates how the babbitt metal shrinks in a cast iron or cast steel shell in the axial direction, when there is no anchoring device employed. In Fig. 4 may

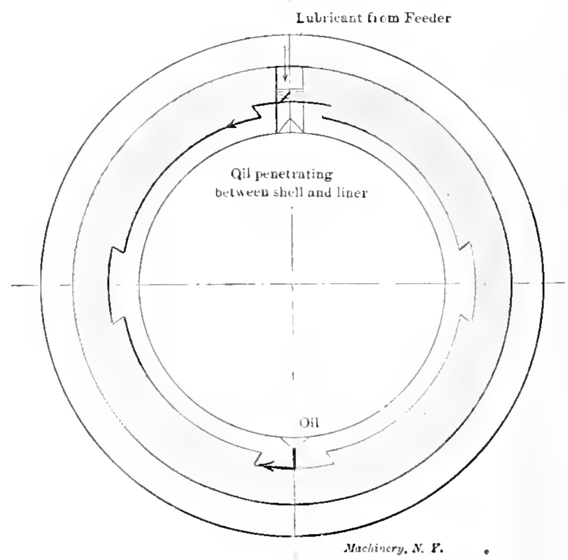

Fig. 6. Penetration of Oil between Shell and Liner.

be seen the old-fashioned dove-tailed groove construction, prohibiting an actual visible shrinkage, but causing shrinkage strains.

Shrinkage Strains Produced by an Unequal Distribution of Babbitt Metal Liner.

By referring to Fig. 5 it will be observed that the babbitt metal at *aa* is about twice as thick as at *bb*. The consequence is that, as the solidifying time of the greater mass *aa* is longer than that of the smaller mass *bb*, shrinkage strains are set up throughout the babbitt liner, which loosen it from the

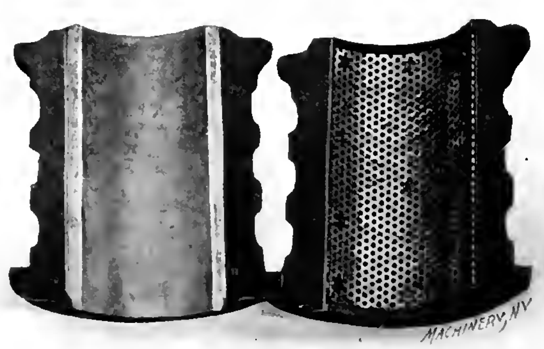

Fig. 7. Main Shaft Glyco Bearing for Large Gas Engine, Before and After Babbitting.

shell and have the tendency, in combination with the regular working pressures and shocks, to produce minute cracks in the liner.

Lack of Contact between Liner and Shell.

In a bearing shell, some parts of the liner are in close contact with the shell, as a result of careful pouring and the use of a properly-made babbitt metal, while other parts of the liner will not be in good contact with the shell, by reason of shrinkage and the formation of air bubbles and oxide gases, which latter are especially liable to be formed in babbitts containing copper. With the idea of filling up the hollow spaces between liner and shell, it is a quite general American practice, and an English one also, to peen or hammer the babbitt liner. The advisability of this treatment is, however, very qnestionable. By the peening process the air will simply

be driven from one point to another, and be forced into places where at first a good contact existed, thus destroying it. To secure a permanent and intimate contact between liner and shell by peening is impossible, on account of the elasticity of the liner material. When the hammer strikes the metal, a contact may be formed, but as soon as the force of the blow is gone, the metal will spring away more or less by reason of its elasticity. Furthermore, the babbitt metal becomes

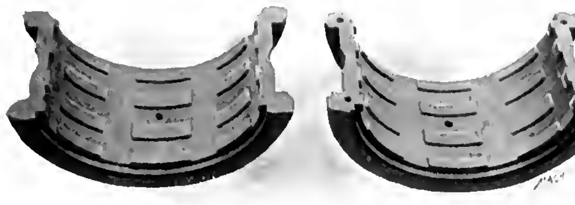

Fig. 8. Ordinary Babbitt Bearing Shell, showing Dove-tailed Anchoring Grooves

more brittle by peening, and its strength diminished; this has been proved by a number of tests made by the writer. Peening, unless performed with the utmost precaution, also produces minute cracks in the structure of the babbitt, which will constantly be enlarged by the regular working pressures. For these reasons, European continental practice has now practically abandoned the peening of babbitt metal liners. Therefore, in spite of good pouring, or peening, or dove-tailed grooves and other similar anchoring devices, the liners are in a greater or less degree loose in the shells.

The Lubricant Penetrating the Hollow Spaces.

When these bearings go into service, the hollow spaces between the liner and shell will gradually become impregnated with an oil film, from the lubricant employed, as shown in Fig. 6. Now, the coefficient of heat-conductivity of oil is only about 1/200th of that of an ordinary babbitt metal, or of cast iron. Therefore the warmth created in the liner by the working friction will not be conducted away to the shell, and thence to the engine frame, as quickly as though an intimate contact existed between shell and liner. The result is that the bearing readily becomes hot, because the babbitt metal liner retains, instead of throwing off, the heat. The regular working pressure also sets up an hydraulic pressure in the oil film, between the shell and the liner, which tends to produce breakages and cracks in the liner, as may sometimes be observed when removing bearings from gas engines, pumping engines and the like, subject to high pressures and shocks. A consequence of shocks is also that a liner which is somewhat loose will become distorted and "work"; this "working" produces additional friction and increased temperatures. All the facts mentioned above tend toward the one result, *viz:* the increasing of temperature in the bearings, even to the extent of melting down the babbitt liner.

From various tests made by the writer, the results of one may be given here. A bearing with a perfect contact between liner and shell was tested under a constant load of 400 pounds per square inch and a constant sliding speed of 480 feet per minute. The same bearing was again tested under the same conditions, but with the liner not in intimate contact with the shell. As the tests were necessarily made under a slightly varying atmospheric temperature, the difference between the actual bearing temperature and the room temperature was taken as the basis of each, and in the former case, the result was 60 degrees F while in the latter 85 degrees F. When such differences are obtained in a testing machine, under the best operating conditions, how much worse must be the influence of the slightest lack of contact under usual working conditions, such as we have them in steam engines, air compressors, pumps, gas engines, etc.!

Summing up the foregoing we may say that in most cases the direct causes of hot bearings are: A lack of contact between liner and shell caused, first, by shrinkage and careless treatment of the babbitt, and second, by shrinkage strains produced by an unequal distribution of the liner masses over the shell; the formation of an isolating oil film, together with its consequences; cracks or breakages in the liner produced as explained. The means of avoiding these troubles, and the principles of a good and safe bearing construction, must consequently be an absolutely intimate and homogeneous contact between liner and shell; an equal distribution of the liner over the shell; and a strengthening of the liner against the shocks and workiog pressures. If these conditions are faithfully carried out, many troubles and much expense may be avoided.

Skeleton Bearings.

The employment of the skeleton-bearing construction is a means for overcoming the foregoing difficulties. This is a

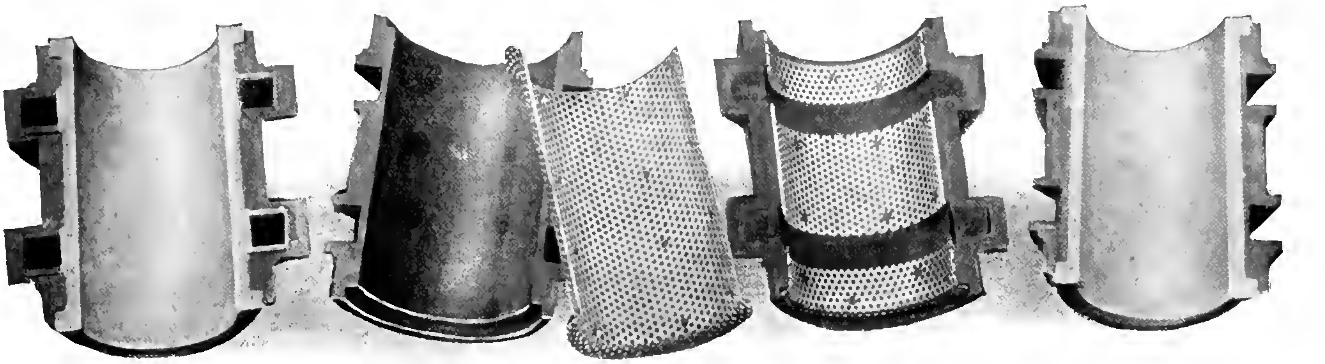

Fig. 9. Glyco Bearings of the Plain and Oil Ring Type, Before and After Babbitting.

bearing construction which has been used, and favorably commented upon, by European engineers, for several years past, and which is now being widely adopted by leading manufacturers of high speed and high pressure engines. In Fig. 7 is reproduced a main-shaft bearing of a large gas engine, constructed by a leading American manufacturer. The bearing is lined with Glyco bearing metal and the skeleton construction mentioned. The dimensions of the bearings are 8$\frac{1}{2}$ x 15$\frac{5}{8}$ inches. The skeleton consists of a No. 10 gage, soft steel perforated plate, thoroughly cleansed and tinned. The skeleton

Fig. 10. Large Bearing Shell and Glyco Liner.

is then fastened to the cast iron bearing shell by means of 5/16 inch countersunk screws. Glyco metal is then cast in and around it and fuses or solders together with the tinned skeleton. The skeleton being tightly pressed against, and fastened to, the shell by the countersunk screws, the whole forms one solid and homogeneous mass, consisting of shell, skeleton and babbitt, all in intimate contact. On account of the large number of small perforations in the skeleton, the Glyco metal is distributed uniformly over the whole surface

of the bearing shell, and shrinkage strains and hollow spaces are thus avoided. Peening is done away with, and furthermore, the strong, soft steel skeleton strengthens and supports the Glyco liner, just as iron does concrete, in our modern building construction, so that even the heaviest shocks will not break the Glyco liner. The skeleton thus not only prevents, in general, the breakage mentioned above, but also gives

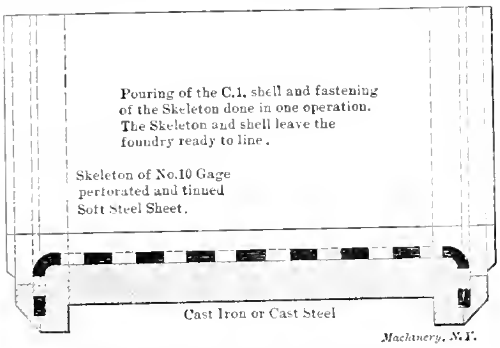

Fig. 11. Glyco Skeleton Cast Integrally with the Shell.

such strength to the babbitt liner that its thickness may be reduced, and economies as high as 50 per cent and more are reported.

On first sight the employment of a perforated skeleton sheet might seem to be a complication of construction, entailing additional expense, but quite apart from the saving by a reduction in thickness of the liner, the economies graphically illustrated in Figs. 8, 9 and 10 would offset any such expense, and may be explained as follows. Fig. 8 shows a bearing shell with dovetailed anchoring grooves; Figs. 9 and 10 show bearing shells, as designed for skeleton construction. The simplicity of the casting in the latter case, as compared with the former, is readily observed. The pattern for the former necessitates coreprints and the employment of core boxes. The pattern for the latter is perfectly plain, not requiring core-prints or core boxes, and the molding may be accomplished quickly. When the casting is made, the time-consuming process of cleaning or chiselling out dove-tailed grooves is also eliminated.

Another Simple Method of Fastening in the Skeletons.

Another method of securing the skeleton to the shell, as shown in Fig. 11, is employed with much success. Here the skeleton is integrally cast with the cast iron or cast steel shell, the skeleton having flanges which are cast into the flanges of the shell. In molding, the skeleton is put in the sand with the pattern. The perforations of the face of the skeleton are of course filled with sand, so that they may be left free. The skeleton cast integrally in this manner then fulfills its purpose, the same as when screwed in, and obviates the use of screws. The skeleton construction has been on the market in Europe for several years, and is patented in all countries.

* * *

In a consular report we find a note which throws some light upon the fact that it is not always the best business principle to appoint general agents in Europe, and then refuse to do business directly. The consul in question received a letter from a French dealer who stated, in substance: "I want ———'s goods, but they have a general agent at London, who has appointed Mr. ——— his general agent in Paris, who in turn has appointed Mr. ——— his agent in Lyon, and I have to pay all these people their commissions before I can commence to think of my own."

CRANE SIXTEEN-SPINDLE DRILL.

The multiple-spindle drill shown in Fig. 1 is an interesting special machine designed and built by the Crane Co., Chicago, Ill., for use in its manufacturing plant. It has 16 spindles, each driven by an independent motor; and still another independent motor is provided for the feed motion, thus giving the machine the unique distinction of having seventeen motors in all. But this is not, by any means, the only radical departure from the conventional forms of multiple-spindle drills. The machine was designed with the view of making each spindle produce to the full capacity possible with high-speed drills, and to be readily changed to any possible grouping of holes within its range. To facilitate changes, each motor and its drill spindle mechanism is mounted on an independent frame or base, which is not clamped down at all, but which depends on its weight and an over-hanging circular plate (for taking the upward thrust) to keep it in any set position.

The frames carrying the motors and drills rest upon a large circular plate *A*, Fig. 2, about 11 feet diameter. This plate is supported by two columns or uprights forming the frame of the machine. The raising of the motor and drill spindle frames by the upward thrust of the drills is prevented by the top plate *B*, which covers the range of lateral movement of

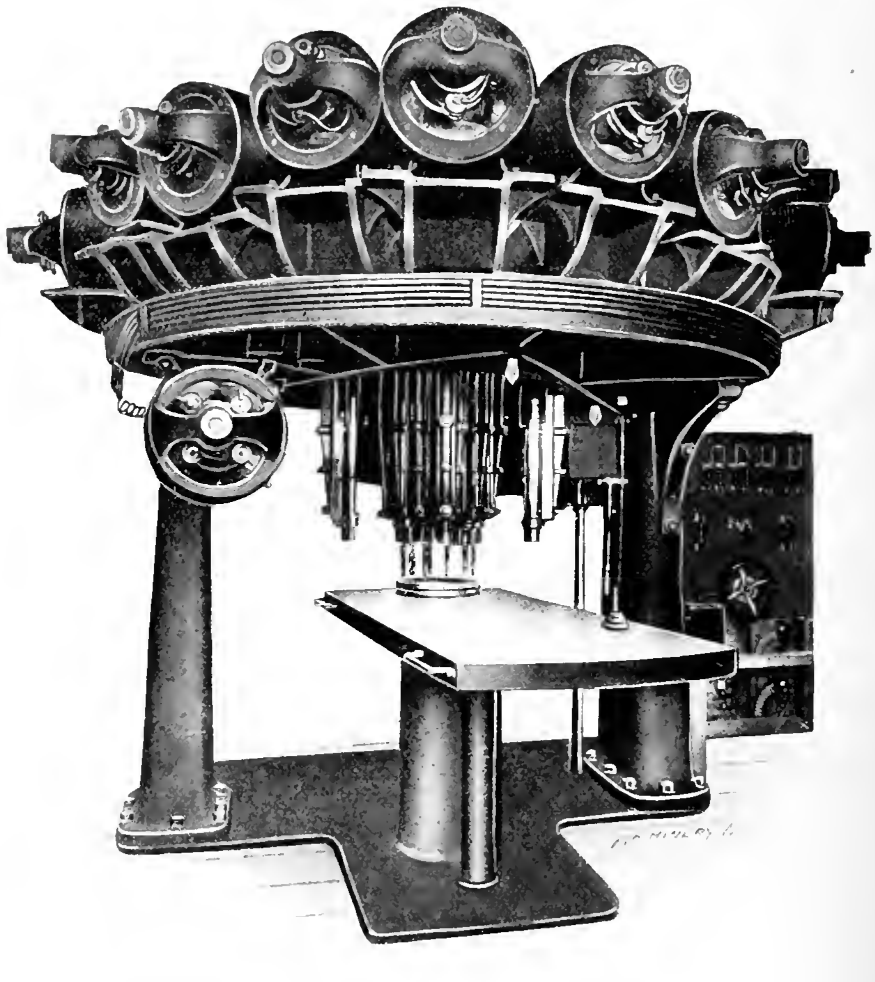

Fig. 1. Crane 16-spindle Drill, driven by Seventeen Variable Speed Motors.

the drills. It is suggested by the designing engineer that the plate *B* might be magnetized to hold the drills more firmly in place, but it has not been necessary to resort to any such expedient with the machine now in use in the Crane Co.'s shops. Thus it is apparent that all adjustments of this machine necessary to change for different classes of work are made without the use of wrenches, drifts or any sort of tool whatever. Only the hands of the operator are necessary. The motor bases are provided with small bearing wheels to facilitate these changes.

The drills may be set all to the same level in a few seconds simply by loosening the clamping nuts (see Fig. 1), holding the drill spindle guides. The drill spindles can be adjusted

to the minimum distance of 3⅛ inches between centers and to a circle of 36 inches maximum diameter. The maximum size drill that can be used is 1⅝ inch diameter.

Each drill spindle is driven through a sleeve coupling connecting the motor shaft and spindle through a pair of special bevel gears and a universal joint. There is no feed rigging attached to the drill spindle, the work table being fed up to the drills from beneath. The table upon which the work rests may be set from 2½ to 50 inches from the floor and the automatic feed covers the entire range of movement. The feed is driven by a variable-speed motor, and quick traversing

bottom of the spindle. This driver is inserted with the drill, and a slight backward turn prevents it from falling out, and brings it up against the feathers in the sleeve. A spiral spring is provided to hold the driver securely in place. The upward movement of the drill, due to thrust, is checked by a threaded nut fastened adjustably to the top of the drill. The thread on this nut and the internal thread of the sleeve are interrupted as is indicated in the cross-section views, this being done, of course, to save time when removing the drills for grinding and when adjusting them downward to compensate for the shortening due to wear.

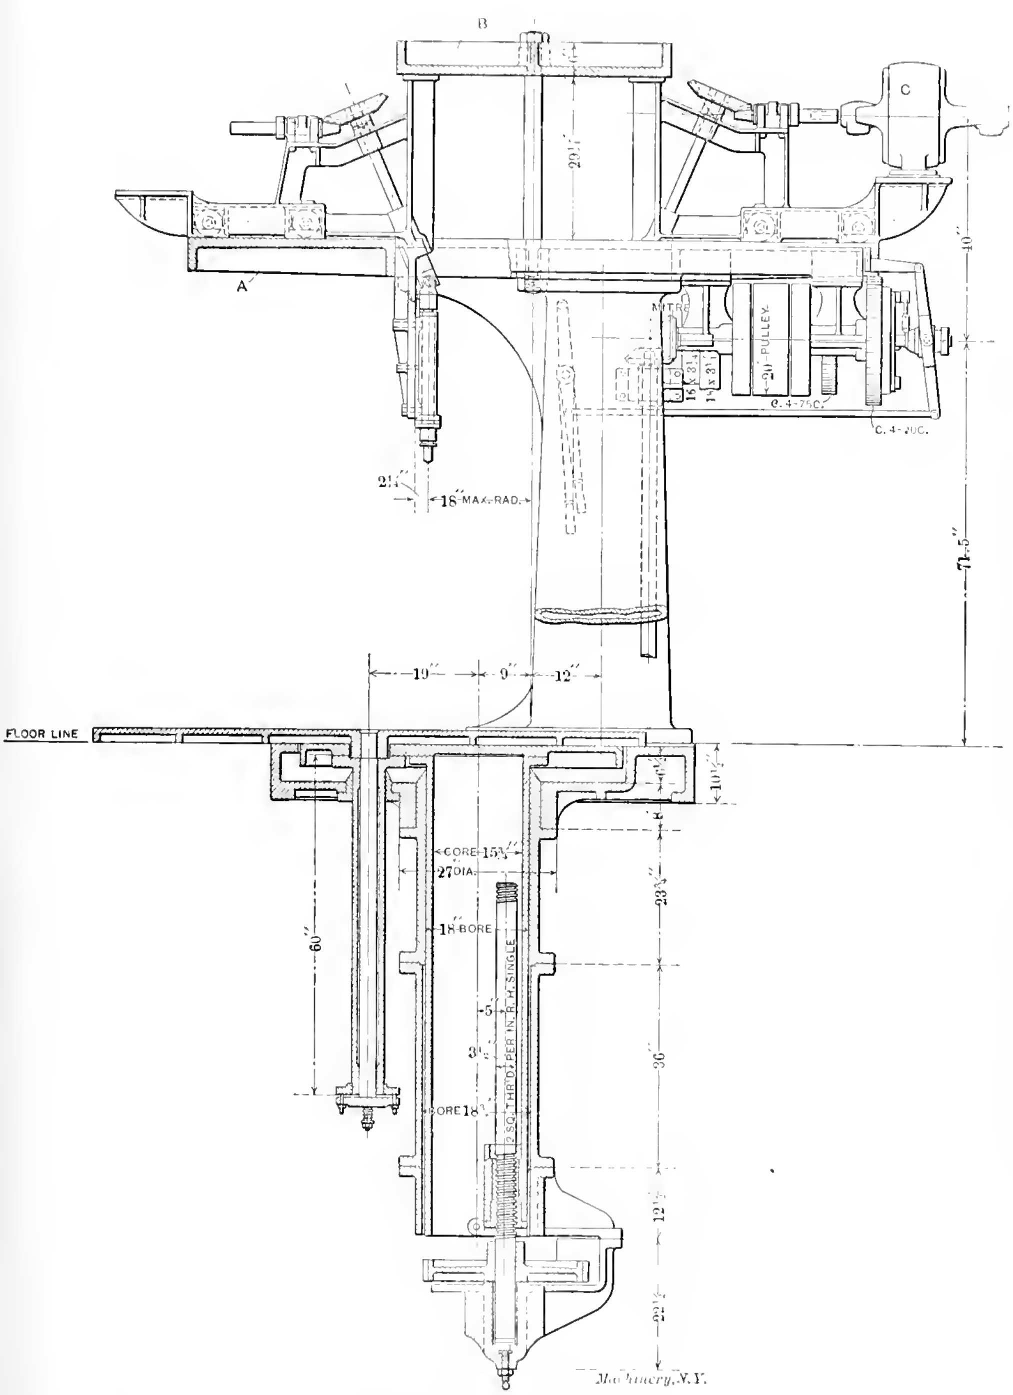

Fig. 2. Vertical Section of Crane 16-spindle Drill, showing Bearing and Thrust Plates, and Motor and Drill Spindle Connection.

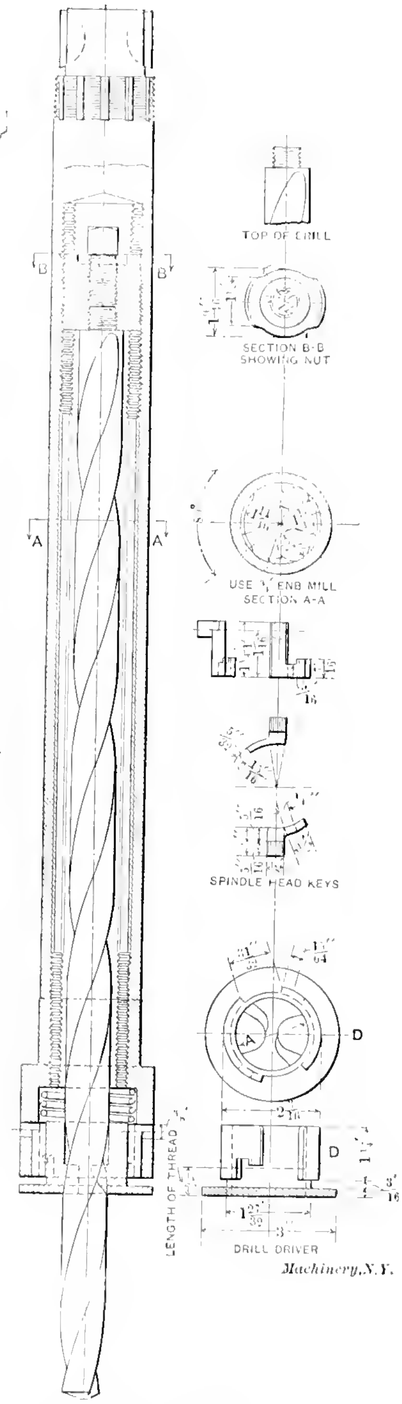

Fig. 3. Details of the Construction of Drill Spindle Sleeve.

movement is provided in both directions for adjusting the table to height. The table is pivoted at its center for facilitating changing the work. While a piece is being drilled upon one end, the other end projects beyond the upright frames where it is convenient for the operator to remove one just drilled and to replace it with another.

The twist drills used are without the usual shank, a short threaded end being provided instead. They are made 24 inches long and are used until there is only 2½ inches remaining in the socket. The drills are not driven from the shank end, but by a driver *D*, Fig. 3, fitting in the flutes at the

The flexibility of the arrangement is quite apparent. Any desired groupings within the capacity of the machine may be obtained, and spindles that are not required may remain idle, thereby avoiding needless consumption of power. Power is required only for the number of drills in use, whether it be one, two, or sixteen.

* * *

A Chicago company lately made for a large sawmill a leather belt which is supposed to be the largest ever manufactured. It is 7 feet wide, three ply in thickness, 114 feet long, and weighs 2,300 pounds.

REAMERS.—4.

ERIK OBERG.

Taper Reamers.

Taper reamers are used for reaming holes for standard taper pins, holes in taper sockets, and, of course, for all other cases where a correct tapered hole is required. In some cases roughing taper reamers are intended merely for removing metal, and the final finish of the work is of minor consideration. The reamers for standard taper pin holes are almost always finishing reamers, whereas for reaming taper sockets, and other work with large tapered holes, usually both roughing and finishing reamers are employed. The roughing reamer is simply intended to remove enough stock so that the finishing reamer can produce a smooth hole, true to size, without being exposed to excessive wear, and thus retain its correct size so much the longer.

Fig. 15. Roughing Taper Reamer.

Fig. 16. Finishing Taper Reamer.

Roughing Taper Reamers.

Roughing taper reamers, such as used for reaming Morse and Brown & Sharpe standard taper sockets are made exactly like the finishing reamers, except that they are made about 0.010 inch smaller in diameter, and are provided with a special groove cut like a thread all around the cutting edges, as shown in Fig. 15. This thread or groove breaks up the chip in the same manner as the nicks in the cutting edges of plain milling cutters. The thread is cut left-hand, with a tool similar to a square thread tool, but with the corners slightly rounded. The width of the tool should vary from about 1/32 inch for the smallest size reamer for Morse taper sockets, to 3/32 inch for the largest sizes. The depth of the groove should be slightly more than one-half of the width of the tool. After being hardened and drawn to a temperature of 370 degrees F., the roughing reamer should be ground with a somewhat greater clearance than the finishing reamer.

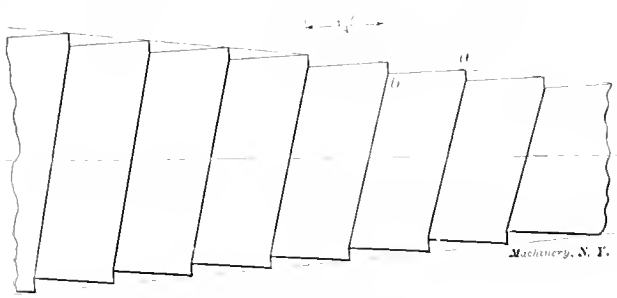

Fig. 17. Method of Making Steep Taper Roughing Reamer.

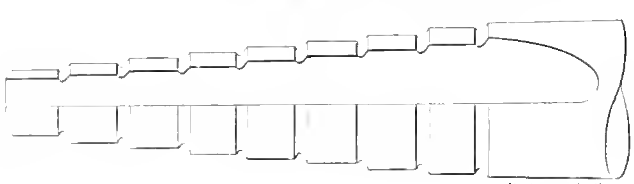

Fig. 18. Step Reamer.

The pitch of the thread should be from one-fifth inch for the smallest sizes of roughing taper reamers up to one-third inch for the largest sizes, that is, there will be from three to five threads per inch, according to size, along the cutting edge.

The cutting edges of roughing taper reamers are sometimes cut spiral. The spiral, or properly helix, may be a right-hand one in this case (on hand reamers, as mentioned in the August issue, the spiral must be left-hand), as there is no danger of the reamer drawing into the work too suddenly, on account of the taper. However, most manufacturers make both roughing and finishing reamers with straight flutes whenever there is not an exceptionally steep taper or a long tapered hole to be reamed. In such a case the roughing reamers are constructed on a different principle from the one just described. The reamer is turned somewhat over-size, and ground to the correct diameter desired before being fluted. It is then returned to the lathe, and a thread cut on the surface with a square-nosed tool, ¼ inch wide. The pitch of this thread is ¼ inch, and the depth such that the ground surface at the end of the cut nearest the end of the reamer is barely touched, as shown in Fig. 17. In this cut, the dash-dotted lines indicate the ground tool blank before the thread is cut, and the full lines the appearance of the blank with its thread. The thread itself is left-handed, and each step is slightly back-tapered, say 0.002 inch in the distance of ¼ inch, that is, the point *a* of each step is 0.002 inch further away from the axis of the reamer than the point *b*. After threading, the reamer is fluted with left-hand spiral flutes, the spiral being so selected that the angle which the cutting edges make with a plane through the axis of the reamer is 15 degrees. Some tool-makers also advocate an odd number of flutes for this class of reamers, but as long as the reamer is provided with spiral flutes, there seems to be no valid reason why an odd number of flutes would add any advantages.

10	9½	7	2½	0.578

Fig. 18 shows another form of roughing taper reamers for steep tapers. This form is known as a step reamer. As a matter of fact, this tool is a kind of multiple counterbore; each step together with the previous one forms a complete counterbore, the smaller step being the guide and the larger the body. All the cutting is done at the front end of each step. The cylindrical portion of the step should not be relieved, but it is preferable to slightly back-taper these portions the same as in the case of the threaded taper reamer. The flutes may be straight or spiral; if the latter, the same angle of spiral as mentioned previously should be selected. The number of the flutes for this kind of reamer is usually four.

Finishing Taper Reamers.

Finishing taper reamers, as shown in Fig. 16, are similar to ordinary hand reamers, except that the cutting edges taper. The flutes are almost always cut straight, but spiral flutes are

of advantage in porous metal or in work pierced crosswise by other holes or openings. The spiral should be right-handed, there being no tendency to draw the reamer into the hole on account of the taper of the hole.

Taper Pin Reamers.

Taper pin reamers, as mentioned, are intended for reaming holes for standard taper pins. The taper is ¼ inch per foot. The diameter of the small end of the reamer should be such that the reamer will project at least 1/16 inch, or, on larger sizes, ⅛ inch, through the hole reamed for the longest standard taper pin of the size in question. The length of the cutting edges should be enough longer than the longest pin to permit the reamer to be ground a number of times without being too small in diameter at the upper end of the flutes for the size pin for which it is intended.

In Table XIII are given the standard dimensions for taper pins as adopted by the Pratt & Whitney Co., and in Table XIV the dimensions for corresponding sizes of taper pin reamers. These reamers are provided with a square on the end of a shank for a tap wrench. The length of the square should be about one and one-half times the diameter of the shank. The size of the square should be three-fourths the diameter of the shank.

TABLE XV. DIMENSIONS OF REAMERS FOR MORSE STANDARD TAPERS.

No. of Morse Standard Taper.	Total Length of Reamer.	Length of Cutting Edges.	Length of Shank.	Diameter at Small End, Finishing Reamer.	Diameter at Small End, Roughing Reamer.	Taper per foot.

17	15	11	4	2.747	2.737	0.500
18	15½	11½	4	2.997	2.987	0.500

The number of flutes in taper pin reamers should be chosen as follows:

Number of Taper Pin Reamer.	Number of Flutes.
000000 — 00	4
0 — 7	6
8 — 10	8

Taper Reamers for Morse Standard Taper Sockets.

For reaming Morse standard taper sockets, two reamers are used, one for roughing and one for finishing, the construction of the former having already been described. The finishing reamer is made like the taper pin reamer, with the exception, of course, that the taper is made according to the Morse standard taper gages. This taper, as is well known, is different for the different sizes or numbers of Morse tapers, but is approximately ⅝ inch per foot. The square of these reamers should have a length equal to about the diameter of shank; the size of the square should be three-fourths the diameter of the shank. This leaves a small round on the corners of the square, which is desirable for the appearance of the tool as well as for the convenience of handling a tool without sharp corners. In Table XV are given the essential dimensions for these reamers. Morse tapers are the most extensively used of all standard tapers, and for twist drills this taper is used almost exclusively.

The number of flutes in roughing as well as finishing reamers should be as follows:

Reamer for Morse Taper Socket No.	No. of Flutes.	Reamer for Morse Taper Socket No.	No. of Flutes.
0—1	6	6	14
2—4	8	7	16
5	10		

Taper Reamers for Brown & Sharpe Standard Taper Sockets.

Roughing and finishing reamers are used in this case, the same as for Morse taper sockets. The taper is ½ inch per foot, except of taper No. 10, which is 0.5161 inch per foot. In Table XVI are given all the essential dimensions for these reamers. In the system of Brown & Sharpe taper shanks there are in certain cases a number of different lengths of taper sockets corresponding to the same number of taper, all, however, being of the same diameter at the small end. While the lengths of the sockets are different, the reamers can, of course, all be made the same for the same number of taper, inasmuch as the diameter at the small end is the same, and the only thing to consider is to make the length of the cutting edges of the reamer long enough for the longest or deepest taper socket of a particular size. In this case they will, of course, also answer the requirements for the shorter lengths. The Brown & Sharpe taper shanks are used mostly on shank end mills and T-slot cutters.

TABLE XVII. REAMERS FOR JARNO TAPERS.

No. of Jarno Taper.	Total Length of Reamer.	Length of Cutting Edge.	Length of Shank.	Diameter at Small End, Finishing Reamer.	Diameter at Small End, Roughing Reamer.
2	2⅝	1⅜	1¼	0.200	0.190
3	3½	2	1½	0.300	0.290
4	4⅜	2⅝	1¾	0.400	0.390
5	5¼	3¼	2	0.500	0.490

17	13⅜	9⅝	3¾	1.700	1.690
18	14	10⅛	3⅞	1.800	1.790
19	14⅝	10⅝	4	1.900	1.890
20	15¼	11⅛	4⅛	2.000	1.990

The number of flutes in roughing as well as finishing reamers should be as follows

Reamer for Brown & Sharpe Taper Socket No.	No. of Flutes.	Reamer for Brown & Sharpe Taper Socket No.	No. of Flutes.
1—5	6	13	12
6—10	8	14—15	14
11—12	10	16—18	16

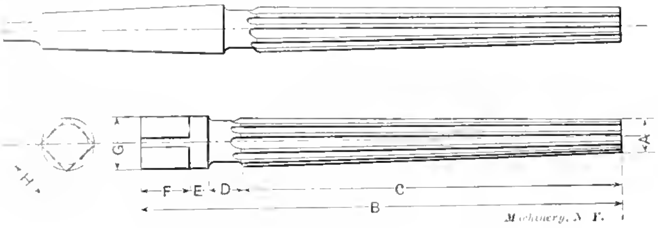
Jarno Taper Reamers.

The general characteristics of the Jarno taper reamers have been referred to in MACHINERY in the "How and Why" section of the April issue, and also in a short article entitled "Table of Jarno Tapers" in the June issue. In Table XVII are given the principal dimensions for reamers used to ream out Jarno taper sockets. The number of flutes in Jarno taper reamers should be as follows:

No. of Jarno Taper.	No. of Flutes.	No. of Jarno Taper.	No. of Flutes.
2	4	11—15	10
3—4	6	16—18	12
5—10	8	19—20	14

Locomotive Taper Reamers.

Taper reamers for locomotive work are generally made in two styles, with squared and tapered shanks, as shown in Figs. 19 and 20. While there are a great many different standards in use in locomotive railroad shops, the commonly accepted standard of taper for locomotive taper reamers is 1/16 inch per foot. In Table XVIII the principal dimensions for locomotive taper reamers with squared shanks, as commonly made, are given. The dimensions for the fluted part of those with taper shank, generally Morse taper, are exactly the same, the only difference being the over-all length, which, of course, is dependent upon the number of Morse taper shank used. The common practice is to use the following number of Morse taper shanks for the sizes given below:



Figs. 19 and 20. Locomotive Taper Reamers.

Sizes of Reamers	Number of Morse Taper Shank
From 1/4 to 9/16 inch	1
From 5/8 to 7/8 inch	2
From 15/16 to 1 3/16 inch	3
From 1 1/4 to 1 11/16 inch	4
From 1 3/4 to 2 inches	5

The number of flutes should be as follows:

Sizes of Reamers.	Number of Flutes.
From 1/4 to 1/2 inch	6
From 9/16 to 1⅛ inch	8
From 1 5/16 to 1¾ inch	10
From 1 13/16 to 2 inches	12

The length of the neck between the taper shank and the cutting portion of a reamer should be from ⅜ inch on the ¼-inch size to 1 inch on a 2-inch reamer. The size of these reamers is measured at the extreme small end of the fluted portion.

TABLE XVIII. DIMENSIONS OF LOCOMOTIVE TAPER REAMERS WITH SQUARED SHANK.

Diameter at Small End of Reamer.	Total Length.	Length of Flutes.	Length of Neck.	Length of Collar.	Length of Square.	Diameter of Collars	Size of Square.

* * *

The steam rock drill is a machine that is applied to a wide variety of uses. Not only is it very effective for its designed purposes—the drilling of blasting holes in rock and channeling—but not infrequently in some western mining camps it is mounted on a frame over an anvil and made to do duty as a steam hammer. Again, in building operations it is frequently put to other than its prime purpose. Not long ago we saw one being used on Broadway, New York, to drive sheet piling, which it did very effectively.

SOME BRITISH MACHINE TOOLS.*

JAMES VOSE.†

The firm of George Richards & Co., Ltd., Broadheath, Manchester, has for a number of years been prominent in several lines of machine tools, and the illustrations and particulars here presented will give a good idea of some of the leading specialties of the company. "Side" planers are built in a range of sizes dealing with work from 12 to 48 inches, and from 2 to 30 feet long. The advantages of this type include, of course, the comparatively small floor space occupied—the tool moving over the work, which is fixed—and facilities for handling awkward shaped pieces by the utilization of a pit in conjunction with the separately adjustable or removable tables. With the tables removed, and work fastened to the vertical platens, or apron plates, pieces up to 10 tons weight may be dealt with on a machine which planes 30 inches wide. The saddles are directly driven by screw, no gearing being used, the thrust of the screws being taken by roller bearings. The traversing arm may be fitted with one or more tool boxes, and if desired double arms may be fitted, each driven by separate screw, so that two distinct jobs may be dealt with at once, or one job set while the other is being tooled. The back shear of the bed is now made the guiding surface for the saddle, with distinct advantage in the reduction of friction, the ratio of length of saddle to width of guiding surface now being about 11 to 1. When both front and back surfaces acted as guides the ratio was about 2½ to 1. A modification of the machine for planing turbine frames consists of two beds with sliding saddles and cross head, the beds supported on legs, the whole mounted on a base-plate 15 inches deep. The cross-head is driven by two sets of driving pulleys through bevel gears, and carries two tool rams which may be swiveled to any angle, and have an automatic down feed of 30 inches. Work 10 feet wide may be planed across the top, or work 8 feet wide planed down the sides. Fig. 1 shows the 30-inch wide size machine, arranged with special swiveling slide for planing the angular bearings of engine beds, etc., no packing of the beds being required, they being placed flat on the machine tables or on the floor. As ordinarily arranged, the weight of such a machine to plane 15 feet long is 15 tons.

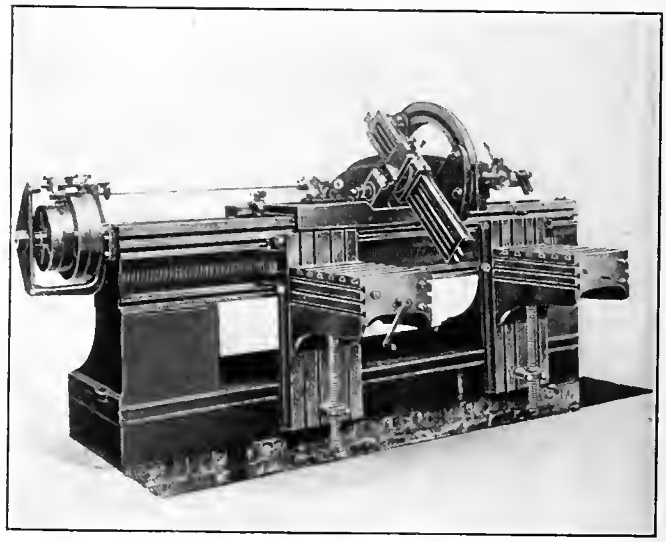

Fig. 1. Thirty-inch Richards Side Planer, with Special Swiveling Cross Rail.

Forty-inch Side Planer.

Fig. 2 represents the 40-inch wide size, to plane 12 feet long, but fitted with a special arm for deep vertical planing. The machine will plane 4 feet deep, the tool having a cross traverse of 3 inches only. The standard arm seen on the floor is interchangeable with the special one. Two tables, not shown, are provided for ordinary work, the users themselves providing a suitable bed plate in front of the machine to suit their own work. The vertical arm is supported at the

* The following articles dealing with machine tools of English design have previously been published in MACHINERY: Some Notes from an English Shop, September, 1897; Some English Lathes, September, 1904; A Vertical Miller and a Turret Lathe of English Design, March, 1907; Recent Development of British Machine Tool Industry, July, 1907.

† Address: 100 Ayres Road, Brooks Bar, Manchester, England.

bottom by a slide formed on the cross girth of the machine, and is fitted with a taper strip for adjustment.

Forty-eight-inch Boring and Turning Mill.

Fig. 3 illustrates the 48-inch special type of boring and turning mill for machining steel tires, or for heavy cutting generally, in hard material. It takes in 36 inches under the cross-slide and tool-holders, which have a down feed of 20 inches. The spur gear driving the table is 40 inches pitch diameter by 5 inches wide and 2 inches circular pitch. The spindle is 10 inches diameter, with a bearing 23 inches long. The section, Fig. 4, shows the special annular thrust bearing which runs in an oil bath, a gage fixed to the side of the machine indicating the amount of oil in the reservoir. A fixed stop in the cross-slide facilitates the setting of the square steel tool-bars when using double-sided boring cutters. One of the tool-bars is usually arranged to swivel. A patent spring balance (see MACHINERY, March and December, 1904, for description) dispenses with weight and chains and generally conduces to easy setting of work. The drive may either be by belt, gear box and friction back gear, or direct-connected variable speed motor and spur gearing. A positive feed gear box, placed on one side of the machine, gives 10 changes or rates of feed. The line of boring and turning mills built for general use under modern conditions ranges from 3 feet to 10 feet swing.

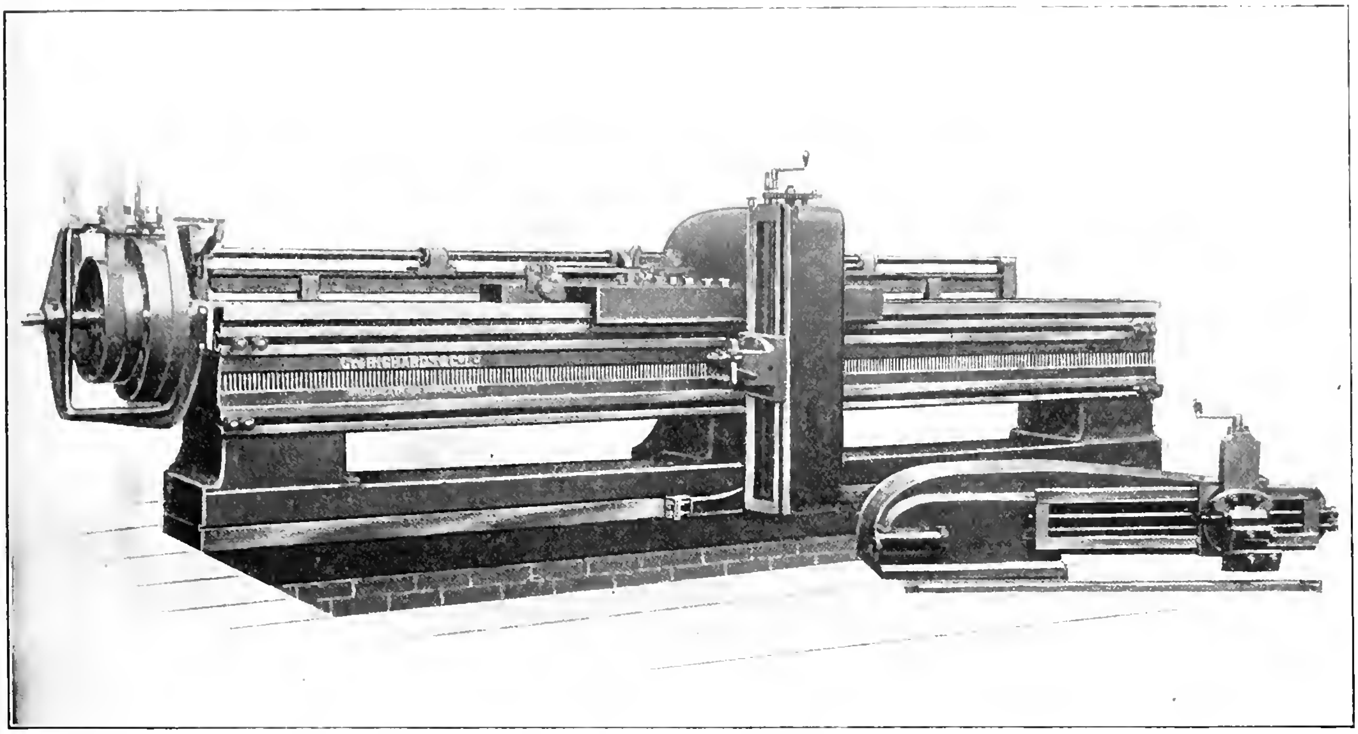

Fig. 2. Forty-inch Richards Side Planer, with Standard and Special Rails for Vertical and Horizontal Cuts.

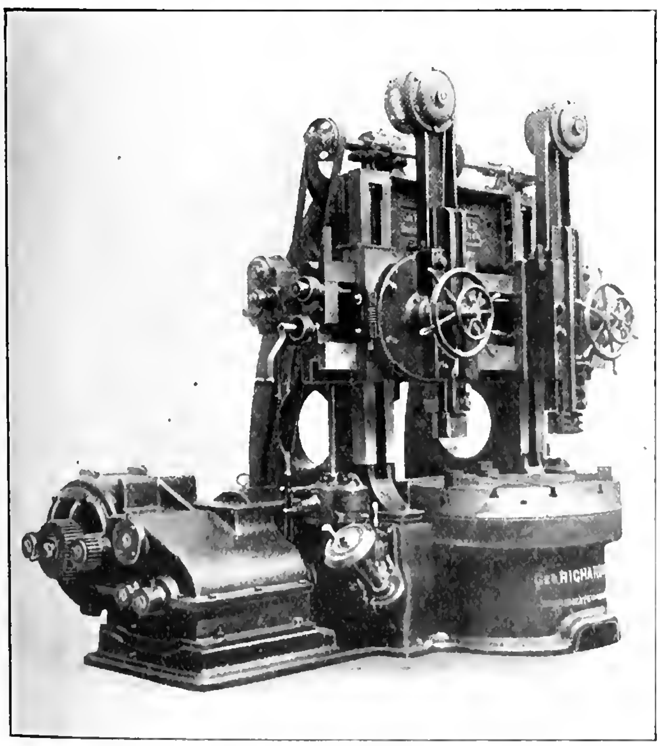

Fig. 3. Richards Forty-eight-inch Boring and Turning Mill.

Duplex Boring and Turning Mill.

Duplex boring and turning mills for work of small and medium diameter find an increasing field in British practice, and Fig. 5 illustrates a range of machines varying from 14 to 30 inches swing. Two machines are arranged right and left-hand and have their bases cast together. As regards their motions, they are entirely independent of each other, being driven by separate countershafts, the tables being started and stopped by individual levers in front. In the case of the 26 and 30-inch machines, the turret slides are arranged to swivel for turning or boring tapers. Four-jaw chuck tables with independent and reversible jaws are fitted on the 14- and 30-inch machines. The 26-inch machine is fitted optionally with plain or chuck tables.

General Line of Machine Tools Built.

Though the machines mentioned, in their ordinary and special forms, represent the types most prominently in demand, several other types of machine tools are also in regular call, amongst which may be mentioned direct belt driven radial drills in which bevel gears are dispensed with, the back gears being mounted on the spindle. These are made with arms from 3 feet to 6 feet radius, and are made with gear-box speed changes if desired, in place of cone drive. Completely automatic slot-drilling and keyway-cutting machines, producing keyways from the smallest sizes up to 3 feet 6 inches long and 2½ inches wide, are a well-established specialty. Horizontal boring machines with spindles from 2 to 4 inches diameter, and, generally, embodying approved modern conveniences in the way of wide range of speeds and feeds and easy handling of work, are another line in constant demand. A machine manufactured for many years, but recently also specially adapted for motor car work, is a vertical milling machine. For general work the tool is supplied with a plain rectangular table, or one with circular feed motion. It is built somewhat on the lines of a planing machine as regards the standards and cross rail; in one size the standards are 4 feet 4 inches apart, and in the other 6 feet apart, the table movements being 36 x 20 inches and 48 x 36 inches, respectively. Eight positive feed changes are provided. The spindle, with six speeds, is driven by worm and wheel sub-

merged in oil. For machining aluminum, and motor car details generally, duplex drive to the machine spindle is provided, the spindle at choice being driven by worm and wheel for the slower speeds, or by spiral gears for the higher ones, when using small cutters. The weights of the two sizes are $2\frac{1}{2}$ and $3\frac{1}{2}$ tons, respectively.

Band sawing machines, with unusually light 30 to 42-inch wheels, and "dimension" circular sawing machines, for patternmakers' use, in which smoothness of finish and accuracy to dimensions of the finished work have received special attention, are also manufactured.

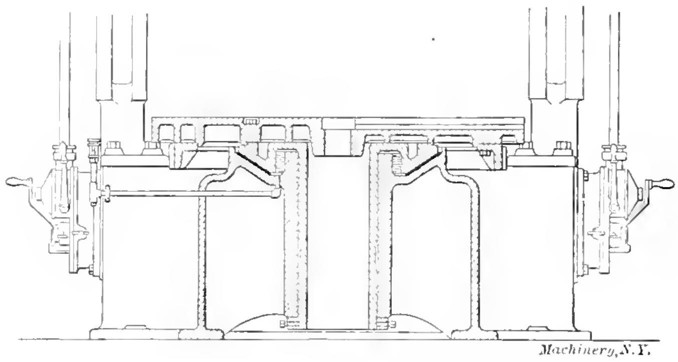

Fig. 4. Special Annular Thrust Bearing Oiling Device.

In another department air compressors for pressures up to 150 pounds per square inch are built in single, compound, duplex, horizontal, and vertical types, for a considerable range of duties. Sand blast apparatus for cleaning castings, removing scale from plates, etc., is another prominent line, also built in its own special section of the works, while still another department is concerned with the manufacture of pulleys and line shaft fittings generally, the pulleys having cast iron arms and steel rims.

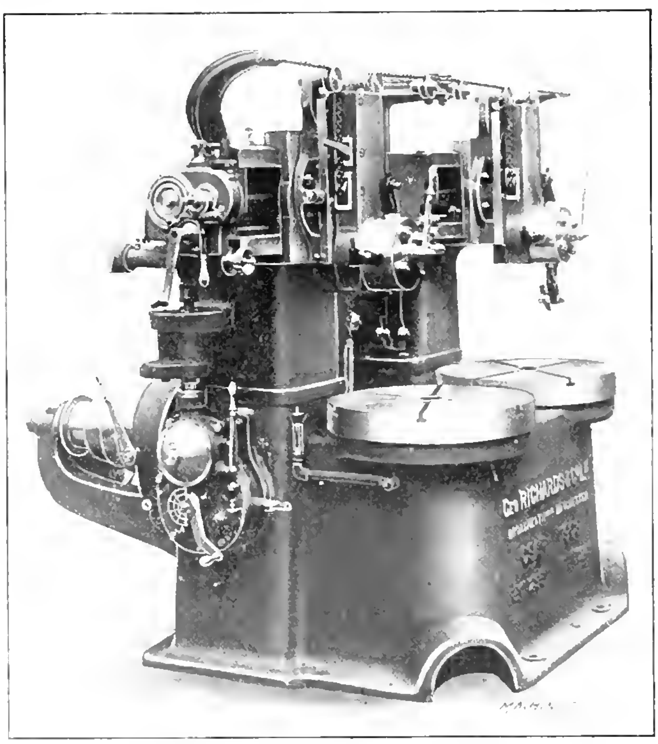

Fig 5. Richards Duplex Boring and Turning Mill.

All the departments are well employed and demonstrate that a reasonably wide range of specialties may be successfully dealt with by the same concern if the organization is arranged to assure consistent attention being given to the different units comprised, and overlapping at the same time avoided.

* * *

Figures recently prepared by a leading English firm for their own information showed that a weekly saving of more than \$2 was being effected in wages for every \$1 of running cost of the pneumatic plant, the latter including interest on capital outlay, depreciation, power charges and maintenance.

THE CONFIDENCES OF A MANUFACTURER.

The manufacturer in question is a real one—not a mythical personage, as might be imagined from the tenor of the ideas he expresses. Not only is he real, but cheerful and prosperous as well, and an advertiser in MACHINERY, though whether this is the cause or the effect of his cheerfulness and prosperity I am unable to say. We met in the course of a railroad journey and (drawn by some affinity in ideas, perhaps) drifted gradually into the conversation of which the gist is given in the following paragraphs.

My traveling companion is the financial and mechanical moving spirit in two manufacturing enterprises, of which one is an old-established firm of many years standing, while the other is a comparatively recent undertaking. Both of these enterprises are successful, though in the case of the latter one, at least, the nature of the product is such that much time and thought had to be expended in overcoming an initial prejudice on the part of the consumer. The most interesting part of the conversation related to his methods of treating his employes, and building up an organization of workmen and foremen into a solid and efficient body, reasonably satisfied as to their own conditions and prospects, and loyal to the firm which employs them.

In his more recent enterprise, especially, care and conscience are required on the part of the workmen. Errors may be made which are not easily detected by inspection, but which are quickly found by the purchaser. Owing to these requirements, my friend has come to the conclusion that for his business, at least, the matter of character is of far more importance than that of quickness of wit or "smartness." There is, of course, nothing new in this idea, and it is being constantly set forth by venerable life-insurance directors with close-cropped side-whiskers, as a rule of guidance for their younger brethren just starting in life. In the case of my friend, however, the conclusion seems to have been arrived at from a "strictly business" standpoint. It has been his experience that lack of technical ability in a workman can be made up—given a little time, a little assistance, and that perseverance which forms a part of the kind of character this man prefers.

In consequence of these ideas, when he finds that he needs a new man for a position of responsibility, his procedure is a little different, possibly, from that usually taken. He selects from among his workmen a man who has shown himself to be intelligent, rather inclined to reserve than otherwise, and above all, conscientious. Such a man might not at first thought seem to make as good boss-timber as a more confident, self-assertive workman. His way of introducing him to his new job, however, inspires these desirable qualities as fast as they are needed.

The most natural thing to do under the circumstances is to tack up a notice in the washroom saying, "On and after November 15 and until further notice, John Smith will be foreman of the Strap Hanger Department, etc." Instead of this my friend does not even tell the man himself that he has been promoted, let alone telling the men under him. Whenever a question arises as to the proper way to do a certain piece of work, the workman who makes the inquiry is told to ask John Smith about it, as the superintendent is busy. John Smith is told to answer these questions as well as he can, and ask help from above when he is unable to answer. Later on the work is given out to the men through John Smith. As time goes on, with occasional assistance, he gradually and naturally assumes more and more authority, and attains to greater and greater self-confidence. In fact the man grows with his position. If it had been suddenly thrust on him at the beginning, the chances are that his self-distrust would have seriously handicapped him, and perhaps also the workmen would not have felt that he was just the kind of man they would have picked out for the position. One of the qualities insisted on is that of reserve. This does not mean grouchiness or conceit, but simply the quality which keeps him just enough removed from his neighbors to prevent them from too easily finding out the weak points in his character.

The commercial value of conscience is shown particularly

in this man's business. There enters into his product a certain part made of tool steel, which has to be manufactured in large quantities. The functions of this part are vital, and the value of the product depends absolutely upon its reliability. The heat treatment given it is especially important. Made in large quantities, as it is, it is necessary to use wholesale methods. In annealing, the pieces are packed into the furnace in a certain unvarying way, subjected to a definitely determined degree of heat for a predetermined time, with fuel and air of unvarying composition; the manner and time of cooling is also uniform. The same definiteness is followed in the hardening process. It will be seen that the same conditions can be repeated absolutely day after day, so that the same results should be obtained day after day—provided that the quality of the steel used is unvarying. I asked him what steel he used, and where he obtained it. He gave me the name of an English maker. "Can they not make as good steel in this country?" I asked. "They know as much, and perhaps more, about making good steel here than they do in England, or anywhere in Europe, so there is no doubt that they can—but they don't. This question of 'care and conscience' enters into the matter too much. The president, treasurer, and chairman of the board of directors of an

". . . to tack up a notice in the wash-room. . "

American steel company may have all the will in the world to make steel of the uniform quality I require, but unless there is a conscientiousness of a high order permeating the whole force, from the highest clear down to the workmen in immediate contact with the metal, some of the hundred-and-one trifles that go to make up perfection in the matter of steel making will be slighted, and the product will show it. American steel does sometimes show this slighting carelessness.

My friend considers it important to have the workmen feel at home in the shop. For instance, if a workman has come there from some other shop, far or near, and proves to be a careful and skillful man, the proprietor feels that he would like to have other men of the same kind, acquaintances of his, working there with him. To this end, if it comes directly or indirectly to his ears that the new man has considerable to say about what "Henry Higgins" used to say and do in the old shop, without letting this man know why or how it was done, the foreman will approach him some day and inquire if he knows of a good workman for the department he is engaged in. "The firm is in need of men of about your kind, and we thought perhaps you might know of some one in the shop you came from who would make a good workman for us." "Sure," says he, "there is Henry Higgins," and so Henry Higgins comes. With the men as well acquainted with each other as they are when the force is collected in this way, there is much less shifting and changing of the force than occurs in shops where no attention is given to matters of this kind.

This proprietor expressed the condition of his shop as being "unbalanced." It is generally the aim to have just enough men in each department of a factory to do the work of that department as fast as it is sent there from the previous one, so that the various operations all move in unison, and the work goes through the shop in a steady stream. Such a shop would be called "balanced." The work of this business, however, is so dependent on getting workmen of the right kind, that the proprietor feels this matter to be of more importance than steady, even production; so whenever a good man is found, he is put to work, even though the department he is placed in piles the work up ahead of the next in order. This, however, acts as a stimulus on the next department, which in turn has to scratch around for more help—and so it goes throughout the shop, there being thus a continual impetus to increase the working force. This unbalanced condition may be likened to the process of walking, which has been described as "continued falling," the body losing the balance at each step, the putting out of the foot saving the man from a tumble, and advancing him by another yard at the same time.

The most startling thing about this manufacturer was the fact that he was an ardent believer in the eight-hour day. "If we cannot shorten to at least eight the hours of what in many lines of work must be more or less drudgery," said he, "then the wonderful improvements in machines and processes which have been made in the last few decades have failed of any useful effect." He is not running his own plant on the eight-hour day, by any means. As conditions are, it would not be quite as profitable as he could wish; and besides that, he believes it unwise to go too far ahead of the procession in a matter of this kind. He has the purpose steadily in view, however, of reducing the hours of labor in his shops to the figure given as fast as the improvements he is introducing will make it profitable, and as fast as the spread of the idea of shorter working hours among other shops makes it advisable.

There are some of these ideas, of course, which my friend has never confided to his workmen. The writer repeats these ideas in the strictest confidence, and earnestly requests his readers to take care that they spread no further. R. E. F.

* * *

FLY-WHEELS FOR PLANERS.

In the *Journal of the Worcester Polytechnic Institute*, Mr. H. P. Fairfield describes a series of tests undertaken to learn something of the conditions which obtain when an induction motor is used to furnish the power to drive a planer with and without a fly-wheel. The tests were made with a 10 horsepower motor driving a 36 x 36-inch x 10-foot planer. The object of the tests was to determine what would be the effect upon the power consumed by changing the length of stroke, and by the use of a fly-wheel. In order to keep the weight and diameter of the fly-wheel as small as possible, it was mounted on the shaft having the highest rotating speed, in this case on the motor shaft itself. The design of the fly-wheel was sufficient to store energy to take care of the shock of reversal without materially changing the speed of the motor. The results of the tests show that on a planer of the capacity of the one tested, at one-half stroke, or 5 feet in length, with no fly-wheel, the current consumption was 1.85 K. W. hour. With a 10-foot stroke, without fly-wheel, the consumption was 1.63 K. W. hour. For the same length of strokes with a fly-wheel the consumption was 1.3 and 1.24 K. W. hour, respectively. In other words, without the fly-wheel the long stroke required 12 per cent less power than the short stroke; with the fly-wheel, the short stroke was performed with 29.5 per cent less power, and the long stroke with 24 per cent less than without the fly-wheel. The fly-wheel was responsible for the greatest saving in power, and the saving gained by grouping the work for a maximum length of stroke was comparatively small as regards power. Another advantage in the use of the fly-wheel was the faster average rate of production due to the absence of slowdowns and tardy reversals. In some shops this would outweigh the power saving in importance. The tests incidentally displayed the value of electric drive when investigating machine performance; with belt drive from a line shaft it would have been difficult to measure the power consumed.

INCREASING THE BOILER CAPACITY.

GEORGE P. PEARCE.*

The article in the August issue, engineering edition, on possible increase in boiler capacity prompts me to point out where a considerable increase in capacity could easily be obtained in many of the mills and factories throughout the country without any expensive equipment at all. As a mechanical engineer, I have been brought into contact with a great variety of power installations, and I should estimate that eight out of every ten of the smaller, say up to 300 H.P., and many of the larger, installations are operated in a very unsatisfactory and unprofitable manner. The boilers have the capacity, but they are run under such miserable conditions that only about 40 to 60 per cent of their rated power can be obtained, when a little "know how" and a comparatively small expense, would easily and safely allow these boilers to be run up to 120 per cent or more, of their rated capacity.

The other day I was called to a small boiler house and asked if there was any way to avoid the purchase of a second boiler, as the one they had did not give enough steam. The boiler was in good shape and was fired nicely, but I noticed the fire did not burn as briskly as it ought to, although the damper was wide open. I stepped outside and looked at the stack; there was the trouble, a miserable 25-foot sheet iron affair with a great dint in one side on account of having blown down several years ago. It was also of smaller diameter than it should be even for a 60-foot stack. "Cut out the dint and add 40 feet to the stack, and you will get all the steam you can handle"—and they did.

"Come to Brown's mill at your earliest and see what is the matter with the power," read a letter one morning. When I arrived there I found that they had just put in some new machinery, and although everything would start up all right in the morning, yet about 10 A. M. the engine would begin to slow down to about two-thirds speed; the same thing also happened in the afternoon, and no matter how the engineer tried he could not get the steam up. "Boilers, again," I said, and we went into the boiler room. There was a nice brisk fire and a good 60-foot stack. This was about 8 A. M. I decided to stay around and wait for the power to drop. I noticed the coal was a poor grade of bituminous, containing a large quantity of dross. Pretty soon one side of the fire began to lose briskness and appear as though the draft was poor. I picked up the scraper and cleared part of a grate bar; there was the "hoodoo," a fine herring bone grate, designed for burning rice coal, the bars of which were becoming covered with a glass-like layer of dross which the engineer could not cut off with the slice bar without leaving the doors open long enough to lose steam. He had thus been getting along the best he could until noon hour, when he would clean his fires and "bar" most of the dross off. Of course the same thing happened in the afternoons. A first-class shaking grate completely cured all trouble here.

Jones had trouble with his boilers. He had two boilers and five engines, and he could not get a sufficient amount of steam. He had a good, well designed boiler-house, evidently equipped by a man who knew the business, so there was nothing wrong there. He was evidently getting plenty of steam and certainly was burning lots of coal. I looked at his engines—small slide valve affairs speeded up to the limit, pounding and rattling around as though every bearing had 1/8 inch wear that needed taking up. I thought I would indicate one, but found it had never been tapped for indicator connections, so I climbed out on the roof to have a look at the exhausts. There was only one exhaust head connected by a tee to two exhaust lines; three engines were on one line and two on the other. The exhaust steam from one line was charging head-on into the exhaust from the other; the exhaust pipes were much too small, and so was the exhaust head. I found out afterwards that only two engines were originally used, and three more had been added on to the old lines. I borrowed the steam gage from the boiler and attached it to one of the exhaust pipes; it showed between 12 and 15 pounds. I also noticed that great quantities of hot water were used for soaking and washing purposes. This was heated with live steam. Upon investigation, it proved that a very small quantity of oil in this water would not be harmful, so I started in to make a few changes. First, two new larger exhaust lines were put in, the one from the two engines going to the old exhaust head, and the one from the three engines discharging into a new head. An automatic back pressure valve was placed on each line and set to three pounds. The engines were all equipped with automatic positive feed lubricators, which I set to feed about 1½ pint per week, or about 1-10 of what was going through the old sight feeds. Then the exhaust steam was connected to the large water heating tanks. These changes alone made a great saving in steam, it now only being necessary to lightly fire the boilers. At the first opportunity I had the engines thoroughly lined up and rebabbitted, and at the same time had them drilled for indicator connections; then I carefully set the valves. This, combined with the lining up and overhauling, reduced the steam consumption so much that one boiler could easily be forced to do all the work. These are only a few instances where considerable expense was saved by proper attention to what may have appeared to be small details.

Let me advise all who are considering the installing of more boilers to carefully go over every detail of their present plant. See that the air spaces in the grate bars are correct; see that the fireman keeps his fires clean, fires evenly, and at regular intervals. Examine the bridge wall and see that it is not built too high or covered with a thick layer of soot; see that the side walls do not allow air to leak in; see that the combustion chamber is clear and the flues regularly kept clean. Next get inside the boilers and see how much scale is round the flues and plates. Be sure that the steam line gets only dry steam. Test the draft, and if poor, measure the stack for length and area and make it right. Look up the feed-water lines, and if you are using an exhaust feed-water heater, see if it is delivering water to the boiler at least 200 degrees F. If not, find out what is the trouble; perhaps the pipes are so choked up with scale that the water has to go through with considerable velocity, thus not being in the heater long enough to absorb sufficient heat. The water is also insulated to a considerable extent by the scale. Then again the drip pipe may not be taking the condensation away fast enough, and the heater be partly filled with cool water. If you have not got a feed-water heater, get one, or make one; a barrel and some old pipe will do. If you now have got the boilers in good shape, and they are generating as much steam as boilers of that size can be expected to do, follow up what is being done with the steam. When did you have the engines indicated last? Are they running up to their full economy? Where is the exhaust steam going? Are you using live steam anywhere, where exhaust would do? Do not say you cannot use the exhaust, because it contains oil; a good oil separator will remove that. Remember exhaust steam is condensed and used for artificial ice—you don't taste oil there. Go over the steam traps and look for leaks. I know of cases where large steam traps have been blowing steam into a sewer for months before the loss was discovered. Also look over the steam lines and see that they are thoroughly protected against condensation. Then, after going over every detail in this manner, if you still find the steam supply insufficient, it is time to start considering an extra boiler. I would warn superintendents against placing too much reliance upon the boiler tests run by the engineer, as he naturally wants to show good results, and so gets conditions that are not every day conditions while running the test.

* * *

A condition of general prosperity in commercial and industrial lines in Cincinnati during the year 1906 is indicated by the annual report of C. B. Murray, of the Cincinnati Chamber of Commerce. The value of machinery, machine tools, etc., manufactured during the year is placed at $18,000,000. The aggregate value of the output of large and small factories of the city and immediate vicinity is estimated at approximately $345,000,000, compared with the preceding year's estimate of $330,000,000.

ITEMS OF MECHANICAL INTEREST.

NEW TYPE OF VARIABLE SPEED MOTOR.

It is well known that variations in the speed of an electric motor are made possible by varying the amount of current passing through the field winding. This variation is obtained by introducing a resistance in series with the shunt field, or by diverting some of the current in the series field through by-pass in the shape of a resistance. A new type of variable speed motor, described by L. Torda in the *Electrician*, has been brought out by the Morris Hawkins Co.,

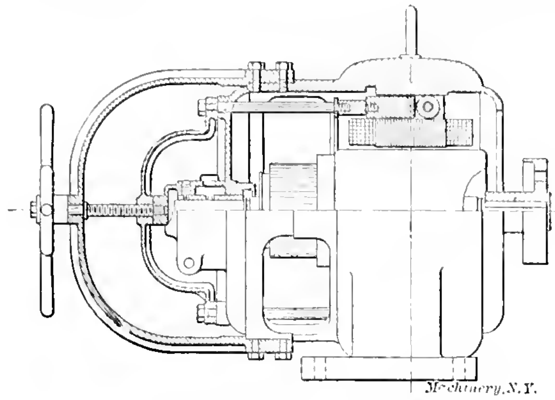

Fig. 1. New Type of Variable Speed Motor.

(address not given), in which a part of the magnet core is withdrawn in an axial direction. This is clearly shown in Fig. 1, where the machine is represented partly in section, also showing the hand-wheel and screw for withdrawing the core. The hand-wheel is mounted outside the end bracket at the commutator end of the machine. In Fig. 2 a diagram of the motor is shown, the armature and end brackets being removed in order to show the air gaps *A* formed by the withdrawal of the magnet core. This machine promises to be a very useful type for machine tool work, where there is a rapidly growing demand for a reliable and easily adjustable variable speed motor. There has been for some time in use in this country another type of variable speed motor working on a similar principle. In this, the Stow motor, however, a portion of the field magnet iron is withdrawn radially instead of axially. (See MACHINERY, December, 1904.) This, while being equally efficient a means for speed variation, does not, perhaps, permit of as simple design as does the motor mentioned.

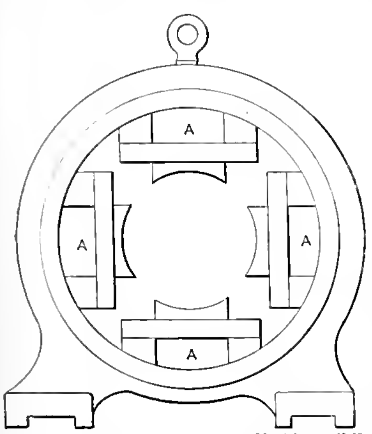

Fig. 2. Diagram showing Air Gaps formed by withdrawal of the Magnet Core.

THE STRESSES IN SCREW THREADS.

In the last report of the British Engine, Boiler and Electrical Insurance Company reference is made to the stresses in threaded bolts, and a graphical presentation of the subject is made, which clearly shows the effect of the difference in lead in bolt and nut upon the stresses in the thread. The difference in lead between the thread on the bolt and in the nut is one that is difficult to overcome. In fact, very few nuts have the same pitch as the bolts they are supposed to fit. The pressure between the threads of the nut and the bolt is therefore, generally, not the same on every thread. If the lead of the thread of the screw is longer than the lead of the nut, the stress will be concentrated on the lowest thread, but if the lead of the thread in the nut is longer than the lead of the bolt, the stress is greatest on the top thread. If the lead of the screw and in the nut be exactly equal, the stresses will be equally distributed. The cut shows in a clear manner the way in which the stresses are distributed in the three cases. It is evident that the risk of stripping the threads is far greater in cases where the lead of screw and nut differ, as there the stresses will be concentrated on one thread, and the threads are stripped or sheared off one by one. The danger of breaking the bolt is also

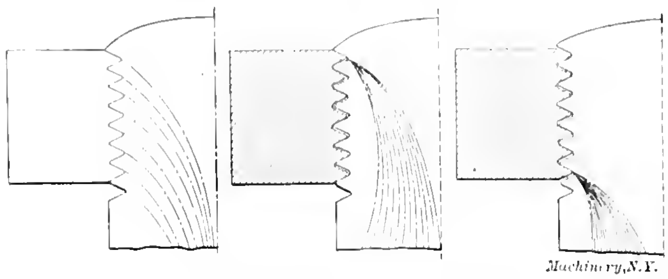

Diagram of Stresses in Screw Threads.

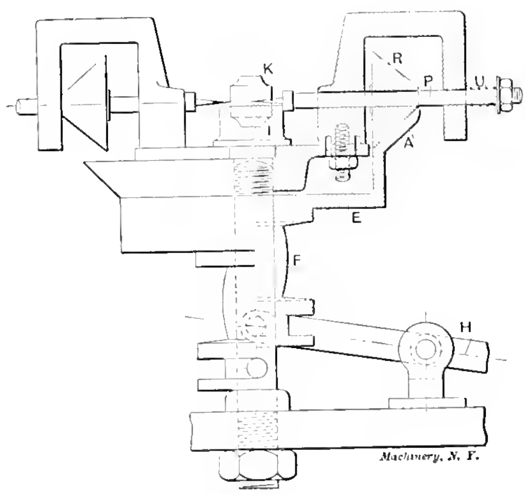
greater in that case, because, if the threads are strong enough to withstand stripping, then the whole force of tightening the nut will be applied on one thread, in the bottom of which a fracture is then the more easily started.

MULTI-SPINDLE DRILL WITH THE AXES OF THE DRILL SPINDLES ARRANGED RADIALLY.

In the *Zeitschrift für Werkzeugmaschinen und Werkzeuge* is shown a device for drilling simultaneously a number of holes radially in a piece of work. The work *K* is held in the collet *I*. The device is driven by a belt on pulley *F*, which is cast in one piece with a friction driver *E*. The pulley *F* with the friction driver *E* is raised up by means of lever *H* to engage with the friction rollers *R*, located on the drill spindles. By continued pressure on lever *H* the friction rollers are pressed inward against the action of springs *U*, and feed the drills into the work. When the pressure on lever *H* is released, the friction driver *E* and pulley *F* will move downward, and the springs *U* will move the drill spindles backwards, pulling the drills out from the drilled holes. In the cut, the one-half of the device which is sectioned shows the friction driver in engagement with the rollers *R* and the spindles fed in full depth, while the other half, not



Multiple-spindle Drill with Axes of Drill Spindles Radially Arranged.

sectioned, shows the spindles withdrawn. The device may, of course, be applied to reaming operations also, and in the cut the device is used for reaming small tapered holes.

[It is evident that the device, as shown, would not be of great practical value, if not somewhat modified in its design, because the surfaces in contact at *A*, being conical, are too wide for producing a good rolling action. A great deal of frictional resistance will be the result in the design shown, on account of the great variation in surface speeds between the outer and inner edges of the roller *R*. If the face of the driver *E* is less wide a better action will result. But even then the speed of the drill will vary greatly as the drill is fed into the work, depending upon that the driver will engage first with the largest and lastly with the smallest diameter of the friction roller, the speed thus increasing as the drill is fed inward.—EDITOR.]

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

49-55 LAFAYETTE STREET, CORNER OF LEONARD,
NEW YORK CITY.

The receipt of a subscription is acknowledged by sending the current issue. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

NOVEMBER, 1907.

PAID CIRCULATION FOR OCTOBER, 1907, 24,007 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

THE FRENCH MACHINE TOOL TRADE.

The Marquis de Dion, of the Dion-Bouton Co., in a late interview stated that without the American machine tools which have been imported during the past few years, the automobile trade of France would practically not exist to-day; but the recent progress made by European machine tool builders has materially changed conditions and affected American trade, and now the French as well as all European automobile builders can purchase almost everything they need in Germany and England, and to some extent in France, at prices generally below those quoted for American tools, although European manufacturers still look to America for ingenious and advanced ideas in machine design which will still further reduce the cost of production and enable them to manufacture higher grades of cars at a lower cost.

It is unfortunate that our manufacturers have been obliged in a way to neglect the French trade during the past two or three years. They have largely lost the benefits which should have come from their exhibits at the Paris Exposition in 1900, and it will be an uphill struggle against German tools sold at much lower prices than we meet, including delivery on the Continent. It is perhaps not generally known that German tool manufacturers receive an allowance from their Government on all machinery sales for export, so that American builders are not only handicapped by our tariff regulations and the high cost of labor and material, but have to meet the —in effect—subsidized German manufacturers when competing for French trade.

* * *

UNIT SYSTEM OF MACHINE DESIGN.

The new vertical spindle milling machine, shown in the "New Machinery and Tools" section of this issue, is a good example of the use of the so-called unit system of machine design. By the unit system we mean assemblages of shafts, gears, clutches, etc., mounted in separate frames or casings, each, when assembled, being a mechanism independent of the support afforded by the main frame. The idea is an old one, the first example probably being the engine lathe head-stock, which almost invariably is built independent of the bed. It has been employed in other examples of machine tool construction to considerable extent, but like some other good things the idea has not been developed as much as it might profitably be, in our opinion.

The gear box for speed or feed change, the lathe apron, lathe head-stock, and many similar parts of machine tools are familiar examples which lend themselves admirably to this plan of design, but can it not be carried further? Not only can the manufacture be standardized more readily for a certain machine, but the design of new sizes, or of entirely different machines, often can be made much quicker and at far less cost by utilizing units of other machines.

The idea is especially worthy of the serious consideration of special machine tool builders; as, for example, of planer type milling machines, horizontal boring machines and other tools, which in the larger sizes are quite commonly modified to suit the individual customer. The cost of designing, of pattern work, and of the shop system of construction that must be followed, makes the building of special machinery much more costly than that of a regular product, of course; but if groups of mechanisms could be standardized and assembled in the various designs, it would considerably facilitate the production, and to an extent reduce the cost.

* * *

MOTOR-DRIVEN MACHINE TOOLS.

An editorial investigation of the proportion of machine tools equipped with individual motor drive, now being put out by the builders, has resulted in some interesting facts. The statement was published recently in a monthly contemporary that 70 per cent of the output of one large machinery house was motor-driven and about 50 per cent of another was so equipped. This appears to be an over-estimate so far as the total is concerned. The real situation seems to be about as follows:

Planer type milling machines, horizontal boring machines, gun lathes, planers 6 x 6 feet and larger, big boring mills, large swing engine lathes, heavy radial drills, and machine tools in general, designated by that vague and indefinite term "heavy," are equipped by the builders for individual motor drive to about 50 per cent of the total output, but on light machine tools the proportion of motor drive is much smaller. One well-known concern building knee-type milling machines states that only 1.2 per cent of its machines is fitted with the motor drive. Another large concern building engine lathes states that from 4 to 10 per cent of engine lathes of 18-inch swing and under are so equipped, and on the larger sizes up to 36 inches the proportion fitted with motor drive runs from 11 up to 40 per cent. The still larger sizes (42 and 48-inch) reported were all fitted with motor drive. In the boring mill field one concern reports that out of 500 mills 112 were supplied with motor drive, this being about 22½ per cent. A machine tool and supply house estimates that not more than 5 or 10 per cent of the machine tools purchased through the house are individually motor-driven. A prominent milling machine company reports from 5 to 10 per cent of its total output fitted with motors. A large machine tool concern in Philadelphia states that 34 per cent of its product, including tool and drill grinding machines, was equipped with motor drive, while exclusive of grinding machines about 50 per cent was so fitted. This report was for the year 1906, and the proportion runs slightly larger for 1907. A well-known lathe builder in Worcester states that about 8 per cent of his output of engine lathes has direct-connected motor drive.

Without further quoting, the situation, roughly, is that about half of the large heavy machines are motor-driven, and from 5 to 10 per cent of engine lathes, milling machines, drills, etc. Very likely the proportion will increase relatively faster with some slackening off in trade, as more attention can be given to this and other features of design. The heavy demand for machine tools during the past two or three years doubtless has had the effect of making some builders disregard the motor drive. They have confined their work to building standard machines, leaving the electrical equipment to the users. Owing to this condition, it is fair to say that probably a considerably larger proportion of machines was actually fitted with individual motors than indicated by the above figures, the users applying the motors themselves.

THE AUTOMOBILE SITUATION.

The slowing down of the automobile business during the past summer is a matter that should have the attention of thoughtful men in any way affected by its general prosperity. Is the industry, as at present developed, on a firm foundation, and what is its probable future, are questions that trouble us. In the October, 1906, issue an editorial appeared in which the probability of the pleasure automobile in a measure experiencing the same fate as has overtaken the bicycle was discussed, and in the December issue the replies of a number of prominent automobile concerns were printed. These naturally defended the automobile, but it was conceded, either directly or by inference, that the *real* future of the automobile is largely whatever its deserts as a business machine may merit.

The present development of high-speed and costly cars, designed for the pleasure of an idle, extravagant class, holds forth little of promise for the future. In the first place, all pleasures which have no object but that of mere gratification of the senses soon pall and become distasteful. Such, we believe, is already the existing condition with a considerable class as regards automobiling. It cannot be expected that the speed madness which has led hundreds and thousands of automobile drivers to rush along country roads, raising great clouds of dust and causing terror and semi-panic throughout the whole countryside, could be a permanent condition. In the second place, even if the class now following this sport could find permanent pleasure in it, the productive power of the country, rich though it is, could not indefinitely sustain such unprofitable diversions on the part of large numbers of its citizens.

The automobile will surely supplant the horse and horse-drawn vehicle, but it will do so primarily for business reasons. For example, a family in town or country which now must keep one horse or two to fetch and carry will eventually come to use the automobile instead for the same purpose, and it will incidentally use it for pleasure also, the same as the horse is used now, but the large majority of such families will not keep an automobile for pleasure alone, nor will they invest in high-priced machines. The business of trucking in all cities and towns has grown more and more expensive from year to year because of the care and maintenance of horses, and it seems that this field also must be profitable for motor-driven trucks, although very little, comparatively, has been done as yet. The reason, of course, is that the manufacturers naturally have catered to the trade that was most profitable for the time being. This may prove to be a short-sighted policy in the long run.

LIABILITY OF EMPLOYERS.

As there is but little question that the President's proposition in regard to employers' liability for injuries inflicted on workmen while at work will be acted upon by our legislative bodies within a near future, it seems that rather too little attention has been given to this matter by the technical press in general. It has been contended, and not without reason, that to make the employer liable for all injuries inflicted upon workmen while at work is not fully just, because many an injury is caused by inexcusable personal carelessness. As an example of this class of accidents an English contemporary mentions a case at Cambridge, England, where two men proceeded to take off the cover of a boiler for cleaning purposes under the impression that there was no steam in the boiler, as the pressure gage stood at zero. They had taken out all the bolts, and then proceeded to force off the cover, when a rush of steam occurred which scalded one of the men to death. Another similar case occurred at Schenectady, where two men proceeded to take off the cover of a large vessel, 5 feet in diameter and 10 feet in length, under the mistaken impression that pressure was relieved, whereas the steam had not been allowed to escape. As reported, after a number of the bolts were removed, the cylinder head was suddenly blown off, killing the two men engaged and causing the cylinder to shoot backward, demolishing a water tower and a windmill, and finally alighting on the railway, where it killed a third man about 500 feet from its original position. The folly of attempting to remove a manhole cover from a boiler before steam pressure is entirely relieved would seem so obvious that one would imagine the necessity for pointing it out would never occur, but these two fatalities, arising from acts of this kind, show not only the possibility of such occurrences, but the necessity of calling attention to them. They also show how carefully some men must be guarded against their own ignorance, carelessness and folly, and that employers may be unfairly charged with responsibility for things not within their control.

But, on the other hand, it is admitted by all fair-minded persons that something must be done in order to relieve the suffering and the burden on those depending on the injured or killed worker, no matter what the cause of the accident. And if, as in Germany and Great Britain, we place the responsibility, financially, on the employer, the result will finally be, not that the employer is burdened directly to any greater extent than now, but simply that he acts as an insurance agent for his men. He will not personally shoulder the liability, but will turn over that responsibility to an insurance company, while, in turn, the premiums he pays originally must come out of the productive labor of his men. The benefits derived from this system, however, are manifold. In the first place the community will be burdened by less dependents forced upon it by industrial activity. Secondly, adequate safeguarding of life and limb will greatly increase in our shops, since the insurance companies will insist upon the best safety appliances in order to accept the risks.

In England the original workmen's compensation act, placing the burden of industrial accidents upon employers, was passed ten years ago, against strong opposition from both employers and labor organizations. Experience has proved, however, that the criticisms of the act were ill-founded, and so experience undoubtedly would prove in this country. At the present time the United States is the only industrial nation in which the burden of industrial accidents is borne nearly wholly by the workmen. The subject is one certain to be agitated with increasing vigor from this time forward, and everybody concerned in our industrial development must sooner or later give some attention to this subject. Our present waste of industrial working force, of life and limb, is appalling, and in many cases due safety appliances are lacking. When proper allowances have been made for carelessness of employes, there still remains a heavy charge against the employer. The liability laws would tend to increase proper safeguarding of the health and life of our industrial workers, and as it seems as if making the employer directly responsible would be the best means for bringing about a better appreciation of the value of human life, this step must be taken. It will in the long run place no burden on the employer. The productive workers in our industries must finally pay the insurance in any case, and an effective means of bringing about a desirable result should not be scoffed at, even if it at first seems as if it placed too much responsibility on the employer of labor.

NEW RAIL-MAKING PLANTS.

It has been announced that the Jones & Laughlin Steel Co., of Pittsburg, will enter the rail-making business, and will establish at its new plant near Aliequippa, Pa., one of the largest steel rail mills in the country. The Jones & Laughlin Steel Co., as is well known, is the largest independent steel company in the country, and it has been the most active competitor of the United States Steel Corporation, commonly called the steel trust, in all other steel manufacture except that of steel rails. It is not known exactly when the new rail mill will be in operation, but the company has made a statement to the effect that it will be within a short time. The Bethlehem Steel Co. started a rail mill in the first part of September, and has been engaged since then in rolling rails for the Union Pacific. This company abandoned the making of rails about ten years ago, but has concluded to take up this manufacture again. The new mill is arranged for the manufacture of basic open-hearth rails, low in phosphorus. Attention will also be given to the manufacture of rails containing special alloys, such as nickel, chromium and vanadium.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

The Pekin-Paris automobile contest, which was mentioned in our May issue, was finished in August, the winner finishing the run in about 60 days.

Work has begun on the electrification of 150 miles of suburban railway leading into San Francisco and Oakland. It is believed that this is warranted by the enormous suburban business of the railroads around San Francisco, which is almost as great as that of the New Jersey roads in the neighborhood of New York.

Necessary funds have been provided for the purchase of a reflecting telescope to be installed at the observatory of the Carnegie Institution of Mount Wilson, California, which will be the largest hitherto made. The mirror of this telescope will be 100 inches in diameter, and the focal length 50 feet, while hitherto 60 inches has been the limit for the diameter. The mass of glass of which the mirror is composed is 13 inches thick, and the weight is about 4½ tons.

It has been proposed, says *Industritidningen Norden*, to use electromagnets for lifting and handling large panes of glass. As glass is a non-magnetic material, the proposition at first seems rather difficult of realization, but it is accomplished by placing a piece of sheet iron under the glass and applying one or more electromagnets on the upper face of the glass. The electromagnets attract the sheet iron and thereby hold the glass suspended while moving.

A correspondent to the *Railroad Gazette*, writing about the rusting of steel rails, refers to a report of J. W. Post, chief engineer of the Netherlands State railroads, relating to iron ties that had been bedded in gravel and sand ballast for thirty-five years. The original weight of the ties was 125 pounds. They decreased in weight from rust and wear, on an average, one-quarter of a pound in every year. Thus the total decrease in weight in thirty-five years was 8.75 pounds.

Attorney-General Bonaparte has directed the various United States Attorneys to institute suits against a large number of railroad companies to recover penalties incurred by them for alleged violations of the safety appliance law. The facts upon which these prosecutions are based were reported to the Interstate Commerce Commission by its inspectors of safety appliances. The violations which constitute the basis of the prosecutions number 287, distributed among 37 operating companies.

The Chicago tunnel system for handling freight, mails, etc., which has been very quietly developed, will in the near future further increase its freight business, it being reported that contracts have been made with twenty-six railways for the handling of their freight in the business district. The system comprises thirty miles of tunnel with narrow gage track. The mail is already carried by these tunnels between the railroad stations and the post office. The large establishments have tracks running right into their basements, while there are six regular freight stations in the business district for the use of smaller shippers.

The new Cunarder *Lusitania* broke all previous Atlantic speed records on her second westward voyage, crossing the ocean at an average speed of 24 knots. The liner arrived in New York early in the morning on Friday, October 11, having left Queenstown in the forenoon the previous Sunday. The time consumed in her passage from Daunt's Rock, off Queenstown, to Sandy Hook Lightship was 4 days, 19 hours, and 52 minutes, due allowance having been given to the five hours time difference. The best previous record is that of *Kaiser Wilhelm II.*, which crossed the ocean at a speed of 23.58 knots. The best day's run was 617 sea miles; the previous record for a day's run, 601 sea miles, was held by the *Deutschland*.

The tendency in Germany when using concrete for railway bridges seems to be to rather use plain concrete than reinforced. It is reported that lately three railroad bridges have been completed on the Bavarian State Railways, all erected of plain concrete and having spans 187, 211, and 211 feet, respectively. In one case the rise of the main arch is only about one-sixth of the width of the span. One of these bridges carries four railway tracks, and the other two only two. It is stated that the cost of these bridges is from 17 to 20 per cent less than that estimated for steel bridges. The ultimate saving will, of course, be considerably more, inasmuch as practically no maintenance is necessary in the case of concrete structures of this character.

The battery tunnel in New York, under the East River, connecting the lower end of Manhattan with Brooklyn, is rapidly approaching completion. The tunnel under the river itself is practically finished. The building of this tunnel presented a number of new engineering problems which developed difficulties which could not be foreseen. The tubes which enclose the tunnel rest partly on rock, partly on silt, and partly on fine sand, and great difficulties have been experienced in regard to preventing the tubes from setting. Concrete piles have been placed under the tubes where they rest on the fine sand, and these piles have been carried down to a depth of 75 feet in order to provide an adequate safeguard, although Mr. George Rice, chief engineer of the construction, considered this precaution unnecessary. If nothing unforeseen arises, it is likely that trains may be run through the tunnel some time during this month.

A horizontal tandem steam engine with cylinders 52 and 90 inches diameter by 60 inches stroke was recently built by the Wm. Tod Co., Youngstown, Ohio, to drive a 43-inch three-high blooming mill in the Carnegie Steel Co.'s plant at Youngstown. This engine is designed to develop 4,000 indicated horse-power at 58 revolutions per minute, and a maximum power of 7,000 indicated horse-power. It is claimed that this is the greatest horse-power ever transmitted by a single crankpin. The weight of the flywheel is 240,000 pounds, this great weight being required on account of the power required to be stored in the fly-wheel when breaking down an ingot, it being estimated that as much as 14,000 horse-power will be required for short periods. The main journals are 30 x 58 inches, and the shaft is 36 inches diameter in the center. The crankpin is 20 x 16 inches, and the total weight of the engine is 500 tons.

We mentioned in the engineering review of our July issue about the salvage of the White Star liner *Suevic*, which had run aground near the Scilly Islands, and the aft portion of which was taken to Southampton, to be provided with a new bow, the old bow having been left on the rocks. According to the *Practical Engineer*, a new bow has now been built for this ship by Harland & Wolff, of Belfast, and this portion of the ship will be towed from Belfast to Southampton, where the ship will be rendered complete once more. It is probably the first time that a ship was ever launched piecemeal. The new fragment, if that expression may be employed, is said to be almost as tall as it is long, and there were some difficulties connected with its launching. The portion of the new bow which will be immediately joined to the old aft portion remaining of the *Suevic*, will be enclosed with a casing of steel plates during the voyage to Southampton.

While aluminum for overhead transmission lines has been employed to some extent in this country, its use in underground circuits has been prohibitive because of the comparatively high cost of aluminum, the impurities which reduce the electrical conductivity, and the difficulty of satisfactory joints. According to the *Mechanical Engineer*, these drawbacks have been successfully overcome by an English firm,

Johnson & Phillips, Ltd., of Old Charlton, Kent. This firm supplies insulated aluminum cables of a conductivity equal to copper at a price which shows a considerable saving when compared with the price of copper conductors, particularly when as high as before the slump in September. The great drawback to the use of aluminum for electrical purposes in the past has been the difficulty of obtaining it sufficiently pure. At the present time aluminum may be obtained with a purity of 99.9 per cent, the average purity of commercial aluminum being 99.6 per cent.

It has been stated over and over again in the daily as well as in the technical press that steam turbines do not find favor with the Germans, and particularly that German naval officers were skeptical in regard to the newly-developed motor. In view of this, the reports of the trials of a new torpedo boat recently launched at Kiel, the most prominent German naval station, are of so much the greater interest. This torpedo boat attained at the official tests a speed of 33.9 knots on the measured test mile with adverse weather conditions, and during a trial of a duration of three hours she attained an average speed of slightly over 33 knots. The turbines indicated 13,000 horse-power. The torpedo boat proved itself capable of going backward at a speed of 16.9 knots against strong wind and heavy sea. The boat has a displacement of 565 tons. The German navy is to be equipped with several torpedo boats driven by steam turbines. The German merchant marine is also reported as considering turbine-driven vessels.

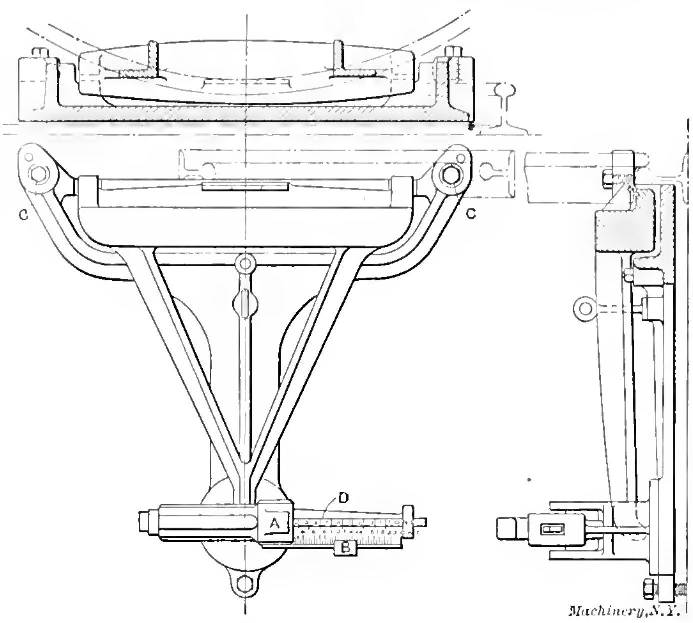
The United States Government has erected a wireless telegraph station at the New York Navy Yard. The station is intended to make possible direct communication between the Navy Department at Washington and the Navy Yard in New York, independent of the commercial telegraph companies. It is stated that it is the purpose of the government to establish a series of wireless telegraph stations which will connect Washington with all important cities along the sea coast, and thus practically free the government from dependence upon the telegraph companies. In view of the difficulties experienced of late in regard to the manner in which the commercial telegraph companies have carried out their duties toward the public, it would seem in place that the government also took such action as to make all legitimate business enterprises of the country independent of the present commercial telegraph companies whose performance of their obligations has been discredited to such an extent as to make governmental action fully warranted.

The question of utilizing the abundant water power of the more mountainous countries in Europe for the electrification of railways has often been referred to in our columns. The latest project of this kind is that of the state railways of Bavaria. It is estimated that 700,000 horse-power can be obtained from Bavarian streams, but it is suggested that only 200,000 horse-power should be reserved by the state for the working of the railways. For a start the ministry for the railways proposes only to utilize 92,000 horse-power. It is claimed that the hydro-electric working of the railways is certain to give a considerable profit over the one now obtained by working the railroads with steam. The annual economy is estimated at $1,750,000, obtainable by working only the railroads in southern Bavaria by electricity. Great attention has also, at the present time, been given to the available water power in France. The available coal deposits in that country will, at the present consumption, be exhausted before many years, and this condition naturally increases the value of the water falls. While the water powers of France have not been gaged with very great accuracy, the total hydraulic power available in France is, according to *Engineering*, estimated to be between 9,000,000 and 10,000,000 horse-power. As the effective horse-power hours used at the present time in the whole country correspond to a continuous operation at the rate of less than 4,000,000 horse-power, the available water power, if fully utilized, would be enough for a long time to come.

LOCOMOTIVE WEIGHING MACHINE.

Engineering, September 13, 1907.

The machine illustrated in the accompanying cut has been designed for the purpose of determining accurately, and with little trouble, the load on any wheel of a locomotive without necessitating the use of a costly locomotive weighing table. The device illustrated consists essentially of a cast steel bracket, with a lever which transfers the weight of the wheel to a balance beam. The bracket is of Y-shape, the extremities of its two arms resting upon the rail, one at each side of the wheel. The lever is fitted with three knife edges, one



Device for Weighing the Load on Locomotive Wheels.

pair of which bear on finished surfaces of the bracket and act as a fulcrum, while the other knife edge is located centrally beneath the wheel. By screwing down the set screws *C* in the arms of the bracket, the lever is raised until the weight of the wheel is taken by the central knife-edge. The scale beam *D* is connected with the weighing lever by a system of compound levers, the same as in an ordinary scale, and the two weights *A* and *B* are each, respectively, the sliding poises for the two scales for the weight in tons and hundredweights.

THE IMPORTANCE OF NITROGEN IN CASE-HARDENING.

Paper by Mr. G. Shaw Scott, read before the Iron and Steel Institute, September Meeting, 1907.

In this paper some experimental data is recorded, showing the importance of nitrogen in the case-hardening process. A certain steel was selected which had been found specially suitable for case-hardening. This steel had the following composition: Carbon, 0.14; silicon, 0.01; sulphur, 0.08; phosphorus, 0.03; manganese, 0.58; iron (by difference) 99.16. Samples of this steel were case-hardened in small cast-iron boxes, being packed in a variety of materials such as burnt leather, wood charcoal, anthracite coal, sugar charcoal, potassium, ferro-cyanide, potassium cyanide, petroleum, gas, bone, horn, graphite, bone black, acetylene, barium carbonate, coal gas, etc. It was demonstrated that there was no carbon penetration in bars heated for four hours at 700 degrees C. (1,292 degrees F.), and that a temperature of 800 degrees C. (1,472 degrees F.) was about the minimum temperature at which carbon penetration took place to an appreciable extent.

Samples treated for four hours at a temperature of 900 degrees C. (1,652 degrees F.) showed a carbon penetration of 0.063 inch. It was demonstrated that this temperature gave uniformly better results than higher temperatures. Barium carbonate and wood charcoal gave about two times as deep a carbon penetration in four hours as wood charcoal alone, and about one-third deeper penetration than burnt leather. But when the heat was sufficiently prolonged, the several mixtures gave approximately the same results. All the case-hardening materials in common use contain nitro-

gen in some form or other, or have the power of utilizing atmospheric nitrogen, and it appears that nitrogen is the active element in promoting carbon penetration, although the free gas has no effect on steel itself. Ammonia, which is a prominent constituent of case-hardening materials, is the chief supplier of nitrogen, and experiments were made that showed that ammonia gas caused deep carbon penetration with materials that without its presence had only slight carburizing effect.

RATIO OF GENERATOR CAPACITY TO MOTOR HORSE-POWER IN ELECTRIC DRIVE INSTALLATIONS.

Mr. George R. Henderson, in *Proceedings of the New England Railroad Club.*

The percentage of generator capacity to the sum of the rated motor horse-powers is somewhat uncertain, but it is lower, perhaps, than generally imagined. At the 1903 convention of the Master Mechanics' Association a committee reporting on electrically driven shops stated that 40 per cent of the aggregate horse-power of the tools could be taken, and to this added the constant and average lighting load in order to determine the capacity of the generators required, without including in the list of such motors those required for cranes, transfer tables or turntables; but the question of a spare unit should always receive consideration. The Master Mechanics' proceedings for 1900 stated that at the Baldwin Locomotive Works, the switchboard load averaged only about 27 per cent of the total motor rating, in this case the crane motors being included. At the Topeka shops a switchboard load equal to 38 per cent of the various motors, exclusive of those on the cranes, was found to obtain. At the McKee's Rocks shop the power consumption was about 30 per cent of the motor rating. The actual installation of some large and modern shops is very interesting. At Collinwood the total generator capacity (after deducting requirements for lights) was 50 per cent of the sum of the motor ratings, not counting those upon the cranes. At McKee's Rocks shop it was 47 per cent on the same basis; at the Angus shop, Montreal, 37 per cent. The new Parsons shop of the M., K. & T. Railway has a generator capacity of about 75 per cent of the total rated motor capacity. Of course the question of the size of generators and also spare units affects this to a certain extent, and the best way to study the question is to lay out a hypothetical load diagram and determine from this the most economical size of units.

PHYSICAL CHARACTERISTICS OF CAST IRON.

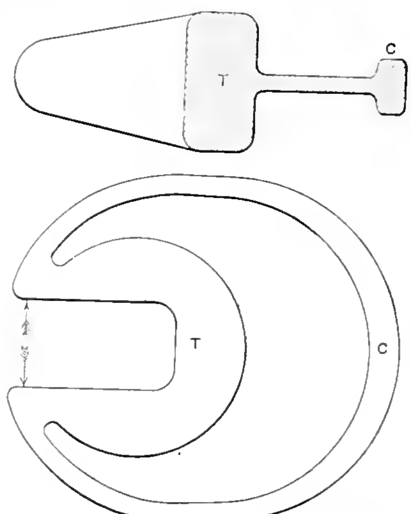
Abstract of paper by James Christie, read before the Engineers' Club of Philadelphia, April 20, 1907.

Cast iron is probably the most complex, variable and uncertain form in which iron is used. Not only is the amount of extraneous metals and metalloids variable, but the condition in which the associated carbon exists, and the character of this association, are determined largely by the influence of silicon and possibly other metalloids. Again, the physical properties of the metal are influenced by casting temperature, rate of cooling, etc., so that altogether we can only assume the probable strength and stiffness of a casting in the most general way, and forecast results, which will suit an average, from which individual castings may vary widely in extremes.

For heavy machinery, where cast iron is used in heavy masses through which working stresses are imperfectly distributed, the metal probably is much softer and weaker in the middle of the mass, where it has cooled slowly, than at outer surface, where the metal has more rapidly cooled. Furthermore, castings are usually under considerable internal strain, due to unequal contraction, and although this internal strain gradually disappears, it may have some disturbing influence after the casting has been put in service. It is good practice to assume an ultimate tensile strength of 16,000 pounds per square inch for ordinary iron castings, and to limit working stresses from 2,000 to 4,000 pounds per square inch, according to the conditions and character of the service.

Cast iron offers a high resistance to compressive stress, and although this resistance varies within wide limitations, it may be assumed as a working basis to be about six times that of the tensile strength, or, say, 95,000 pounds per square inch of section.

In the middle of the past century, as cast iron became extensively applied to structural purposes, its physical properties were studied with great care, and the experiments of Hodgkinson and Fairbairn in England, and of their contemporaries, yielded a valuable fund of information on the subject. Seeking a section of beam which should exhibit the highest ultimate strength in proportion to area of cross-section, or of the weight of metal employed, Hodgkinson advocated a section in which the tension flange exceeded the compression flange about six to one in sectional area, the web usually tapering in thickness from the tension flange, diminishing toward the other flange. This form of beam was largely adopted, and took precedence as long as cast iron was used for beams in structures. We find that the same method of reasoning influenced the machine designer in disposing cast iron to seeming advantage in the construction of machines, massing the metal to resist tension, and permitting high unit stress on metal in compression; and especially is this observed in machines of the open jaw or gap type, such as presses, punching and shearing machines, etc. The author of the paper here abstracted believes that usually the unit stresses should be little, if any, higher in compression



Machinery, N.Y.

Illustration of Common Design Intended to Equalize Stresses in Cast Iron.

than in tension, for the following reasons. In machinery rigidity or stiffness is usually the chief consideration; many machines do not fulfil the intended purpose properly, not by failure through fracture, but by want of sufficient stiffness. Deflection has to be limited, and when that is done, breaking from excessive tension is sufficiently guarded against. As cast iron yields to compression as much as with the same unit stresses it yields to tension, it follows that the compressive stress should not exceed the tensile strength per unit of section if it is desired to dispose a given mass of metal with least deflection. It is believed that rupture sometimes occurs in a machine apparently through tension, where the origin of the weakness could be traced to a want of material to sufficiently resist compression, the improperly supported tension side severing by cross-bending or transverse stress.

Taking for illustration an open gap machines with frame as illustrated in the cut, with tension at *T* and compression at *C*, if the section is so shaped that the compressive unit stress is six times that of the tensile unit stress, then, elastic moduli being equal, the frame will yield at *C* six times as much by compression as it does by tension at *T*. This permits an oscillation of the mass at *T* around its center. If this oscillation becomes dangerous, by extent or frequency, the frame will break by cross-bending at the mass *T*, giving the impression that more material is needed to resist tension, whereas the fact may be that more material should be placed at *C* to prevent excessive yield by compression.

When rapidly alternating stresses occur, it is acknowledged that provision must be made for something more than the greatest stress in one direction alone. There are still dif-

ferences of opinion and practice on this subject among bridge designers. Some maintain that when the alternations are of slow recurrence, so as to permit actual rest between reversals, no special increase of section is required. Others specify that the sum of the sections required for the stress in opposite direction should be used to suit the conditions. There can be little doubt that the latter estimate is not too great for machinery when the oscillation of the forces occurs with great rapidity, and especially when the metal under consideration is cast iron, with a modulus of elasticity about one-half that of steel or wrought iron. It is a safe general rule for ordinary cast iron in machine construction to limit tensile stress to 4,000 pounds per square inch of section, under the most favorable circumstances; to 3,000 pounds when loads are suddenly applied; and to 2,000 pounds when the force alternates in direction; these unit loads are to be further limited to suit the ratio of length to section, as required for columns or any members in alternate extension or compression, or for beams or members subjected to alternating transverse stresses.

MODERN MACHINERY AND ITS FUTURE DEVELOPMENT.

Abstract of paper by Mr. H. I. Brackenbury, read before the British Association.

In the following it is intended to touch but slightly on the design of machinery, but rather to give an account of those forces which have tended to make machine tools develop along certain lines, and to show that there are forces now at work which considerably alter our views and ideas as to the value of certain classes of machinery. These remarks will be limited to small machinery, as being of the most general interest, and only those machines which cover the same ground as the engine lathe will be considered.

Classification of Machine Tools.

Modern machine tools may be classed as follows:

a. Automatic machinery, for which the tools are designed, made, and set in the machines by highly skilled labor, the material being fed into the machines by unskilled labor.

b. Semi-automatic machines, for which the tools are generally formed to give the work the required shape, and stops set on the machine to give the required lengths and depths of the cuts, the operator having little more to do than to pull or turn certain handles. Under this class come turret lathes, screw milling machines, screw machines, etc., in fact, all those machines where the tools can be made and set by skilled labor, and then worked by less skilled labor.

c. Machines which develop the work under the guidance of skilled labor to a drawing or sample, the sizes being obtained by the use of gages or the micrometer. Such machines are the engine lathe, heavy turret lathes fitted with lead screws, etc.

d. Grinding machines for finishing work, where considerable skill is required in the handling of gages, but very little skill to work the machine.

It has been the aim of many machine users to push work from class *c* into class *b*, and from *b* to *a*, and this the machine builders have encouraged, bringing the automatic and semi-automatic machines to great perfection. But they have tried to carry this too far, even under the old conditions; and it might be proved that the conditions, upon which the value of automatic and semi-automatic machines rested, have been completely upset by the general adoption of high-speed steel, and that the claims of the old simple type of engine lathe come once more to the front. These are the days of specialization. Manufacturers tend to specialize in one size of article as much as in one class of article. Meanwhile machine tools have become more and more complicated, one type of machine being suitable to cope with a large variety of work, but in the future they will tend to return to the simpler patterns of former years; but one machine will be designed for turning out one class of article, or rather for doing one or two operations on one article.

Relative Cost of Hand and Automatic Machinery.

Until a few years ago, the time and labor required for rough drilling, turning, etc., was a very large consideration in the total cost, including material; and it was, therefore, desirable to do much of this work with automatic machinery, where one man could attend to, say, four machines. But by the introduction of high-speed steel the cost of roughing-out has been immensely reduced, certainly as low as one-third the former cost. The price of material and of the more intricate types of machines has risen, the result being a complete alteration of the proportionate value of the labor to the cost of material and machine charges. The production of one automatic machine on the larger class of work is slower than the production of a hand-worked machine; and, therefore, extra capital charges are involved for shop room.

The price of an automatic machine is at least double the price of a hand machine suitable for turning out the same piece of work; and very often on the automatic, more material must be used, and of a more expensive nature, a point which the machine builders are apt to leave out of consideration. Future development will not be in the direction of larger and more complicated turret or automatic lathes, but in the direction of simple machines which can be attended to by operators of average intellect and who have not had much previous experience of machinery.

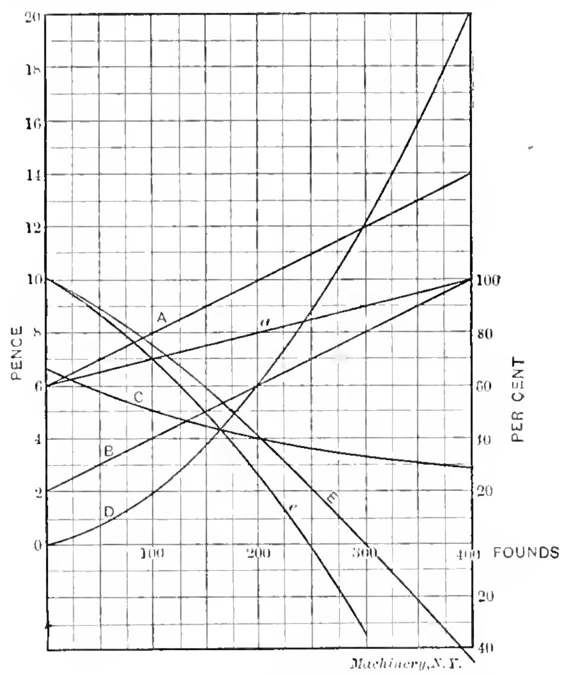


Fig. 1. Diagram of Relation of Cost of Running Automatic and Hand Machines.

Formula for Determining the Cost of Machine Operations.

The following formula may be used to compare the value of various machines in turning out work:

$$\text{Cost per piece in cents} = \frac{\text{Wages per hour in cents} + \dfrac{\text{Price of machine in dollars}}{125}}{\text{Number of pieces made per hour}} + \frac{\text{Cost of tools and setting up in cents}}{\text{Total number of pieces}} + \text{cost of material per piece in cents.*}$$

This formula seems complicated, but all this must be taken into consideration in comparing the economic value of different machines for producing the same piece of work.

If we now turn our attention to the curves drawn in the diagram, Fig. 1, we will find there the relative cost of running ordinary lathes and automatics. (In this diagram the English money standards have been retained.)

The curve *A* indicates the cost of running hand machines of various first costs, with a charge for attendance of 6 pence per hour, and a charge of $\frac{\text{cost of machine}}{5}$ per annum for interest, depreciation, floor space and repairs, which works out at 2 pence per hour per 100 pounds.

Curve *B* indicates the cost of running automatic machines with a charge for attendance of 2 pence, and machine charge as above. The 2 pence is supposing a charge of 8 pence an hour for attending four automatics; and except on the simplest work, this figure would be exceeded.

* In this formula the money values given have been reduced to American money standards.

Curve *C* represents the saving of running automatic machines in place of hand machines. It must be understood that this comparison involves running cost only, and does not take, so far, into account the amount of work turned out.

Curve *D*, finally, shows the actual cost of doing on an automatic machine a number of pieces of work which could be done on a hand machine in an hour. The automatic is taken at the same price as the hand machine. It is assumed that more work can be done in an hour by an automatic machine of under 200 pounds cost than can be done by a hand machine, and that above 200 pounds cost the automatic does less work than the hand machine. This is confirmed by actual practice. In the curve, which shows merely the tendency of the piece price to rise on expensive automatics, the ratio of production of the automatic is to the hand machine as 2 is to the price of the machine in hundreds of pounds, that is, if the machine costs 100 pounds, the production is in the ratio of 2 to 1. At a price of 200 pounds for the automatic, the ratio is 2 to 2. At 300 pounds 2 to 3, etc.

It may be said that the automatic machines show a saving when the capital cost is not more than 250 pounds each. After this figure a loss is shown which increases very rapidly. This is best shown by curves *E* and *e*, which give the percentage gained or lost by using automatic machines of various values, as compared to hand machines. Curve *E* is for automatic machines of the same value as hand machines, but in curve *e* the hand machines are taken at half the cost of the automatics; probably a suitable hand machine, to do work being done in an automatic, would cost less than half the automatic.

Figures are often shown which seem to prove the great value of even large automatics and expensive and complicated turret lathes. In certain cases these figures are correct, but in many cases the saving is largely due to the carefully thought-out method of doing the work, where formerly little, if any, attention had been given to the study of economy in the old machines. A case is pointed out where the time for doing a piece of work was reduced by the use of a large and expensive turret lathe from 4½ hours to one hour. There being more of the same work to do, it was determined to try what could be done in the old lathes. A few special tools were made, and the method of procedure very carefully thought out. The result was a time of 1 hour and 10 minutes for the work.

We now turn our attention to a set of curves, Fig. 2, showing the actual proportionate cost of wages only on bolts made, *A*, in an engine lathe, *B*, in a turret lathe, and *C*, in an automatic. It will again be noticed that the automatic shows a large saving on the smaller sizes; for the larger sizes the engine lathes show the cheapest method. The turret lathes show much the same as the engine lathes, but the machine charges would be much higher for both the automatics and the turret machines.

The Proper Application of Automatic Machines.

The automatic shows to the best advantage on simple work, when the cutting time is a large proportion of the whole time. The reason for this is that the time taken to change from tool to tool on the automatic machine is longer than that required on the hand turret machine. Thus, the longer the cutting time, and the fewer the number of tools employed, the better is the result from the automatic. Of course, these curves are hardly even approximately correct for any article of manufacture, but they show the tendency very clearly of the work to become more and more expensive as the size of the automatic machine increases. It is certain that more than one manufacturer who has started a new shop with the idea of doing as much as possible by automatic machines to keep down labor cost, has been surprised to find that some other shop with a few cheap machines is turning out the work quite as cheaply, and when slack time comes he considers with sorrow the capital locked up in his beautiful battery of automatics. Now, from the foregoing we may safely argue that the large automatic machine is a creation of the past, and that the future will bring no further development in this direction. The simple automatic machines of small size are of the greatest value. The complicated machines for work requiring many short operations are not economical. Tracing the history of the automatic machinery, we find it was largely due to the bicycle becoming such a universal favorite, thousands and thousands of small parts being required of an exact similarity. Comparing the price of the first safety bicycles to the present prices, one will obtain an idea of what this automatic machinery has done to cheapen the production of small parts in large numbers.

The turret lathe has increased in size and power within recent years. For many purposes, when there are many short operations to be done at one setting, and little material to be removed, these machines are very valuable. The proper sphere for large and expensive turret lathes is for finishing work of a complicated nature, and it is in this direction that the machine will be developed. To occupy a machine costing perhaps 500 pounds with work which can be roughed out in a machine costing a little over 100 pounds, and worked with cheaper labor, is quite out of the question.

We come then to this conclusion: The use of automatic turning machines is for small work of a simple nature; the use of large, expensive turret lathes is for finishing work of a complicated nature or form, requiring considerable variety of tools.

The Future of Simple Hand Machines.

To rough the work to nearly the finished sizes we require simple machines: *a*, heavy, simple, and cheap turret lathes for boring and chuck work; *b*, heavy, simple, and cheap engine lathes; *c*, similar to *b*, but fitted with scroll or plate for forming the work to shape. Curiously enough, these machines, which seem the most simple and easy of perfection, give the most room for development. The reason of this is that the great value of roughing-out work in cheap machines with cheap labor has not been sufficiently grasped. In the design of these roughing-out machines the driving should be done by means of a single pulley running on a back shaft with a wide belt, and not a cone pulley; the change of speeds would be obtained by means of sliding gear wheels made, of course, of steel. The teeth should be of small pitch, and not necessarily wide. We may take a lesson here from what the small gears in motor cars are able to stand.

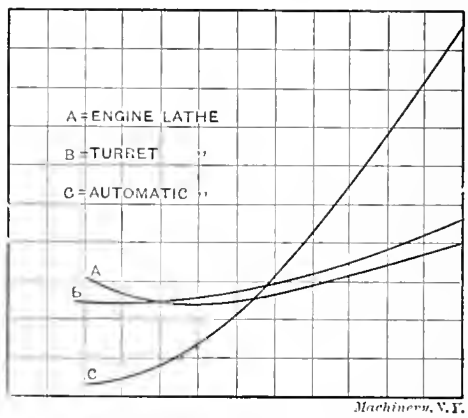

Fig. 2. Diagram showing Relative Cost of Labor for Bolts made in Different Machines.

The obvious disadvantages of the cone pulley are two: *a*, with wide belts to change the speed it is a time-wasting process and apt to be dangerous to the inexperienced; *b*, a varying power is passed through the belt. Taking as an example a lathe of well-known make, the horse-power carried by the belt varies from 12.95 to 4.57. Evidently the value of a large range of speeds is very doubtful when it is combined with such a range of horse-power.

The feed should be obtained by means of a lead screw of ample dimensions, bearing in mind that the pressure required to feed the tool is equal at times to the pressure required for cutting. The feed changes should be given by sliding gear wheels. The nut should be of cast iron, as this gives a longer life than the usual gun-metal nut. The bed and headstock should be cast in one, and should be of ample weight. The bed should be one with square edges and a step on the cutting side, permitting of less twisting action on the saddle. The section of bed should be of the double-H beam type. Ample provision must be made for taking up the thrust by

means of ball bearings or wide collars. In designing these machines one must keep in mind that the aim is not a perfect machine, but a machine of simple construction, simple to work and cheap to buy, and of considerable power. These machines should not be arranged for screw cutting.

There remains now the question of threading work. Bolts and such work should, of course, be threaded by means of self-opening dies, as this is much the cheapest method. But where great accuracy of pitch, or threads of coarse pitch, such as worms, are required, recourse must be had to either the lathe or the thread milling machine. This latter machine is the most universally useful, and there is a great future before this type of machine.

Concluding his paper, the author said that he feared many would come to the conclusion that he advocated a retrograde policy in drawing attention to the merits of the simplest machines. "But in advocating these machines," he said, "I do not wish to bring back the old methods of using them, for the most careful consideration is required to find the method which will give the best results. I, least of anyone, would wish to belittle the value of the small automatic and large complicated turret lathes which have been brought to such wonderful perfection in modern times, but I ask machine users to keep such machines in their proper places, and weigh carefully the merits of simpler and cheaper machinery."

AMERICAN MACHINE TOOLS IN EUROPE.

Page's Weekly, August 1, 1907.

An English journal devoted to the motor car industry recently stated that American as well as German machine tools were used in that industry in preference to British tools, and that the British manufacturer, owing to his lack of appreciation of modern requirements, falls short when his product is compared with that of American and German origin. From an inquiry which was made by the publication from which the present article is abstracted we find that while the original charge made by the motor car journal mentioned is undoubtedly overdrawn in some respects, in some British shops American tools are used even to a greater extent than one would at first feel inclined to believe. Thus we find that Messrs. Dean & Burden Brothers, Ltd., of Scout Motor Works, Salisbury, state that they regret to say that of their machine tools only about 15 to 20 per cent are British. "The majority of the British machine tools," they say, "are not so accurately made, neither are they so handy to manipulate as the foreign, except, perhaps, in the case of one or two English machine tool manufacturers whose prices are very high indeed. These particular manufacturers do not make all machine tools necessary for the motor work, so that if a motor firm felt inclined to pay the price, even then it would be difficult to get all the tools from British firms."

Another firm, that of Legros & Knowles, Ltd., of Willesden Junction, says that of all their machines 40 per cent are of American origin. Others report a large proportion of American tools, while, of course, a great many state that they use British tools to the greatest extent and find them fully satisfactory.

What really is most interesting to American manufacturers of machine tools, however, is not so much the praise of American tools, although that is gratifying, but rather the criticism of some American tools and methods. One firm, while stating that the Americans excel in drilling and grinding machines, mentions that for tool-room work, the British lathe is superior to the average American lathe. Slow deliveries, of course, continues to appear as the standing charge against the American manufacturer, but it seems as if this charge applies to British makers as well. One firm finds that American tools are not, generally speaking, equal to the British for continuous use for any length of time under the stress of high-speed steel. It appears that as a rule the comparative lightness of American tools, which has always been a characteristic feature, is a strong argument against American machine tools. The many special features and attachments of American tools, not to be found in British machines, seem to be one of the strongholds of American tools on the British market.

POWER REQUIRED FOR CRANES AND HOISTS.*

ULRICH PETERS.†

Ulrich Petera.‡

Whatever the type may be—traveling, gib, gantry and similar travelers, except such as derricks, shear cranes and other special hoisting devices—there is ordinarily, at least, a so-called trolley by means of which the functions placed in a hoisting machine are performed, that is the hoisting, holding, traversing and lowering the load. In one sense of the word, a crane or traveler without a trolley or single crab finds little representation in the present industry for permanent service in yards, shops, mills and factories.

The distinction between trolley and crab is most easily decided upon by noticing whether the load is suspended from a truck which usually carries its own power generator for hoisting and traversing, independent of the other parts of the crane, or whether the load is hung on a truck helpless without the driving mechanism attached in connection to the crane. In the first case we speak about a crane trolley, while in the other often about a crane crab. Of course, there are instances, sometimes,

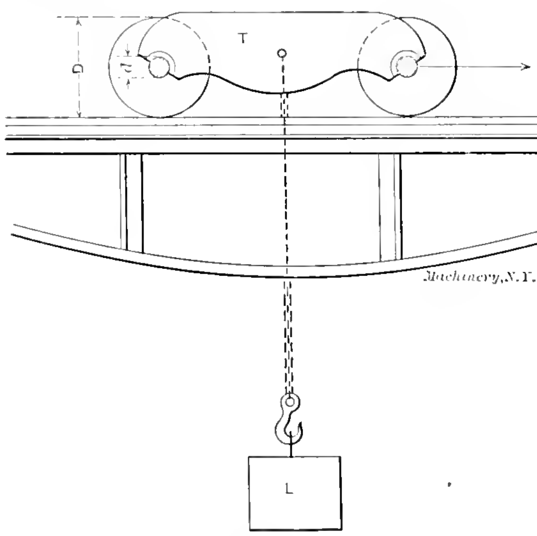

Fig. 1. Diagram of Crane Trolley.

where it is not so easy to decide whether we have a crab, a trolley, or a mongrel of both before us.

The intelligent figuring of the motive and hoisting power required for certain types of trolleys and crabs may cause us some little worry. No doubt, a short repetition of the elementary mechanics of the parts entering into crane and trolley construction may be helpful to many interested readers in following up the derivation of the later formulas covering the whole combination of a trolley or crab construction.

I. Power Required to Move a Trolley or Crane Bridge.

The resistances to be overcome are:

1. Rolling friction of trolley wheels $= P_1$.
2. Journal friction of trolley wheel axles $= P_2$.
3. Inertia or kinetic energy of trolley and load $= P_3$.

Considering all resistances applied at the axle, Fig. 1, we know

* For previous articles on this and kindred subjects, see: The Efficiency of Mechanism, March and April, 1903; and Formulas for Force Required to Move Crane Trolleys, October, 1907.

† Address: Kenwood St. and Beechwood Boulevard, Pittsburg, Pa.

‡ Ulrich Peters was born in Russia, in 1876. After coming to this country he was employed by the General Electric Co., Schenectady, N. Y.; Canada Tool Works, Dundas, Ont.; Midvale Steel Co., Philadelphia, Pa.; Garrett Cromwell Engineering Co., Cleveland, Ohio; Clairton Steel Co., Clairton, Pa.; National Tube Co., and other firms of Pittsburg, Pa. Mr. Peters has worked as blacksmith, machinist, dynamo tender, draftsman and mechanical engineer. His specialty is steel mill engineering, mill machinery and steam specialties. He has been a frequent contributor to the technical press for the last eight years.

$$P_1 = \frac{f_1\,(T + L)}{D}$$

and

$$P_2 = \frac{f_2\,(T + L)\,d}{D}$$

in which

T = weight of trolley (see Fig. 1).

L = load.

f_1 = coefficient for rolling friction = 0.002 (f_1 about 0.001 to 0.003 for cast iron on steel).

f_2 = coefficient of journal friction. (For starting, f_2 = 0.1

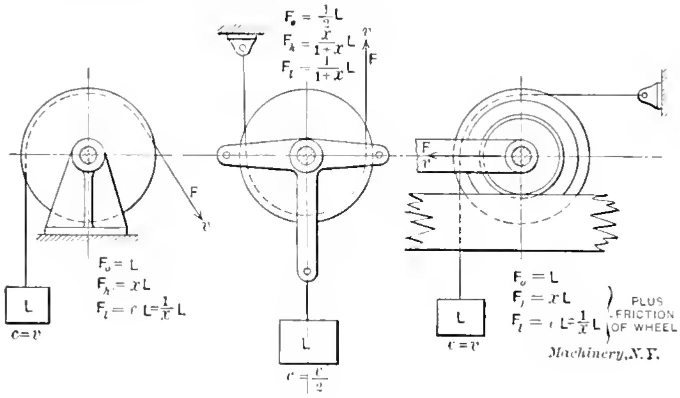

Fig. 2. Fig. 3. Fig. 4.

and running, f_2 = 0.01, assuming a load on brasses 1,000 to 3,000 pounds per square inch.)

d = diameter of journal.

D = diameter of trolley wheels.

Combining

$$P_1 + P_2 = \frac{L + T}{D}\,(f_1 + f_2\,d) \qquad (1)$$

gives a formula for the power required when neglecting the inertia, or when the trolley is in motion.

Denoting the specified trolley speed as v feet per minute, and t as the time in seconds in which the trolley under full load is required to come to the full or maximum speed v, then in accordance with the principles of mechanics, the accelerating force

$$P = \frac{v\,(T + L)}{1{,}932\,t}.$$

It is obvious for exact calculations that the resistance P of the trolley, trolley gearing and load, due to inertia, is to be added to equation (1), especially when the stipulated maximum trolley speed is over 100 feet per minute.

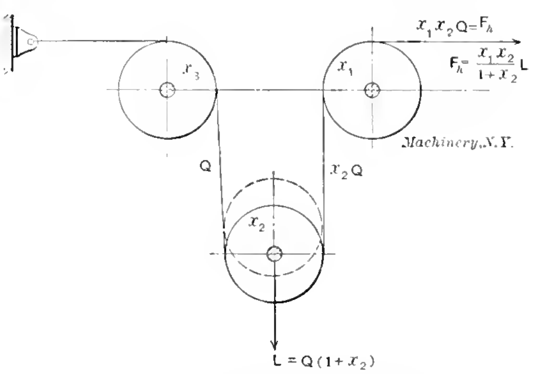

Fig. 5. Notations, Fixed and Movable Sheaves, Two Parts of Rope.

The reduced final equation for the total force P_t required to move or set in motion a trolley under full load is therefore

$$P_t = P_1 + P_2 + P_3 = (T + L)\left(\frac{f_1 + f_2\,d}{D} + \frac{v}{1932\,t}\right) \qquad (2)$$

Similar conclusions can be drawn for the required motive power of crane bridges.

Here I wish to remark that it is close enough for all practical cases to assume that the moments of inertia of all rotating parts of trolley or bridge (gears, drum, brake, etc.) are counterbalanced by the more or less flexible inertia of the suspended weight or load which effects the unavoidable swinging of the lower hook block when suddenly starting or stopping the movement of the trolley. For practical purposes it would be a useless attempt to construct "ounce-wise" formulas on "pound-fool" relations of the actual conditions under which cranes do the work; as, for instance, in regard to variation of load, greasing, attendance, repairs and exposure. In respect to these circumstances, it is, however, not absolutely necessary for the crane builder to contrive the most extreme working conditions in order to design and build a crane. The factors of safety of sufficient allowance (5 to 10) in the elementary parts making up the crane trolley will generally—not always—take care of abnormal conditions that may arise, such as, in particular, initial overload caused by improper greasing and attendance. The friction coefficients already noted, and the coefficients given later on, are for average normal conditions which, of course, may be subjected to certain flexibilities, according to the whims of the attending or not-attending craneman, or the whims of the designer. So, for instance, the axle journal brasses could be replaced by roller bearings, etc. On the other hand, the trolley track, which is perfectly level, may become considerably inclined under the deflection of the bridge caused by the trolley loaded to its capacity. Especially will this deflection be the more noticeable on long span or cantilever cranes, causing often a considerable additional trolley resistance due to the created grade of trolley track.

The advisability of roller bearings in cranes has been questioned very often. But on the other hand, the practical crane designer will foresee the deflection, and, if necessary, allow an appropriate artificial deflection in the top chord of his girder in an opposite direction, instead of leaving it to the

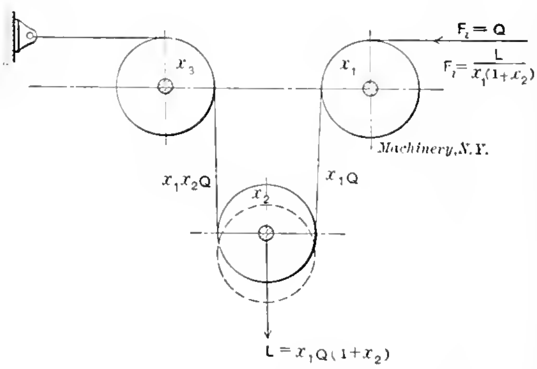

Fig. 6. Notations, Fixed and Movable Sheaves, Two Parts of Rope.

superintendent, as an afterthought, to send up his machinists with so-called "Dutchmen" pieces to fix up the trolley track.

Example: A 10-ton crane trolley, weighing 3½ tons, is to have a trolley speed of 100 feet per minute. The size of trolley wheel is D = 10 inches; and axle journal d = 2 inches. How much power will it require:

1. To start the trolley when loaded to its capacity?
2. To bring it up to full speed in 10 seconds?
3. To move the trolley at a constant speed?

Answer 1.

$$P_t' = 27{,}000\left(\frac{0.002}{10} + \frac{0.1 \times 2}{10} + \frac{100}{1932 \times 10}\right)$$
$$= 686 \text{ pounds.}$$

Answer 2.

$$P_t'' = 27{,}000\left(\frac{0.002}{10} + \frac{0.01 \times 2}{10} + \frac{100}{1932 \times 10}\right)$$
$$= 200 \text{ pounds.}$$

Answer 3.

$$P_t''' = 27{,}000\left(\frac{0.002}{10} + \frac{0.01 \times 2}{10}\right)$$
$$= 60 \text{ pounds.}$$

The equivalent for 33,000 foot-pounds per minute is one horse-power. It follows, therefore, that for a maximum trolley speed of 100 feet per minute,

$$\frac{686 \times 100}{33{,}000} = 2.1 \text{ H.P. is required for starting the trolley;}$$

$$\frac{200 \times 100}{33{,}000} = 0.6 \text{ H.P. is required while speeding up the trolley;}$$

and
$$\frac{60 \times 100}{33{,}000} = 0.2 \text{ H.P. is required for moving the trolley at uniform speed.}$$

In case an electric motor, coupled to a series of cut gear reductions, the total efficiency of which is assumed to be about 80 per cent, furnishes the motive power, the required size of motor follows from

$$\frac{2.1}{0.8} \cong 2.5 \text{ H.P.}$$

[NOTE.—The sign $\cong$ signifies "approximately equals."]

The motor should have a high starting torque, and a permissible overload of about 50 per cent (100 per cent is not unusual).

II. The Fixed, Loose and Moving Sheaves.

If we now refer to Figs. 2, 3, 4, 5 and 6, let

F_o = theoretical force or pull.

F_h = actual hoisting force.

$$F_l\, v = L\, c \qquad (4b)$$

Substituting from above for $F_h = \frac{1}{e} F_o = x F_o$, in which $\frac{1}{e} = x$ symbolizes the coefficient of efficiency.

This coefficient has been determined experimentally for several hoisting elements, such as the sheave, block, windlass, gearing, reduction, etc. Even for complete cranes of certain types and definite design the coefficient of efficiency has been determined by experiments. For any new design, this coefficient can be figured as per following analysis:

It has been proved by mathematics that the efficiency c of a whole machine is the product of all the efficiencies of each elementary part of which the machine is constituted. Knowing once the efficiency of each elementary part, the total efficiency of any combination can then be easily found by multiplying

$$e_1\, e_2\, e_3\, e_4 \ldots\ldots = e. \qquad (5)$$

Or, as $\frac{1}{e} = x$, the coefficient of efficiency

$$x = \frac{1}{e} = \frac{1}{e_1} \times \frac{1}{e_2} \times \frac{1}{e_3} \times \frac{1}{e_4} \ldots = x_1\, x_2\, x_3\, x_4 \ \ldots \qquad (5a)$$

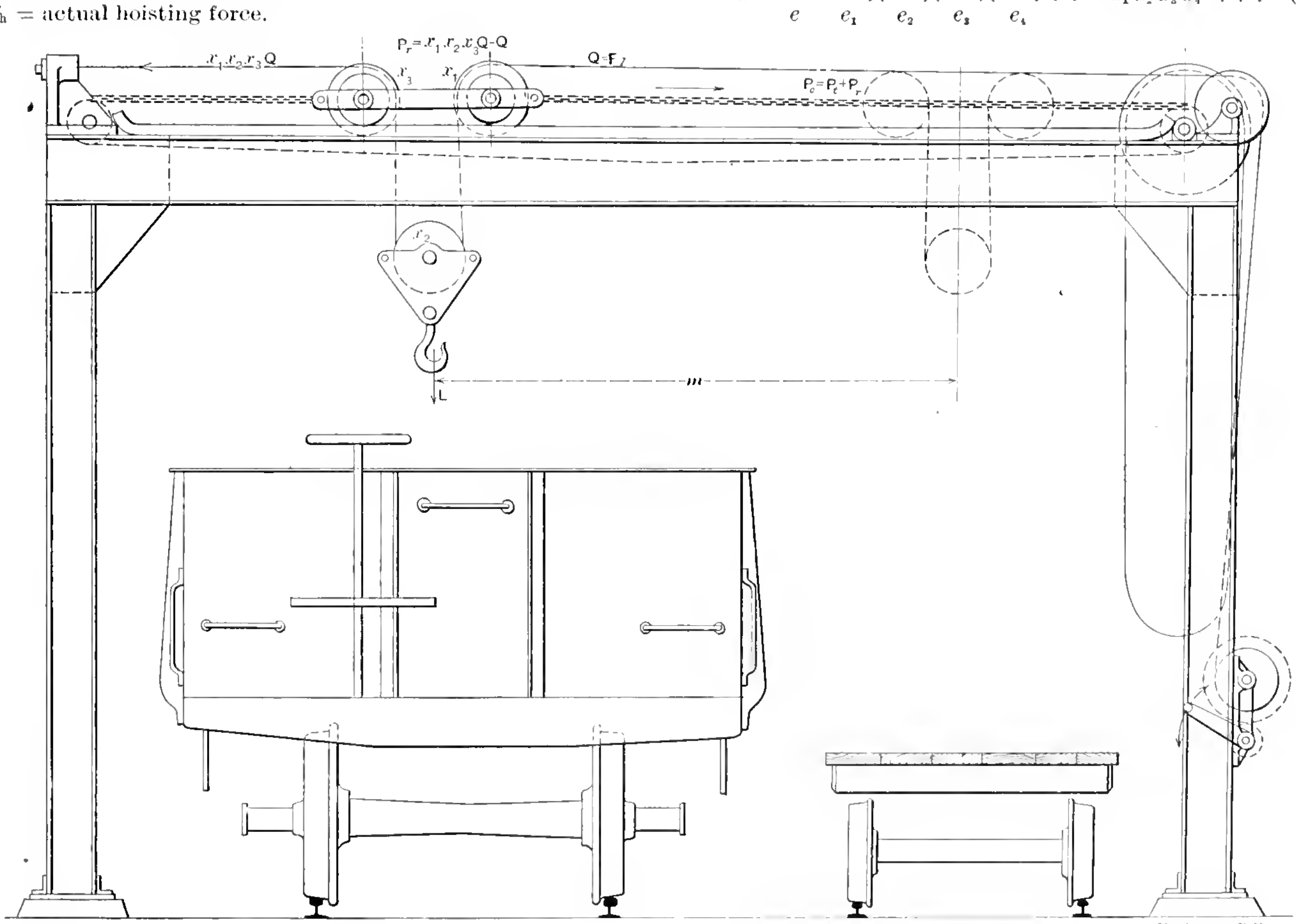

Fig. 7. Hand Crane Trolley Traversing with Suspended Load.

F_l = actual lowering force (brake resistance).

L = load.

Q = tension of rope.

The efficiency of any hoisting rig is:

$$e = \frac{F_o}{F_h} \qquad (3)$$

If, further,

v = the speed of the rope or chain end at which the force F_h, F_l or F_o is applied,

c = the hoisting or lowering speed of load L,

Then $\frac{c}{v}$ = the transmission ratio of the hoist.

The theoretical work required, per velocity time unit, to lift or lower the load:

$$F_o\, v = L\, c \qquad (4)$$

The actual work to raise the load:

$$F_h\, v = L\, c \qquad (4a)$$

The actual brake work to lower the load:

In order to raise the load in Figs. 2, 3 and 4, it is obvious that F_h must be greater than the tension L, from load. On the other hand, F_l will be smaller than L when lowering the load. This is all due to the pin friction in the sheave, chain friction, or stiffness of rope. As a rule, it could be said that the greater tension is always on the side from which the chain or rope runs off the sheave.

For hemp rope sheaves the coefficient of efficiency is:

$$x = 1 + \frac{0.06 \text{ to } 0.18\, i^2}{R} + \frac{2\, f\, r \sin\frac{a}{2}}{R} \qquad (6)$$

For wire rope and chain sheaves the same is:

$$x = 1 + \frac{0.2 \text{ to } 0.3\, i}{R} + \frac{2\, f\, r \sin\frac{a}{2}}{R} \qquad (6a)$$

In these equations

i = diameter of chain or rope;

f = friction coefficient of sheave pin $\cong 0.08$;

r = half diameter of sheave pin;
R = half diameter of sheave;
a = angle of rope or chain turn.

For parallel tension members, a = 180 degrees:

$$x = 1 + \frac{0.06 \text{ to } 0.18\ i^2}{R} + \frac{2f'r}{R} \text{ for hemp rope sheaves;}$$

$$x = 1 + \frac{0.2 \text{ to } 0.3\ i}{R} + \frac{2f'r}{R} \text{ for chain or wire rope sheaves.}$$

The coefficient for wire rope sheaves is not as yet sufficiently determined. Approximately it may be figured to the same formula as used for chain sheaves.

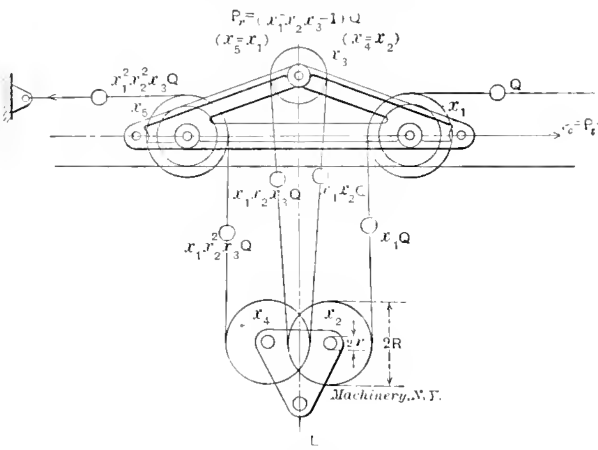

Fig. 8. Notations used in Calculating Efficiency, Four Parts of Rope.

For sprockets a value $x \cong 1.06$ is often used.

For gear reductions, about 1:5, the efficiency is on an average: $e \cong 0.92$; $x \cong 1.087$.

As seen in diagrams Fig. 5 and Fig. 6, the hoisting force $F_h = \frac{x_1 x_2}{1 + x_2} L$, and the force for lowering the load $F_l = \frac{1}{x_1(1 + x_2)} L$

Combining and evolving the above we have, in general, for n sheaves.

$$F_h = x_1 (x_1 x_2 x_3 \ldots x_{n-1}) F_l \qquad (7)$$

Or, if the coefficient of efficiency of the first sheave $x_1 = x_n$ of the last sheave, then

$$F_h = (x_1 x_2 x_3 \ldots x_n) F_l \qquad (7a)$$

As examples we will investigate the single sheave crab Fig. 7, the double sheave crab Fig. 8, and the triple sheave crab Fig. 9.

Without any hesitation, we could say that in all three cases the total power P_c to move the crab will be composed of:

1. The total force P_t to move the trolley as already discussed, and
2. The total resistance P_r of crab rigging.

Therefore

$$P_c = P_t + P_r.$$

a. Resistance P_t of crab trolley.

Neglecting the weight T and the inertia force P_3 of the trolley or crab, the pull P_t to move the crab will be simply

$$P_t = \frac{L}{D}(f_1 + f_2 d)$$

Assuming in our examples:	Fig. 7	Fig. 8.	Fig. 9.
The maximum load	L = 3 tons	5 tons	10 tons
Diameter of truck wheel	D = 7½ in.	8¾ in.	10 in.
Diameter of truck wheel pin ...	d = 1½ in.	1¾ in.	2 in.

Inserting the values, and choosing $f_1 = 0.002$ and $f_2 = 0.08$:

$$P_t = \frac{6000}{7.5}(0.002 + 0.08 \times 1.5) = 976 \text{ pounds for } L = 3 \text{ tons,}$$

$$P_t = \frac{10000}{8.75}(0.002 + 0.08 \times 1.75) = 1623 \text{ pounds for } L = 5 \text{ tons,}$$

$$P_t = \frac{20000}{10}(0.002 + 0.08 \times 2) = 3240 \text{ pounds for } L = 10 \text{ tons.}$$

b. Resistance P_r of crab rigging.

If we move the crab to the position shown dotted in Fig. 7, the load L will, of course, move the same distance horizontally, but its height or elevation will not be changed; that is, the potential energy of the load will remain the same. The shifting of the crab, however, will cause the rope or chain to run off the same distance in feet over all sheaves in a direction opposite to the motion of the crab, Figs. 7, 8 and 9.

Considering now the rope tension, we can assume a certain tension Q in one end of the rope or chain, Figs. 7, 8 and 9. While the rope is passing over the several sheaves x_1 x_2 x_3 . . . etc., the tension in the rope increases on the paying off side; and, as already pointed out, by the amount $x_1 Q$ after passing the first sheave, $x_1 x_2 Q$ after running off the second sheave, etc., all due, each time, to the friction of sheaves, rope or chain. The final tension will be in Fig. 7 = $x_1^2 x_2 Q$, in Fig. 8 = $x_1^2 x_2^2 x_3 Q$, and in Fig. 9 = $x_1^2 x_2^3 x_3^2 Q$, by making the corresponding sheaves alike.

Assuming, now, such a slippery track as that there will be no friction whatever in the trolley wheels, so that the trolley resistance may be placed at $P_t = O$. It is evident, then, that the rigging resistance:

$$P_r = x_1^2 x_2 Q - Q = (x_1^2 x_2 - 1) Q \text{ in Fig. 7.}$$
$$P_r = (x_1^2 x_2^2 x_3 - 1) Q \text{ in Fig. 8.}$$
and
$$P_r = (x_1^2 x_2^3 x_3^2 - 1) Q \text{ in Fig. 9.}$$

In this equation $Q = F_l$, the force for lowering the load, and from $L = x_1 Q + x_1 x_2 Q$ (Fig. 7), we have

$$Q = F_l = \frac{L}{x(1 + x_2)} \qquad (8)$$

From

$L = Q[(x_1 + x_1 x_2) + (x_1 x_2 x_3 + x_1 x_2^2 x_3)]$ (Fig. 8) we get

$$Q = F_l = \frac{L}{x_1(1 + x_2)(1 + x_2 x_3)} \qquad (8a)$$

From $L = Q[(x_1 + x_1 x_2) + (x_1 x_2 x_3 + x_1 x_2^2 x_3) + (x_1 x_2^2 x_3^2 + x_1 x_2^3 x_3^2)]$ (Fig. 9) we have

$$Q = F_l = \frac{L}{x_1(1 + x_2)(1 + x_2 x_3 + x_2^2 x_3^2)} \qquad (8b)$$

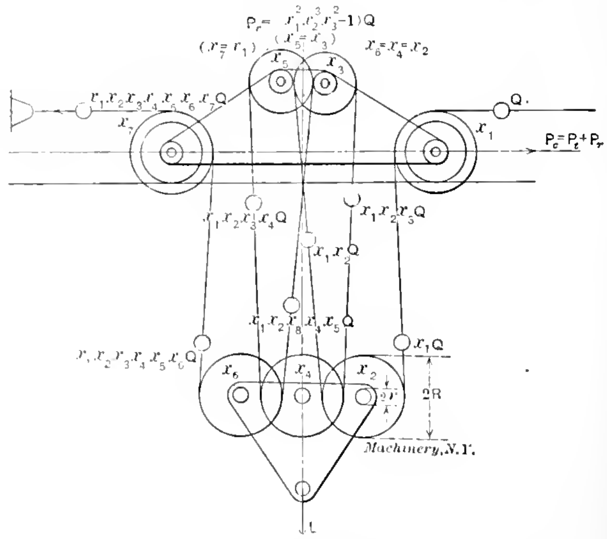

Fig. 9. Notations used in Calculating Efficiency, Six Parts of Rope.

Analogous will be the hoisting force or pull:

$$F_h = x F_l = \frac{x_1 x_2}{1 + x_2} L \text{ .... in Fig. 7.}$$

$$F_h = \frac{x_1 x_2^2 x_3}{(1 + x_2)(1 + x_2 x_3)} L \text{ .... in Fig. 8.}$$

$$F_h = \frac{x_1 x_2^3 x_3^2}{(1 + x_2)(1 + x_2 x_3 + x_2^2 x_3^2)} L \text{ .. in Fig. 9.}$$

Substituting the value found for Q in above equations for P_r, we finally get:

$$P_r = \frac{x_1^2 x_2 - 1}{x_1(1 + x_2)} L \text{ .... in Fig. 7.} \qquad (9)$$

$$P_r = \frac{x_1^2 x_2^2 x_3 - 1}{x_1(1 + x_2)(1 + x_2 x_3)} L \text{ .... in Fig. 8.} \qquad (9a)$$

$$P_r = \frac{x_1^2 x_2^3 x_3^2 - 1}{x_1 (1 + x_2)(1 + x_2 x_3 + x_2^2 x_3^2)} L. \text{ in Fig. 9.} \quad (9b)$$

The more the number of sheaves of various diameters in a rigging, the more voluminous these formulas become.

Illustrating the proceeding by numerical examples, we will assume for the sheave crabs, Figs. 7, 8 and 9:

	Fig. 7. Single Sheave.	Fig. 8. Double Sheave.	Fig. 9. Triple Sheave.
The maximum load..	$L = 3$ tons.	5 tons.	10 tons.
Size of chain or rope.	$i = \frac{1}{2}$ inch.	$\frac{1}{2}$ inch.	$\frac{1}{2}$ inch.
Size of sheave pin . .	$2r = 1\frac{1}{2}$ "	$1\frac{3}{4}$ "	2 "

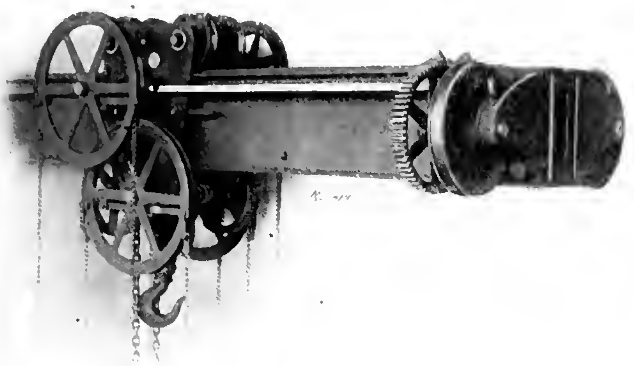

Fig. 10. Typical Hand Chain Crane Trolley.

As usual we may take the chain sheave diameter $2R = 20\ i = 10$ inches, and the sheave diameter for wire ropes $2R = 30\ i = 15$ inches.

To assure a more uniform wear inside as well as outside of the rope, the sheaves should, if possible, be made even larger. Adopting, therefore, for ½-inch steel wire rope $2R = 18$ inches, in general, and $2R = 15$ inches for the equalizing sheaves, Fig. 8 and Fig. 9.

For the sheaves x_1, referring again to Figs. 5, 6, 7, 8 and 9, we have from formula (6a):

For chain sheave $2R = 10$ inches.

$$x_1 = 1 + \frac{(0.2 \text{ to } 0.3)\ \frac{1}{2}}{5} + \frac{2 \times 0.08 \times \frac{3}{4}}{5} \sin 45^\circ$$

$= 1.037$ to $1.047 \cong 1.042$ for $2r = 1\frac{1}{2}$ inch, Fig. 7.
$x_1 = 1.040$ to $1.050 \cong 1.045$ for $2r = 1\frac{3}{4}$ inch, Fig. 8.
$x_1 = 1.043$ to $1.053 \cong 1.048$ for $2r = 2$ inches, Fig. 9.

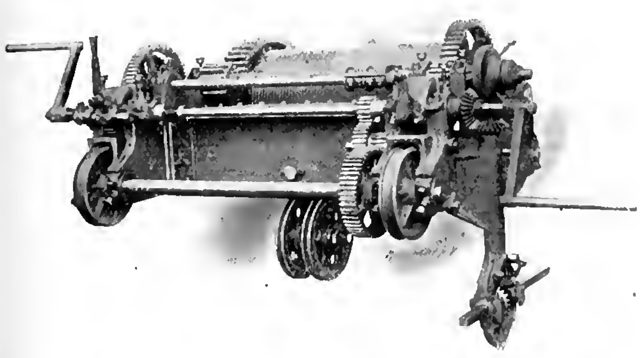

Fig. 11. Typical Crank Crane Trolley.

For wire rope sheave $2R = 18$ inches.
$x_1 = 1.021$ to $1.027 \cong 1.024$ for $2r = 1\frac{1}{2}$ inch, Fig. 7.
$x_1 = 1.022$ to $1.028 \cong 1.025$ for $2r = 1\frac{3}{4}$ inch, Fig. 8.
$x_1 = 1.024$ to $1.030 \cong 1.027$ for $2r = 2$ inches, Fig. 9.

For the loose sheaves x_2 and x_3 we have for chain, if $a = 180$ degrees, $2R = 10$ inches:
$x_2 = 1.044$ to $1.054 \cong 1.049$ for $2r = 1\frac{1}{2}$ inch, Fig. 7.
$x_2 = 1.048$ to $1.058 \cong 1.053$ for $2r = 1\frac{3}{4}$ inch, Fig. 8.
$x_2 = 1.052$ to $1.062 \cong 1.057$ for $2r = 2$ inches, Fig. 9.

Using wire rope, $2R = 18$ inches:
$x_2 = 1.0246$ to $1.0312 \cong 1.0279$ for $2r = 1\frac{1}{2}$ inch, Fig. 7.
$x_2 = 1.0267$ to $1.0333 \cong 1.0300$ for $2r = 1\frac{3}{4}$ inch, Fig. 8.
$x_2 = 1.0289$ to $1.0355 \cong 1.0322$ for $2r = 2$ inches, Fig. 9.

and for equalizing sheaves x_3 if $2R = 15$:
$x_3 = 1.0299$ to $1.0363 \cong 1.0331$ for $2r = 1\frac{1}{2}$ inch, Fig. 7.
$x_3 = 1.0321$ to $1.0388 \cong 1.0335$ for $2r = 1\frac{3}{4}$ inch, Fig. 8.
$x_3 = 1.0346$ to $1.0413 \cong 1.0380$ for $2r = 2$ inches, Fig. 9.

According to the above values for x_1, x_2, x_3, we get for the required holding or brake pull $F_1 = Q$ for lowering the load L, from equations (8, 8a, and 8b), the numerical values:

Fig. 7. $L = 6{,}000$

$$Q = \frac{6{,}000}{1.042\ (1 + 1.049)} = 2{,}801 \text{ pounds for chain.}$$

$$Q = \frac{6{,}000}{1.024\ (1 + 1.0279)} = 2{,}890 \text{ pounds for wire rope.}$$

Fig. 8. $L = 10{,}000$

$$Q = \frac{10{,}000}{1.042\ (1 + 1.049)\ (1 + \overline{1.049}^2)} = 2230 \text{ pounds for chain.}$$

$$Q = \frac{10{,}000}{1.024\ (1 + 1.0279)\ (1 + 1.0279 \times 1.0331)} = 2335 \text{ pounds for wire rope.}$$

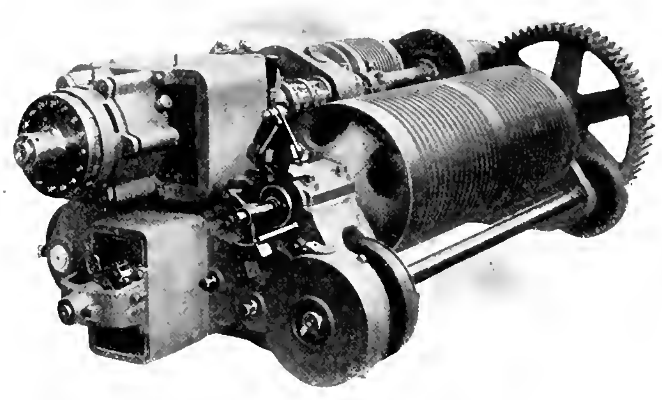

Fig. 12. Typical Two-motor Crane Trolley.

Fig. 9. $L = 20{,}000$

$$Q = \frac{20{,}000}{1.042\ (1 + 1.049)\ (1 + \overline{1.049}^2 + \overline{1.049}^4)} = 2775 \text{ pounds for chain.}$$

$$Q = \frac{20{,}000}{1.024\ (1 + 1.0279)\ (1 + 1.0279 \times 1.0331 + \overline{1.0279}^2 \times \overline{1.0331}^2)} = 3020 \text{ pounds for wire rope.}$$

In the hoisting direction, the pull or tension $F_h = x F_1$ for this kind of rope distribution. In other words, we have to multiply the above with the total coefficient of efficiency:

Fig. 7. $L = 6000 \begin{cases} F_h = x_1^2 x_2\ Q = 1.139 \times 2801 = 3190 \\ F_h = x_1^2 x_2\ Q = 1.078 \times 2890 = 3115 \end{cases}$ as above

Fig. 8. $L = 10000 \begin{cases} F_h = x_1^2 x_2^3\ Q = 1.253 \times 2230 = 2794 \\ F_h = x_1^2 x_2^2 x_3\ Q = 1.145 \times 2335 = 2674 \end{cases}$ as above $x_3 = x_2$

Fig. 9. $L = 20000 \begin{cases} F_h = x_1^2 x_2^5\ Q = 1.379 \times 2775 = 3827 \\ F_h = x_1^2 x_2^3 x_3^2\ Q = 1.215 \times 3020 = 3669 \end{cases}$ as above $x_3 = x_2$

Above results show that, according to existing chain and wire rope tables, the sizes of chains or wire ropes were chosen about right in the beginning. Otherwise, new calculations with respective changes in the dimensions would be required. The figures also show plainly that in general a chain rigging requires more power than a wire rope rigging.

Figuring out, now, the resistance in traversing the crab due to the rigging only, from 9, 9a and 9b:

Fig. 7. $L = 3$ tons $\begin{cases} P_r = 0.093 \times 2801 = 260 \\ P_r = 0.053 \times 2890 = 153 \end{cases}$ as above

Fig. 8. $L = 5$ tons $\begin{cases} P_r = 0.203 \times 2230 = 452 \\ P_r = 0.118 \times 2335 = 276 \end{cases}$ as above

Fig. 9. $L = 10$ tons $\begin{cases} P_r = 0.323 \times 2775 = 896 \\ P_r = 0.187 \times 3020 = 565 \end{cases}$ as above

And summarizing at last the total pull P_c for the crab, we get from $P_c = P_t + P_r$.

Fig. 7. $L = 3$ tons $\begin{cases} P_c = 976 + 260 = 1236 \text{ pounds for chain} \\ P_c = 976 + 153 = 1129 \text{ pounds for wire rope} \end{cases}$

Fig. 8. $L = 5$ tons $\begin{cases} P_c = 1623 + 452 = 2075 \text{ pounds for chain} \\ P_c = 1623 + 327 = 1950 \text{ pounds for wire rope} \end{cases}$

Fig. 9. $L = 10$ tons $\begin{cases} P_c = 3240 + 754 = 3994 \text{ pounds for chain} \\ P_c = 3240 + 565 = 3805 \text{ pounds for wire rope} \end{cases}$

In the preceding examples we have again demonstrated the old fact that comparatively a much higher efficiency of wear in ropes, étc., as well as of motive power, can be attained from the individually or direct driven cranes now in general use, Figs. 10, 11 and 12. In practice, there are, however, sometimes, the factors of first cost, frequency and speed of handling, etc., which suggest a much cheaper and simpler hoist.

* * *

CONSTRUCTION OF THE DETROIT RIVER TUNNEL.

The building of a railroad tunnel in a shipyard would seem to be about on a par with the manufacture of post-holes in a factory, but that, in part, is actually what was done in the construction of the Detroit River tunnel which is to connect Windsor in Canada with Detroit in the United States. It is being built by the Lake Shore & Michigan Southern Railroad, which for many years has maintained a costly car ferry service there for its freight and passenger traffic. The tunnel is being built to give an all-rail connection, and will contain two tracks, or rather, the twin tubes will contain two tracks, there being a tube for each track. The river bed is of a character that discouraged the building of a tunnel close to the river-bed surface, and this location was highly desirable in order to keep the dip down under the river within a limit (41 feet) that would give a readily negotiable grade. In fact, it was desirable that the tunnel should be actually above the river bed at its deepest parts in order to keep within the desired grade, and the construction employed permitted this to be done.

The method adopted is largely the plan of Mr. W. J. Wilgus, formerly vice-president of the New York Central Railroad, and broadly consists of dredging a ditch or channel across the river bed and sinking a pair of steel tubes in the bed thus prepared. The twin tunnel tubes were built in sections 260 feet long, ten sections in all. Each tube is 23 feet 4 inches diameter, and is built of ⅜-inch steel plate. The twin tubes are joined sideways by transverse steel plate diaphragms which embrace the tubes and project beyond them a short distance all around. The diaphragms are spaced about 12 feet apart and are an important part of the construction. The accompanying cut shows one of the twin tunnel sections being floated down the river from the shipyard at St. Clair. They are enclosed in a scow-like structure composed of 3-inch planks bolted onto the ends of the diaphragm sheets. The ends of the tubes were planked across also, the tubes then displacing water sufficient to float them. The end planking served the purpose of floating the twin tubes to the desired location and the side planking formed a cofferdam or enclosing box for tons of liquid cement that were poured around the tubes after they were sunk into the river bed and connected. When completed the tunnel will consist of a massive concrete shell surrounding the steel tubes.

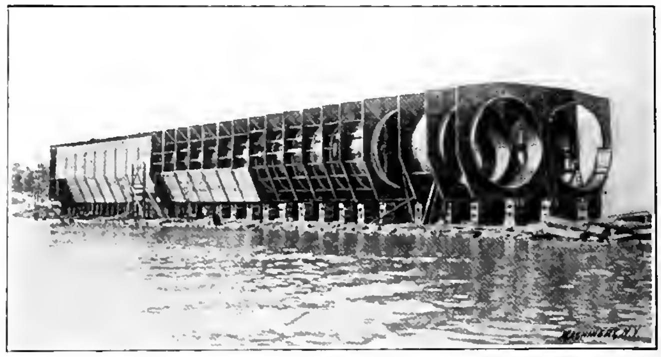

Fig. 1. Section of Tunnel in St. Clair Shipyard, showing Diaphragm Construction.

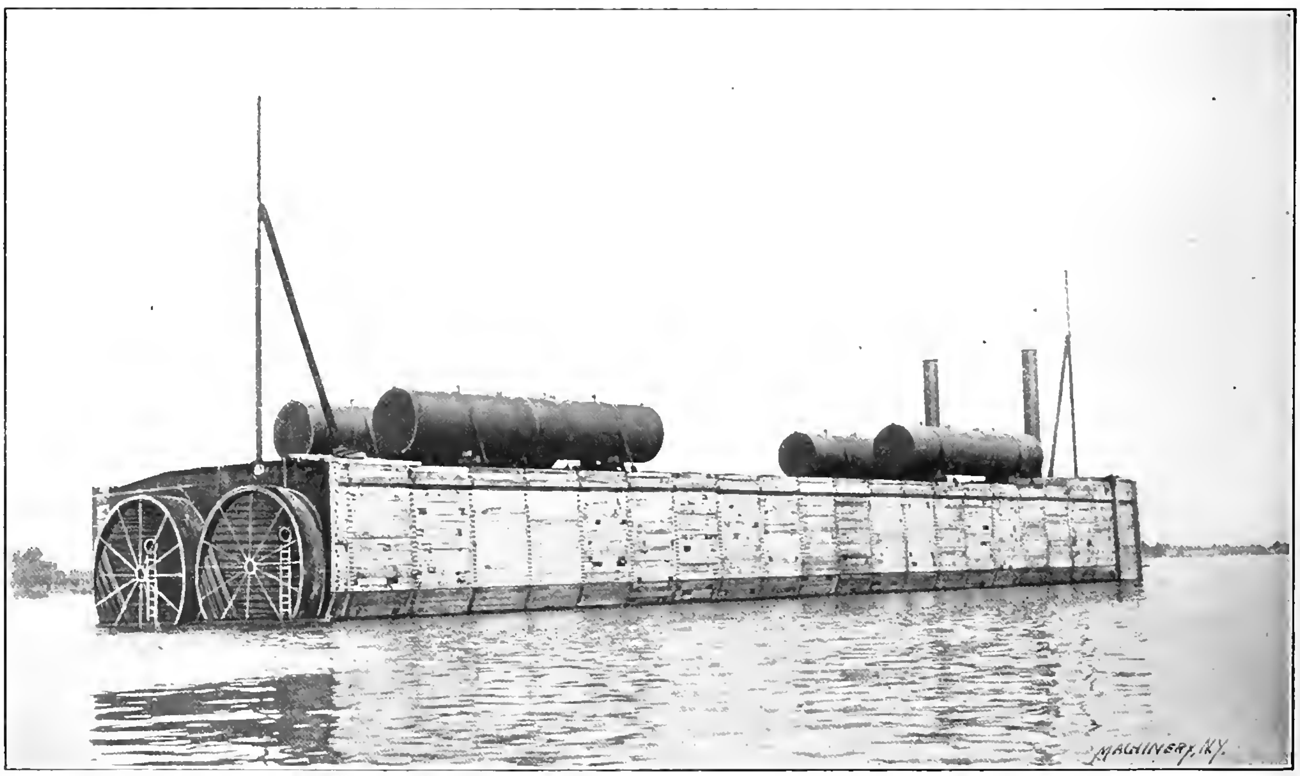

Fig. 2. Complete Tunnel Section being Floated down the River to the Tunnel Location, where it was Sunk to the River Bed.

The cylinders shown on top of the tunnel section are temporary attachments employed for slowly lowering the section to the river bed. An idea of the size of the section is obtained from the fact that the four cylinders are each 10 feet diameter and 60 feet long. After they have served their purpose in lowering a section they are raised and used again on the succeeding sections.

The sub-aqueous section of the tunnel is 2,625 feet long, the westerly open cut 1,540 feet, the westerly approach 2,129 feet, easterly approach 3,193 feet, easterly open cut 3,300 feet, making a total distance of excavation 12,786 feet, or a trifle more than 2.42 miles. The tunnel will cost $10,000,000 and will be completed by June, 1909. Its annual capacity will be 1,000,000 cars, or three times the present facilities afforded by the car ferries.

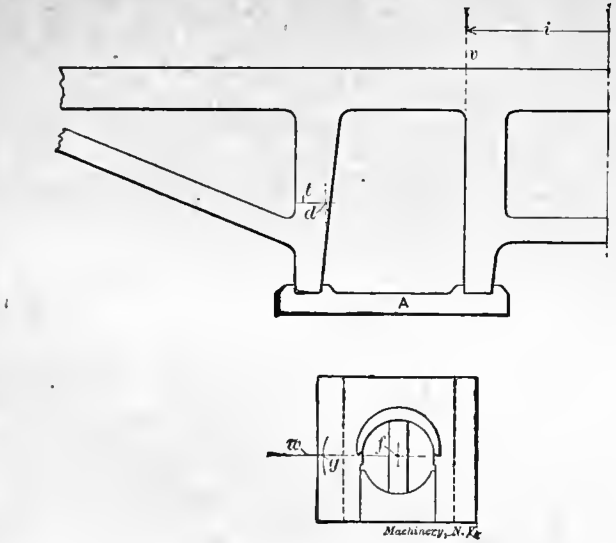
SHOP OPERATION SHEET NO. 43.

Franklin D. Jones. MACHINERY, November, 1907.



To Line Up Locomotive Shoes and Wedges.

1. Run fine lines through each cylinder, and let them extend back of the main jaws. Set the lines perfectly central with the front and back counterbores of the cylinders.

2. Place a straight-edge, *B*, upon the supports *C*, and across the faces of the front main jaws. Set the straight-edge *B* at right angles to the lines through the cylinders.

3. Scribe horizontal lines *t* on the inside and the outside of all back jaws, keeping the distance from the top of the frame to these lines, equal to the distance from the top of the frame to the center of the straight-edge *B*.

4. Hold a pair of hermaphrodite calipers against the straight-edge *B*, and scribe arcs intersecting those horizontal lines *t* which are on the main back jaws. The points of the intersection of these lines, will be the square centers *a*.

5. Remove the straight-edge *B*, and clamp both main wedges *D* in position, placing them about 1/4 inch above the pedestal braces, as shown by the dotted lines. Place a square on top of the frame, and scribe a line *r*, from the inner top edge of each main wedge *D*. Remove the wedges.

6. Insert between the pedestal braces and the frames, on both sides, wooden centers *E*, placing them flush with the outside of the frames. Scribe lines *s*, *u*, and *v*, from the faces of each front jaw, on both sides of the engine. With a pair of dividers, locate the center *b*, midway between the lines *r*, and *s*. Scribe a line at right angles to the top of the frame, through the center *b*, and down far enough to intersect the horizontal line *t*. The intersection of these two lines is the jaw center *c*. In a similar manner, locate the jaw center on the opposite side of the engine. With a pair of dividers, see if the distances from the square centers *a*, to the jaw centers *c*, are equal on both sides of the engine. If they are not,

To Line Up Locomotive Shoes and Wedges (Continued).

move one jaw center forward, and the other backward, one-half the difference, making the distances equal.

7. Set a long pair of trammels, equal to the distance *i*. Try the corresponding distance on the opposite side of the engine. If these two distances are not equal, move the trammel point one-half the difference; then with one trammel point into the main square center *a*, scribe an arc intersecting the horizontal line *t*. The point of intersection will be the square center *d*. In a similar manner, locate a square center on the inside of the jaw, also on both sides of the opposite jaw. Now set the trammels to the distance *j*, try the opposite side; if there is a difference, again move the trammel point one-half this difference, and proceed to locate square centers *e* as before.

NOTE.—When the connecting-rods have solid ends, set the trammels to the length of the rods when locating square centers *d*, and *e*, from the main square center *a*.

8. Place all driving boxes on the floor in their respective positions, with their tops toward the rail, and their outer sides upward. Locate the centers *f*, which represent the centers of the axles. On the outside back flange of each box, scribe lines *w*, through the centers *f*, and at right angles to the back edge of the flange. Now set a pair of dividers equal to the distance from the main jaw center *c*, to the square center *a*. Transfer this measurement to all the driving boxes, locating the centers *g*.

9. Remove the wooden centers *E*, and clamp all the shoes in their respective positions. Hold the transfer plate *F* against the front face of one of the driving boxes, and set the hermaphrodite calipers to the distance *k*. Now insert the point of the calipers into the square center of the jaws to

To Line Up Locomotive Shoes and Wedges (Continued).

which the box belongs—say square center *e*—and determine the thickness of the liner to be riveted to the shoe. Remove the shoe and rivet a liner of the required thickness to the back, allowing an extra 1/32 inch for planing the face of the shoe.

10. After liners have been riveted to all the shoes, again clamp them in position, and beginning with, say shoe *G*, chip away a small spot *s*, on the face of the shoe just opposite the square center *e*. Chip and file this spot, until the hermaphrodite calipers set to distance *k*, touch it lightly. Chip and file a second spot, opposite the inside square center, until the hermaphrodites (calipering from the inside square center) touch the spot lightly as before. Scribe a line *x*, which is at right angles to the top of the frame, on the outside flange of the shoe.

11. Clamp all wedges in position, placing them 1/4 inch above the pedestal braces. Caliper each box, and determine the thickness of the liner to be riveted to each respective wedge, adding enough to allow for planing.

12. After liners have been riveted to all the wedges, again clamp them in position, and beginning with say wedge *H*, chip and file spots on the face of the wedge, opposite the spots *s* on the face of the shoe, making the distance between them equal to the thickness *l*, of the driving box. Scribe a line *y* on the flange of the wedge, parallel to the line *x*.

NOTE.—After all the shoes and wedges have been treated in this way, they are ready to be planed. They will be set lengthwise on the planer by the lines *x* and *y*, and crosswise by the spots *s*, which are parallel with the square centers. The planer tool should just scrape these spots, allowing them to remain visible.

EMERGENCY METHODS IN GEAR CUTTING.

The accompanying cuts tell the story of two jobs of gear cutting which were performed in rather unusual ways. The pictures were taken in the shops of Gould & Eberhardt of Newark, N. J. The work illustrated was done some little time ago, but it is not less interesting on that account.

Fig. 1 shows the way in which a wide face internal gear was cut. The length of the travel required for milling the teeth was considerably greater than it was possible to obtain with the usual internal gear-cutting attachment for the automatic gear cutter. The teeth also were quite large (being 4-pitch), so that an internal attachment would have been worked nearly to its limit in forming the teeth. On account of these difficulties, when the order for cutting this internal gear came to the shop, the ingenuity of the man in charge of the work was at once taxed to provide some means of completing it accurately and cheaply. The half-tone shows so well how this was done that little description is needed.

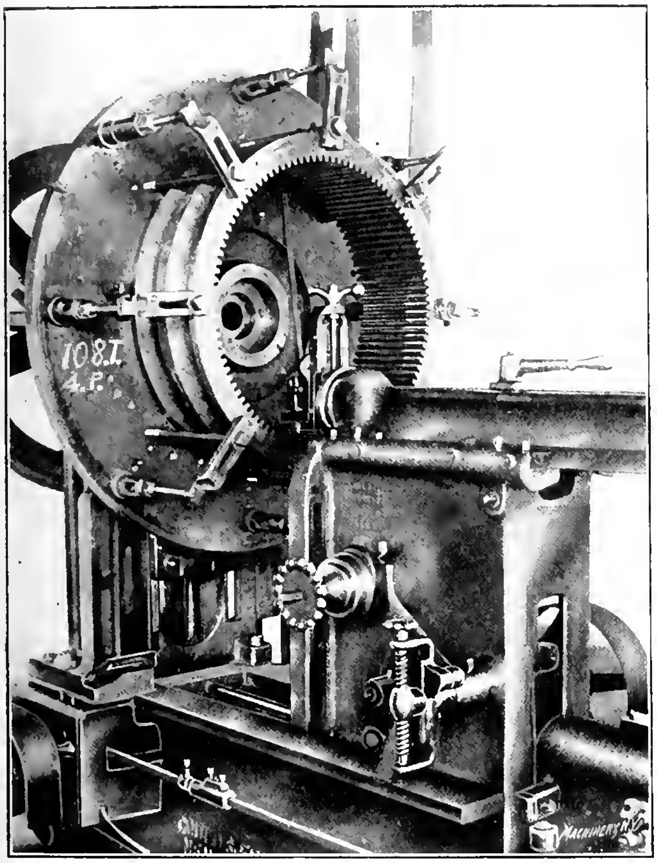

Fig. 1. A Hybrid Machine, at Work on a Wide-faced Internal Gear.

As may be seen, the cutter slide was removed from an automatic gear cutter, and the column of a shaper clamped in place on the plane top of the machine in its stead. The work was clamped on the face-plate in the usual manner, and the proper change gears placed on the machine for the required indexing. Roughing and finishing tools properly shaped for the teeth of the gear were provided, and used in the regular tool-post of the shaper. The work spindle was raised to bring the work to the proper height in relation to the tool. With the shaper driven at the proper speed from a temporary countershaft, the teeth were worked out by feeding the tool-post of the shaper down by hand. When a tooth had been cut to the proper depth, the tool was raised again, and the work indexed, the operator tripping the indexing mechanism, which was connected with the countershaft.

Fig. 2 shows an unusually large pair of spiral gears for operating some large valves in the New York Subway power house. Figs. 3 and 4 show how the teeth were cut in the larger of these two gears. At present, the shops are fully equipped with machinery which makes it possible to handle spiral gearing of this size without resorting to unusual means, but at the time the work was done there was only one machine in the shop capable of handling it, and that was over-burdened with work to such an extent as to make it inadvisable to change off to cut the teeth in this gear, if it could be avoided. Therefore an engine lathe was rigged up as shown.

Fig. 4 shows best the details of the special rigging used. In spite of its apparent complexity, it is almost entirely composed of parts of other machines and involves very little that

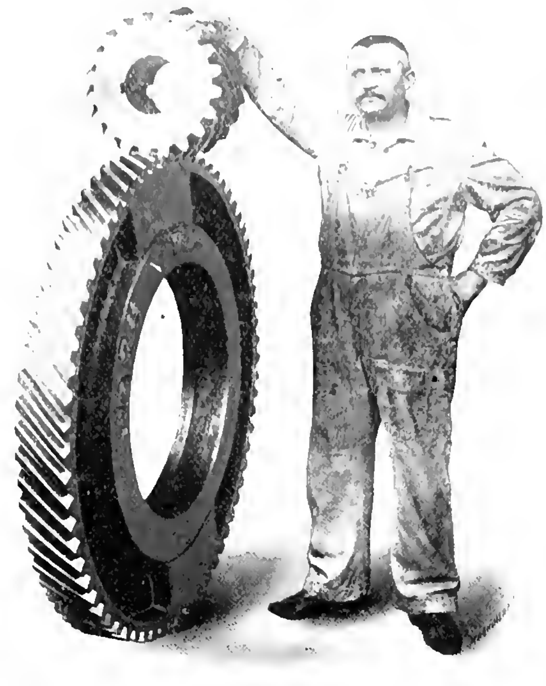

Fig. 2. A Pair of Spiral Gears of Unusual Size.

had to be made specially. As may be seen in Fig. 3, the teeth are cut by end mills formed to the normal section of the tooth spaces desired. Two roughing and one finishing cutter are shown. A suitable head, *F*, Fig. 4, with a spindle for these end mills, was provided, and fastened to the tool slide of a New Haven lathe of about 4 or 5 feet swing. This spindle was driven by a pressed steel pulley, *P*, belted to an electric motor, *G*, temporarily brought into position for that purpose; a pair of intermediate weighted idlers on arm *E* served to keep the belt tight and still allow movement to the spindle.

In cutting a spiral, it is necessary to rotate the work and

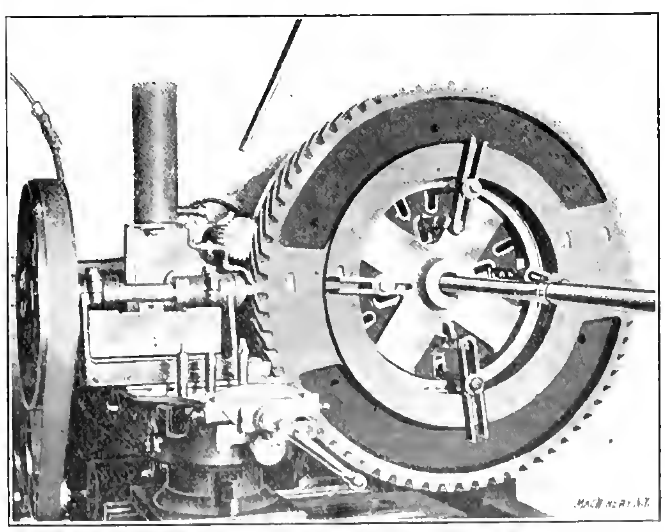

Fig. 3 View of Completed Gear in Lathe.

feed the tool longitudinally at the same time. The connection between these two movements must be positive, with the proper ratio to give the pitch of spiral desired. To effect this, a spur gear of large diameter was clamped between the work and the face-plate, as shown at *A* in Fig. 4. This meshed with pinion *B*, keyed to a shaft which, at its other end, carried gear *C*, which is the first of a train of gearing ending in pinion *D* on the feed screw of the compound rest of the lathe. The top slide of the compound rest, as shown, was arranged to be parallel with the lathe spindle. With this arrangement and with gears of the proper ratio between *C* and *D*, if the

feed motion of the compound rest is operated, it is evident that the face-plate and the work will be revolved at a ratio producing the spiral desired for the gear being cut. To obtain a power feed, the following mechanism is used. Driving pulley O of the motor was wide enough to accommodate, beside the spindle driving belt, a narrower one driving pulley K, which was supported in boxes mounted in lathe steady rests H, suitably located and fastened for the purpose. The shaft driven by pulley K carried at its inner end a bevel gear meshing with another shaft, supported in the same way by lathe steady rests. This shaft carried a small pulley L, belted to the lower feed cone of the lathe. From here the feed mechanism is carried to the feed screw of the compound rest, through the usual lathe mechanism. It is understood, of course, that the regular spindle drive was not used at all, the driving belt being thrown off and the cone and back gears thrown out, so that the only motion imparted to the face-plate was that due to the compound gearing connecting it with the feed mechanism of the cutter spindle.

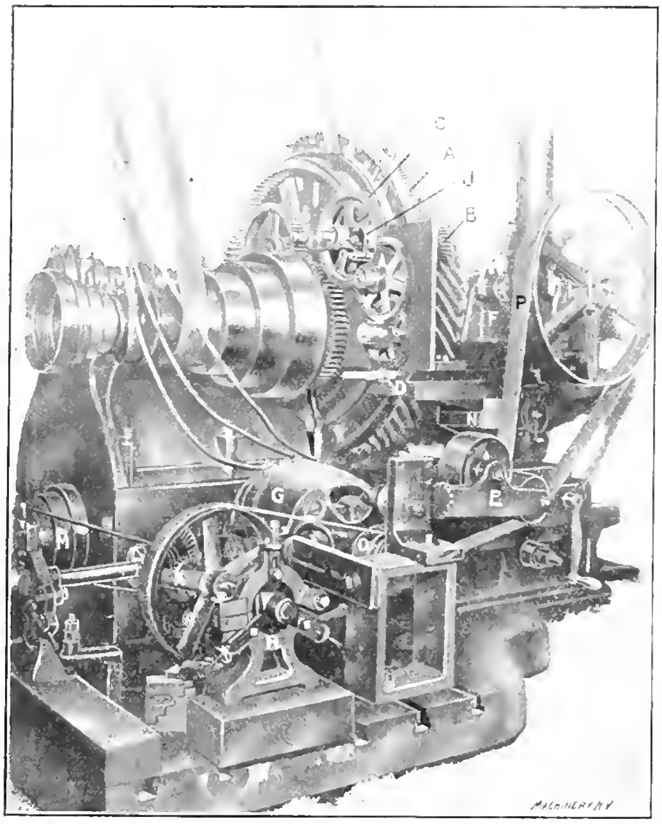

Fig. 4 New Haven Lathe, Rigged up to Cut Spiral Gears.

Provision had to be made for indexing, of course. Owing to the selection of a suitable number of teeth for gears A and B, this was done quite simply. Gear C is loose on its shaft, and arm J is pinned to it. This arm carries a locking-pin, as shown, which may engage with either one of eight holes in the rim of gear C. After one tooth has been cut, the locking-pin in arm J is withdrawn, and the arm rotated the required number of holes in the rim. This rotates the face-plate and the work independently of the spiral mechanism. For withdrawing the cutter from the work to return it for a new cut, and also for adjusting the depth of the cut, it is necessary to use some other means than the regular cross slide of the carriage. This had to be located permanently in position in order to keep pinion B properly in mesh with gear A. To give the cutter the required adjustability in and out from the center line of the lathe, the head on which it is mounted is arranged to slide in and out on a supplementary base which is clamped to the slide, X, of the compound rest.

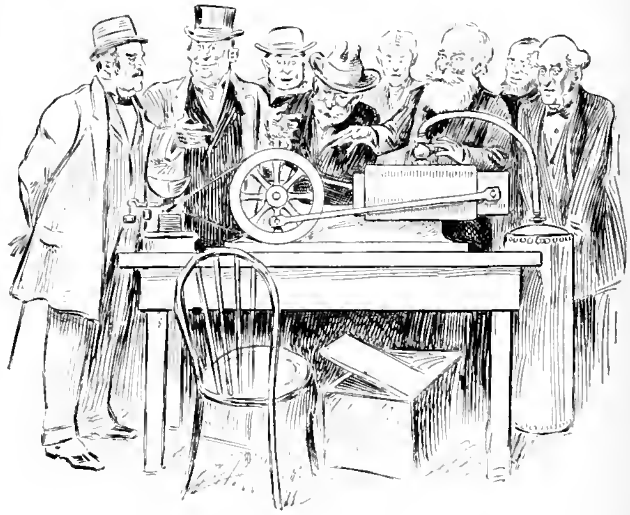
These photographs are interesting as showing what can be done if it has to be done. The rigging up of the second job was somewhat complicated, perhaps, though justified by the circumstances. The first arrangement shown is one worth while remembering. While it is a makeshift combination, it is by no means an inefficient one, and may well take a place in accepted practice for work of unusual dimensions.

DEMONSTRATING AN INVENTION.

M. E. CANEK.

We all are like the man from Missouri—"we want to be shown;" so if you have an invention that makes two blades of grass grow where only one grew before, so to speak, the way to change your opponents' ridicule into open admiration is to actually demonstrate that you can do what you claim.

In this way reasoned Algernon Stonesaw, who had discovered a fact utterly missed or ignored by all steam engineers or designers from the time of the immortal Watt down to the existing NOW—and Stonesaw. "What is this alleged fact?" you inquire. Simply that in any ordinary engine cylinder—steam or gas—at least half the power is wasted because the pressure on the cylinder head is not utilized! There the piston is working back and forth under thousands of pounds pressure, but the cylinder head stands stock-still doing not an ounce of work. "Now," reasoned Stonesaw, "if I provide a movable cylinder head in the form of a second piston and connect it to the crankshaft with a connecting-rod or a pair of them, I will get twice the power." So forthwith he built an engine having two pistons in one cylinder bore, one piston being connected to the crankshaft in the usual way, and the other connected to it by a pair of connecting-rods alongside the cylinder.



"Here is a practical demonstration of the value of our idea, gentlemen."

After having completed the model he made a trial and found to his satisfaction that his logical deduction was sustained by the facts. Thereupon followed the period of forming a stock company with the very modest capital of $60,000 (considering the importance of the invention) and the floating of the stock. The eminent patent lawyer, S. Moothtalk, who had taken out the solemnly-worded patent papers by which this great invention was protected, was made chief promotor. But somehow the public seemed shy. Mechanical engineers had a very irritating way of saying that the thing could not develop an ounce of power more than an ordinary engine for the same steam or gas consumption.

Stonesaw proceeded to show them that they were mistaken, and his original model was brought to New York and rigged up in a handsome office for the purpose of demonstration. In the absence of a boiler plant, a cylinder of carbonic acid gas was installed which added a certain degree of scientific mystery to the outfit. Then a small prony brake was rigged on the flywheel, and all was ready for the "before-and-after-taking" test. The double connecting-rods attached to the rear piston were disconnected and the rear piston blocked. Then with 80 pounds pressure the single piston driving the crankshaft was able to sustain a load of say 25 pounds at the end of a lever arm one foot long. Having shown the utmost power obtainable by this rig to the assembled and admiring spectators, Stonesaw would quickly attach the forked connecting-rods and release the rear piston. Upon turning on the pressure, the prony brake would now sustain a load, not of 25 pounds only, but of over 50 pounds. And then the chief promotor would say: "Here is a practical demonstration of the value of our idea, gentlemen. How much stock will you take?"

ACME AND SQUARE THREAD TAPS IN SETS.*

While it has not become the generally adopted custom to make the three taps in a set of hand taps with the U. S. or V standard thread of different diameters, so that each tap cuts a certain proportion of the metal to be removed in forming the thread, this construction becomes imperative when making taps with Acme or square threads. The reason for this is that the pitch of the thread of taps with the latter class of threads is usually coarser for corresponding diameters, and the same size tap is therefore required to remove more metal in this case than if it were provided with 60-degree threads. The shape of the Acme and square threads, with their wide flats at the top of the thread, also increases the

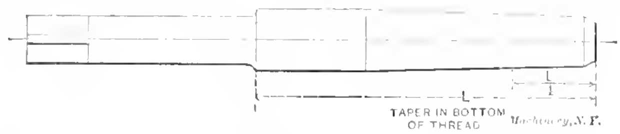


Fig. 1. General Appearance of Acme Thread Tap.

resistance to the cut, if the full depth of the thread should be produced with one tap. For these reasons Acme and square thread taps, intended for cutting a complete thread from a nut blank, and not intended merely for finishing a thread cut in a lathe, are always made in sets, each tap in the set being smaller in diameter than the one following.

While for Acme and square thread taps, three taps in a set are undoubtedly the most common, these taps may be made with only two taps in a set for very fine pitches, and with as much as five taps in a set for very coarse pitches. The last tap in these sets is not made on the principle of a bottoming tap, as Acme and square threads are seldom used except in nuts which are threaded straight through. There is, in fact, a more liberal chamfer on all the taps in the set than is common with ordinary taps.

Formulas for Diametral Dimensions of Acme and Square Thread Taps in Sets.

On account of the clearance required, by the standard formulas for Acme threads, on the top of the thread between the screw and the nut, the actual diameter of the last or finishing tap in the set must be larger than the standard or nominal diameter of the screw. If

A = actual diameter of finishing tap, and

B = root diameter of the thread,

the relations of these values to the nominal or standard diameter of the tap are

A = nominal diameter + 0.020 inch.

B = nominal diameter —

$$\left(\frac{1}{\text{No. of threads per inch.}} + 0.020 \text{ inch.}\right)$$

In the square thread there is no standard clearance allowed on the top of the thread, and as the depth of the square thread equals one-half of the pitch, we have:

A = nominal diameter of tap, and

B = nominal diameter — pitch of thread.

As mentioned above, the most common way of making Acme and square thread taps is to make them with three taps in a set. The values necessary to obtain the diameter of the various taps in the set are given for Acme taps in Table I, and for square thread taps in Table II. These values are determined for Acme taps by means of the following formulas:

Diameter of first tap $= B + 0.45(A - B)$,

Diameter of second tap $= B + 0.8\ (A - B)$,

in which formulas (as before)

A = actual diameter of finishing tap = nominal diameter + 0.020 inch.

B = root diameter = nominal diameter —

$$\left(\frac{1}{\text{No. of threads per inch}} + 0.020 \text{ inch.}\right)$$

TABLE I. TABLE FOR MAKING ACME THREAD TAPS IN SETS OF THREE TAPS.

TABLE II. TABLE FOR MAKING SQUARE THREAD TAPS IN SETS OF THREE TAPS.

No. of Threads per inch.	Amount in inches to be Added to Root Diameter of Tap to Obtain Diameter of Straight Part of Thread of		No. of Threads per inch.	Amount in Inches to be Added to Root Diameter of Tap to Obtain Diameter of Straight Part of Thread of	
	1st Tap.	2d Tap.		1st Tap.	2d Tap.
1	0.410	0.800	5	0.082	0.160
1½	0.273	0.533	5½	0.075	0.146
2	0.205	0.400	6	0.068	0.133
2½	0.164	0.320	7	0.059	0.114
3	0.137	0.267	8	0.051	0.100
3½	0.117	0.229	9	0.046	0.089
4	0.102	0.200	10	0.041	0.080
4½	0.091	0.178	12	0.034	0.067

For the square thread, Table II, the values are derived from the formulas:

Diameter of first tap $= B + 0.41(A - B)$,

Diameter of second tap $= B + 0.8\ (A - B)$,

in which formulas (as before)

A = actual diameter of tap = nominal diameter of tap.

B = root diameter = nominal diameter — pitch of thread.

The diameter at the end of the chamfer of the first tap should be equal to the root diameter of the thread + 0.010 inch. The diameter at the end of the chamfer of the second and third taps should be equal to the diameter of the straight portion of the next preceding tap — 0.005 inch.

It must be understood that the figures given in the tables possess a certain degree of flexibility, inasmuch as the making up of formulas necessarily requires some assumed standard to be selected embodying the best practice. Certain conditions may require deviations from the rules given. While the tables may not suit all possible conditions, they are made up so as to suit ordinary needs, and they are particularly valuable in suggesting the possibility of systematizing the making of tools altogether too often given up to guess work. In using

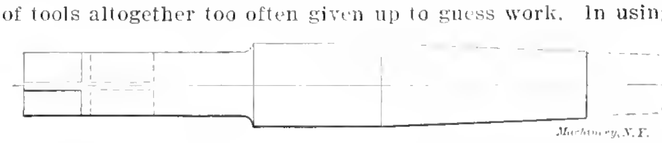

Fig. 2. Construction of Acme Thread Tap when Provided with Pilot.

Tables I and II, it is necessary first to find the root diameter by subtracting the double depth of the thread from the nominal diameter of the tap, and then add the amount stated opposite the pitch for the respective taps in the set.

It is difficult to draw a distinct line between hand taps and machine taps when these are provided with Acme or square threads, for while these taps are as a rule used as hand taps, the construction is that of a machine tap. In general practice, however, these taps are generally classified as hand taps.

When the dimensions for the diameter of each tap in the set have been ascertained, Table III may be used for finding the length dimensions for Acme taps, in sets of three taps, from ½ to 3 inches diameter. The dimensions in this table apply to single threaded taps. For multiple threaded taps, or taps with very coarse pitch relative to the diameter, it is advisable to lengthen the dimensions for the chamfered part of the thread, leaving the other dimensions as given in the table. The size of the square of these taps is not given, depending as it does upon the varying diameters of the shank, which in turn depend on the depth of the thread. The square

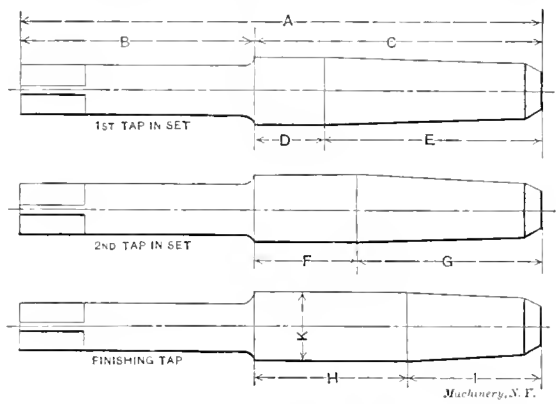
* For additional data relating to taps made in sets see the following articles previously published in MACHINERY: Acme Taps in Sets, January, 1905; Square Thread Taps in Sets, March, 1905; Proportions of Hand Taps in Sets, December, 1905.

should, however, always be made equal to ¾ × diameter of shank. Square thread taps are made according to the same table as Acme taps with the exception of the figures in the column K in Table III, representing the full diameter of the last tap in a set of Acme thread taps. In the case of square thread taps the column K should be equal to the nominal diameter of the tap, because, as has already been mentioned, no oversize allowance is customary in regard to these taps.

General Construction of Acme and Square Thread Taps.

It is here in place to point out some of the peculiarities in the construction of Acme and square thread taps. The first fap in a set should be turned to a taper in the bottom of the thread for a distance of about one-quarter of the whole length

TABLE III. DIMENSIONS OF ACME TAPS IN SETS OF THREE TAPS.



Nominal Diam.	A	B	C	D	E	F	G	H	I	K
½	4 ¼	1 ⅞	2 ⅜	½	1 ⅞	⅝	1 ¾	⅞	1 ½	0.520

of the threaded part as indicated in Fig. 1. The diameter at the root of the thread at the point of the first tap should thus be less than the standard root diameter. If the taper selected is such that the root diameter will be about 1/32 inch smaller at the point than the root diameter proper of the tap, that will be found to greatly increase the ease with which the tap can be started in the nut. The first tap in the set should also be provided with a groove or a secondary thread on top of the ordinary thread. This will aid in preventing the tap from reaming, instead of actually cutting a thread in the nut. This secondary thread may continue the full length of the chamfered portion of the first tap. The first tap should also preferably be provided with a short pilot as shown in Fig. 2 to guide the tap straight into the nut. When the pitch is very coarse, as compared with the diameter of the tap, or when the number of taps in a set is small in proportion to the work they are to perform, the first tap in the set should be provided with spiral flutes, forming a right angle with the angle of direction of the thread. In other words, the spiral of the flutes should be left-hand for a right-hand tap, and *vice versa*. This will greatly increase the cutting qualities of the tap. In fact, it evidently would increase the efficiency of all taps to flute them in this manner, but whenever it is not imperative it is avoided on account of the increased expense and difficulty.

When the first tap in a set is provided with a pilot, the diameter of this should be made a trifle smaller than the hole in the nut to be tapped (from 0.002 to 0.005 inch smaller). The length of the pilot should be about equal to the diameter of the tap, or, at least, not shorter than 0.75 times the diameter. The length of the pilot should project from the regular length of the thread of the taps in the set, but in order to make the total length of all the taps in the set the same, the length of the pilot should be subtracted from the length of the shank in the first tap. This is indicated by the dotted lines in the cut, Fig. 2, where the full lines show the second and third taps in a set, and the dotted, the pilot and the modification in the shank of the first tap.

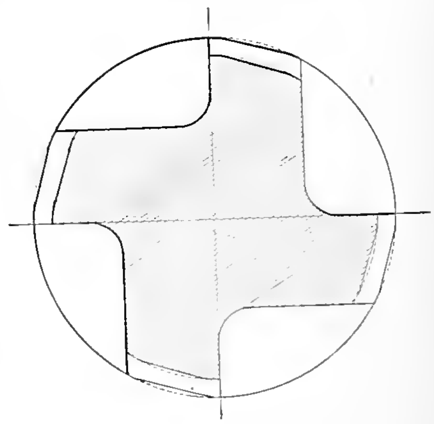

Fig. 3. Relief in the Center of the Thread.

Acme and square thread taps should be relieved on the top of the thread on the chamfered portion on all the taps in the set, and the finishing tap should be given relief in the center of the land (Fig. 3) on its straight or parallel portion. In such cases where the taps are used as machine taps, rather than as hand taps, they should be relieved in the angle of the thread, as well as on the top, for the whole length of the chamfered portion.

JAPANESE LACQUER.

According to the *Brass World*, the beautiful color found on high grade Japanese wear, produced by Japanese lacquer, has so far never been attained in any other country. While the metals and designs of Japanese goods can be readily produced, attempts to imitate the exact color and lacquering have resulted in failure. Nothing produced in America or Europe can approach it, even approximately. Japanese lacquer is the product of a tree known only in Japan, and is collected by a process similar to that used in obtaining turpentine from the pine tree. The sap is in the form of a thick white fluid; this turns dark brown and finally black. It is strained through a cloth and solidified by evaporation, after which the various varieties of lacquer are made from it by processes which are considered trade secrets. Some of it, the best quality, is bleached in the sun.

The liquid is applied to the surface of the metal with a brush and allowed to dry in a *moist* atmosphere for days. This practice is wholly unlike that of our own country, where the utmost care is taken to preserve the dryness of the room where varnishes or lacquers are baked. It is said that as many as 15 or 20 coats are given to the finest wares. The lacquer does not fade, but improves with age. It is not affected by water, spirits, nor acids. The Japanese are said to have applied it to the hulls of vessels to protect them from the action of the sea water, but the success of the trial is unknown. In the Centennial exposition at Philadelphia articles of wood were exhibited that had been in the sea for fifty years. The surface was covered with marine growths, but the lacquer remained unattacked. Crude lacquer is corrosive to the skin, and much care is required in handling it.

* * *

Many have smiled at the absurdity of "as big as a lump of chalk" or "as long as a piece of string" comparisons, but perhaps these are no more indefinite to many people than one noticed recently in a technical description of the manufacture of fountain pens. In the course of the account the writer mentions that raw rubber "is imported in lumps as large as the eggs of an ostrich." Now, when we stop to consider that perhaps not one American in 5,000 has ever seen an egg of an ostrich, the comparison has about as little significance to the average reader as the lump of chalk proposition.

LETTERS UPON PRACTICAL SUBJECTS.

GRINDING THREADING DIE CHASERS.

In the use of threading dies which must be ground at an abrupt angle to allow a full thread to be cut up to a shoulder, or to a neck, as in a set screw, the following is a common procedure. When resharpening, the dies, or chasers, as the case may be, are put in a fixture which is so arranged that the angle of the cutting edge relative to the center line of the die is the same on all the chasers, and also so adjusted that all the edges are ground to the same depth. When the die is used, however, it will often be found that in spite of

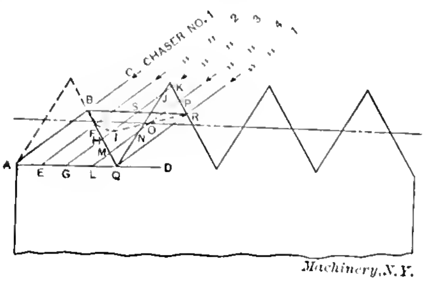

Fig. 1.

all precautions for getting the chasers similarly ground, one or two of them will be doing most of the work, and will accordingly become dull while the others are in good condition. Then the die is put back into the fixture and ground back an equal distance, on all chasers, using the same grinding angle as before, and it will often be found to be improved. Sometimes a second grinding is necessary before the die will work properly.

This matter had been brought to the writer's attention a number of times and had been the cause of a great deal of annoyance, so that an investigation of the causes was made, which resulted in the following solution of the difficulty. By grinding the chasers in accordance with this method, the trouble entirely disappeared, and it became possible to grind our chasers so that each one always did the proper amount of work.

In Fig. 1, the line *A B* represents the cutting edge of a chaser, the outline of a section of which is shown by the full lines. This chaser is ground at an angle *D A C*, with the center line, which angle will be called the grinding angle, and this angle is selected at random, as is usually the case, being in this instance rather abrupt, for cutting a full thread close to a shoulder. The total cutting edge on chaser No. 1 is *A B*. The line *E F* represents the total cutting edge on chaser No. 2, counting the chasers in a left-hand direction on a right-hand thread, and on a four-chaser die. Lines *G H* and *J K* are the cutting edges of chaser No. 3, and *L M* and *N P* the cutting edges of chaser No. 4, while *Q R* would be the cutting edge of chaser No. 1 again. In this case, chaser No. 3 is the first one to have the cutting edge divided into two or more parts. To get the total length of this, make *H I* equal to *J K*, then *G I* represents this total length. In the same way, *L O* is the total length of the cutting edge of chaser No. 4, *M O* being equal to *N P*. It will readily be seen that these cutting edges are not of the same length, and the discrepancy is made more graphic by connecting the points *B F I O R*; and also the points *B R* with a straight line. The line *B F I O R* will be called the indicating line. The distance *I S* is the amount that the cutting edge of chaser No. 1 is longer than that of chaser No. 3.

In service, a die having its chasers ground in this manner, will act as follows: Chaser No. 1 will take a broad, thin chip, and will crowd the work over on the opposite chaser, No. 3, which will be forced to carry a very thick chip, and if there is considerable difference in the length of cutting edges, this action seems to be all out of proportion to this difference. In fact, in this case, with the cutting edge of No. 3 only about 25 per cent less in length than No. 1, it probably would carry a chip three or four times as thick. By grinding the chaser back a distance *X Y* (Fig. 2), with the cutting edge at the same angle as in Fig. 1, it will be noted that the indicating line shows a much smaller variation in the length of cutting edges, those of No. 2 and No. 3 being approximately equal, and No. 1 and No. 4 also being nearly the same. The chasers will now show a marked improvement in operation. If they are ground back a little further the old trouble will reappear.

Fig. 3 shows a set of chasers which are ground at an angle of 30 degrees with the center line; that is, the grinding line connects the bottom of one thread with the top of the next thread behind. In this case it will be found, by measurement, or by reference to geometry, that the indicating line becomes straight, parallel to the center line, and midway between the top and bottom of the threads. This indicates that by grinding the chasers at this angle, the cutting edges become equal, and practice proved that each chaser will do its proper share of the work.

In Fig. 4, the grinding line connects the bottom of one thread with a point between the tops of the second and third threads behind, which makes the grinding angle less than 30 degrees and greater than 19 degrees. Here the indicating line deviates again from a straight line, but this deviation is very much less than in the first example. Fig. 5 shows a grinding angle such that the grinding line connects the bottom of one thread to the top of the third thread behind. Considering the pitch as the unit, this angle will be seen to be such that its tangent $= \frac{0.866}{2.5} = 0.34641$. This makes the angle a trifle over 19 degrees. It will readily be seen by comparing similar sides of similar triangles, that the cutting edges on all four chasers have the same length, and the indicating line is straight, as in Fig. 3.

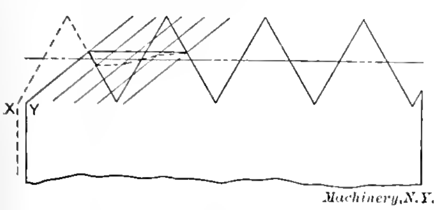

Fig. 2.

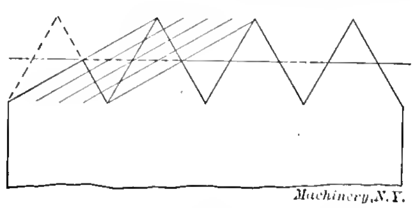

Fig. 3.

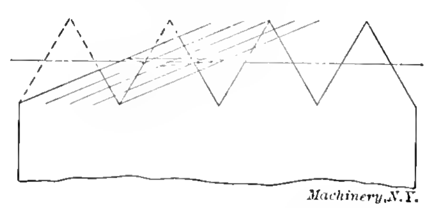

Fig. 4.

In general, in order to make the cutting edges of all the chasers equal, where the thread angle is 60 degrees, it is necessary to make the grinding angle such that its tangent will be equal to 0.866 ÷ (a whole number plus 0.5), or in other words, so that the grinding line will always be parallel to a line connecting the point at the root between two threads, with the top of some other thread. In a 60-degree thread, these angles will be found to be 60, 30, 19, 14, 11 degrees, etc. When ground at any angle less than 14 degrees, that is, with the chip distributed over four threads or more, the difference in the total lengths of cutting edges becomes negligible, and no attention need be paid to the angle other than to see that all chasers have the same angle, but as stated in the beginning, when the angle is abrupt, so that two or three threads do all the work, an observation of the foregoing

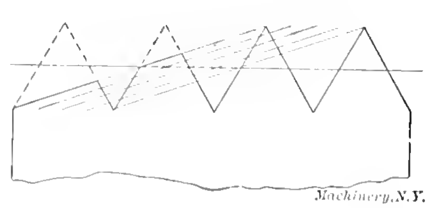

Fig. 5.

principles for securing equal lengths of cutting edges, will solve a surprising number of threading die enigmas.

Three Rivers, Mich. C. C. CLEVERDON.

OBTAINING THE PITCH OF A PROPELLER.

The word pitch, whenever applied to a propeller, is understood to mean the distance the wheel would travel forward in one revolution, provided it was working in a solid medium, as a bolt working in a nut. This is not the case with water, as it is displaced, or forced backward, causing a certain percentage of the propeller's theoretical forward movement, to be lost. This loss is generally termed the slip, and it will vary with the design of the propeller, and the conditions under which it is run. There are many ways, both graphical and mathematical, of determining the pitch of the blades of a propeller casting, but none will be found more simple than the one illustrated and discussed in this article, although, of course, the results obtained are only approximately correct.

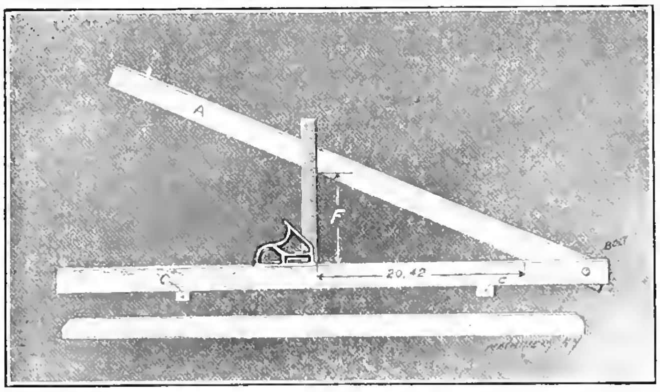

Fig. 1. The Tools necessary for obtaining the Pitch of a Propeller.

For an example, let it be assumed that the screw to be measured is 6 feet 8 inches diameter, with a pitch of 9 feet 3 inches; the latter dimension, of course, being the one to be found. In Fig. 1 is shown the necessary outfit required, consisting of three parallel strips about 36 inches long, 2 inches wide, and ¾ inch thick; also two little blocks about ¾ inch square. Two of the strips are fastened together with a bolt or screw, in the form of an angle, as shown, this arrangement permitting the adjustment of the leg *A*, while trying for the pitch. The two blocks *C* are bradded to the outer edge of the lower leg, and are intended for bearing points, as the edge of the strip would not rest evenly upon the winding surface of the blade.

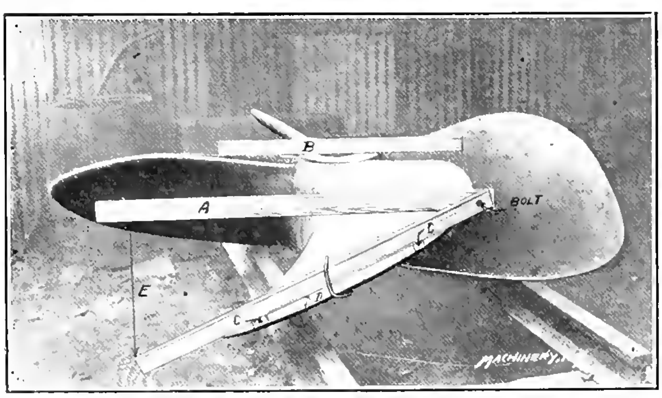

Fig. 2. Measuring the Pitch of a Propeller.

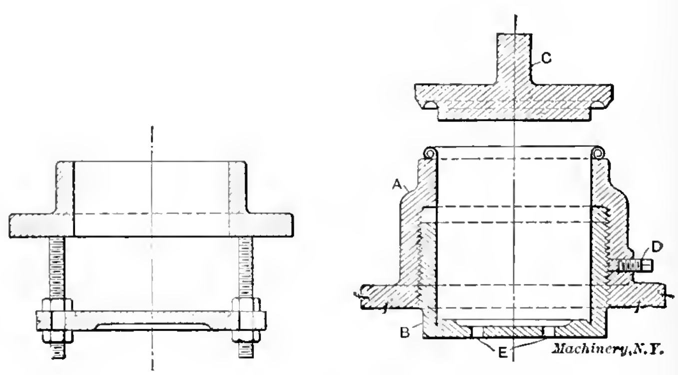
Fig. 2 illustrates the manner in which the device is applied. The strip *B* is placed across the hub, parallel with the angle, which is placed near the tip of the blade. Now, by sighting over the upper edge of the leg *A* of the angle, the leg is adjusted until it lies in the same plane as that of the upper edge of strip *B*. This operation is identical to sighting over parallels to detect the twist in a board or surface; only, in this case the leg of the angle is adjusted to suit the variation. Owing to a slight distortion, which is very apt to appear in the different blades of a screw, it is advisable to try each one, and then take the average of any difference which may be found. To obtain this variation, the distance *E* can be measured after each adjustment of the angle to the various blades, and then the angle set midway between the two extremes, for making our calculations. The distance *D*, which is the horizontal distance between the angle and the tip of the blade, is next measured, and then we are ready to calculate the pitch of the propeller.

Since the propeller is 6 feet 8 inches diameter, and the angle was placed 1 inch in from the tip of the blade, as shown at *D*, the diameter upon which the pitch was taken would be 6 feet 6 inches, and this diameter would have a circumferential length of 20.42 feet. Now, by applying the scale of 1 inch = 1 foot, we lay off 20.42 inches upon the upper edge of the lower leg of angle, as shown in Fig. 1, and applying a square as shown, measure the perpendicular distance *F*. This distance *F* is equivalent to the pitch of the screw, to a scale of 1 inch = 1 foot, and it would be 9¼ inches in this instance. This dimension, to a 1 inch = 1 foot scale, would equal 9 feet 3 inches, which would be the pitch of the screw. The reason for the above method is: since a true screw is formed by a right angle triangle wrapped around a cylinder, the base of said triangle will equal the circumference of the screw, the perpendicular will equal the pitch, and the hypothenuse will equal the length of the winding thread or helix.

Cleveland, O. H. J. MCCASLIN.

TWO CURLING DIES.

In Figs. 1 and 2 are shown two adjustable curling dies, such as are used for the curling, or false wiring, of straight tin buckets. Dies of this style can be used for curling the rims of buckets of various depths, by adjusting the bottom of the die to the depth of the bucket to be curled. The die



Figs. 1 and 2. Curling Dies for Curling the Rims of Buckets.

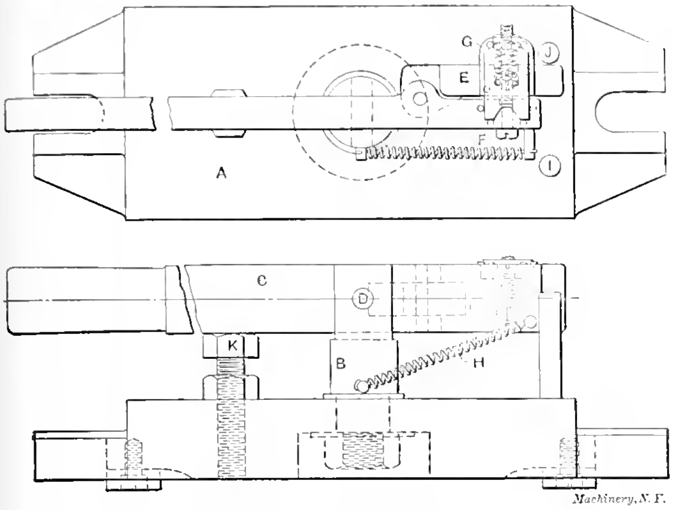
shown in Fig. 1 is an old-timer, and it was somewhat difficult to properly adjust the bottom of this die, as one side was very apt to be a little higher than the other, which caused trouble. Because of this trouble in connection with the adjustment, a new die was made, as shown in Fig. 2. The cast iron body *A* was faced off as indicated by the finishing marks *f*, and a thread cut on the inside as shown. The part *B* was then threaded to fit *A*, and these two parts were screwed together. They were then clamped to the face-plate of a lathe, and set by the finished surfaces *f* of *A*. The hole on the inside was then bored, and it was given 1/64 inch taper, so that the body of the bucket would enter with ease. The punch *C* was also made of cast iron, and finished so that it would give the diameter of curl desired.

This die is operated in a wiring press, which has a sliding table. The bottom part *B* is screwed down to nearly the depth of the bucket body, just enough stock projecting above the die to make the curl. The amount of stock required for the curl can easily be found by trial. When the part *B* is adjusted (which is done by inserting a suitable wrench in the holes *E*), it is held in place by the set screw *D*, which forces a threaded brass plug against it. At first this die was used for curling the tin over wire, but subsequently for double-curling, as shown in Fig. 2. To do this, it is first necessary to make a single curl, then screw the part *B* in about ¼ inch, and repeat the curling operation. Much time is saved when curling buckets in this way, and they are almost as strong as when wire is used. JULIUS F. A. VOGT.

Buffalo, N. Y.

SLOTTING FIXTURE FOR A HAND MILLER.

The accompanying drawing shows a slotting device, the principle of which can be applied to a variety of work where it is necessary to slot many pieces with rapidity. The part *A* is a cast iron block, which is bolted and keyed to a hand miller, and *B* is a post which swivels in *A*. At *C* is shown a lever with its fulcrum on the pin *D*. The jaw *E* is hinged to the lever and is held in a closed position by means of the spiral spring on the fillister screw *F*, the tension being controlled by lock-nuts. The tool-steel plate *G*, on which one end of the piece to be slotted rests, is screwed and doweled to the jaw *E*. The spring *H* holds the end of the lever down clear of the cutter, when it is not in operation.



Slotting Fixture for Hand Miller.

The fixture is first brought clear of the cutter by moving the machine table back; the jaws are then swung out from the machine, bringing the jaw *E* against the pin *I* which compresses the spring on *F* and thus separates the jaws, so that the piece to be slotted can be put in between the six locating pins. The pressure being then removed from the spring allows the latter to bind the piece securely in place. The lever is then swung so that the jaw *E* comes up against the pin *J*, and the lever itself rests on stop *K*. The table is then fed forward, bringing the piece against the bottom of the cutter, which slots it to the desired depth. The piece is released by a reversal of these operations. This fixture has proved satisfactory, as it is possible when the machine is ready for operation to turn out 300 pieces per hour. The principle of this fixture could be used for slotting screws.

Candiac, Canada. S. A. McDonald.

ANNEALING HIGH-SPEED STEEL.

From time to time there has appeared in the various trade papers directions for annealing high speed steel. As I have had a great deal of experience with annealing and hardening, being at the present time employed as a tool-hardener in the Government's service, and previously having been employed in this line of work in several large manufacturing establishments, I thought that an explanation of my methods might be of interest to some of the readers of Machinery.

In the first place there should be on hand a cast iron box, large enough to permit proper packing of the pieces to be annealed. Charcoal ashes or cast iron chips may be used for packing. Pack the work carefully, placing the larger pieces to the outside of the box, and the smaller pieces in the center. After the pieces are packed, they are then ready for the furnace. Heat slowly, raising the temperature to 1,470 degrees F. (dull cherry red). Then hold the heat at this point for about 5 hours, and finally raise the heat in the furnace to 1,650 degrees F. (cherry red). Shut off the fire, close the door, and let the furnace cool for 12 hours. The entire heating can be done in 5 hours, and the steel can be worked as nice as any annealed by the steel mills. This is not the only method of annealing, but it is the best method when the steel is considered.

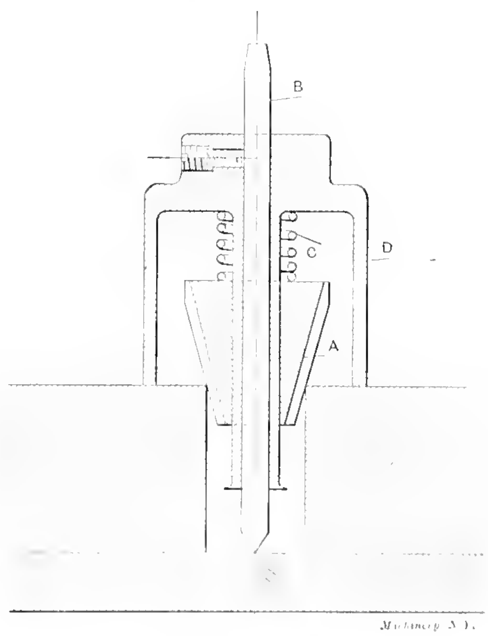
Annealing after hardening of high speed steel can be accomplished by the following method in about one hour. Where a change in the tool is required to be done quickly, I often take the tool and heat to 1,290 degrees F., then let it cool in the open air. Then heat the tool again, raising the temperature to 1,290 degrees F. (somber red), and hold it there for 40 minutes. It is then taken from the fire, and permitted to cool in the open air. When I have 5 hours to anneal in, however, I prefer the heat anneal. That I accomplish by heating the tool or piece constantly for 5 hours. After the piece has been heated for 5 hours at 1,290 degrees F. or less, I take it from the fire and let it cool in the open air. One can also raise the heat to 1,470 degrees F. (dull cherry red) and put the tool in lime to cool. Do not raise the heat to this degree, however, unless the piece is to be placed in lime. I only use these methods where a loss of time is to be considered. It is possible to anneal high speed steel at as low a heat as 977 degrees F., red visible in daylight, but this heat will not make the steel very soft.

There is also another method of annealing high speed steel. That is where a lead bath is in use. Take the piece to be annealed and place it in the lead while it is at a dull cherry red. If the lead is of sufficient bulk to hold the heat for several hours, it will not be necessary to continue the heat. Leave the work in the lead and remove it the next morning, by heating the lead again. Remove the tool as soon as the lead is hot enough not to adhere to the work. Then dip the work in oil, and then, returning to the lead bath, the lead will leave the work if the work is removed just as the oil burns off. After this the piece should be allowed to cool in the open air. Great care should be taken in heating high speed steel, as it is easily checked. C. U. Scott.

Davenport, Iowa.

CENTER PRICK PUNCH.

Having had occasion to drill a number of holes in a plate, which were to be laid out from a cumbersome piece already drilled, I had great trouble to get them located accurately. The holes were the same size as the bolts which had to enter both plates. I first tried marking out with a scriber, but owing to the number of holes this method was not satisfactory. This being a job which would be repeated, I thought it worth the punch shown in the cut. This consists of a center cone *A*,

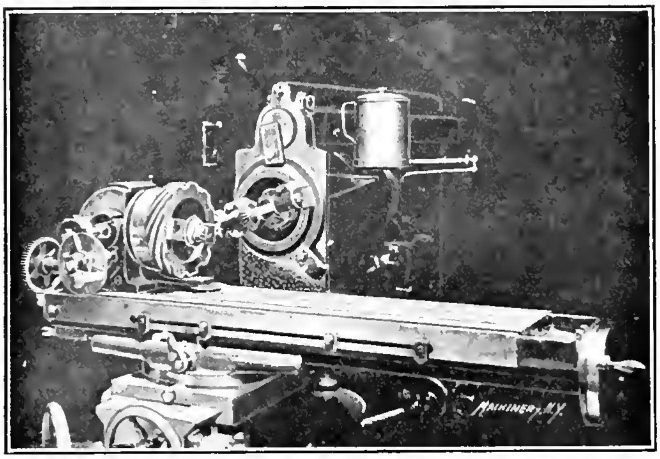


Center Prick Punch.

which is relieved so as to give a three-point contact, and serves to center punch *B* in the hole. The cone and spring *C* are placed on the body *D*, and the end knocked over as shown. The function of the body *D* is to insure the punch being perpendicular. By placing the cone in the hole and pressing the body until it rests on the top plate, the punch is accurately located in the center. With the headless screw and small spring the punch is prevented from slipping out, thus making a very neat and self-contained tool. Trixie.

HOME-MADE UNIVERSAL MILLING ATTACHMENT.

The cut shows a simple universal milling attachment, primarily intended for cutting spiral gears beyond the capacity of the universal milling machine, and illustrates plainly the cutting of a gear where the angle of the teeth is 78 degrees. Of course, the makers of milling machine attachments furnish special devices for this purpose, but they are quite expensive, and hardly as rigid or as well adapted for this particular work. As will be noticed in the design shown, the cutting is done on the side of the gear, level with the center



Home-made Universal Milling Attachment

line, instead of at the top, which greatly increases the capacity of the machine, as far as concerns the diameter of the work possible to handle. We have cut a number of spiral gears 24 inches in diameter on a No. 3 machine with this device. We have even used it for cutting some spur gears whose diameter was too large to be cut in the regular way. The whole device is extremely simple, being nothing but a circular flange fitted around the spindle bearing of the milling machine, with a pair of lugs carrying bearings, one inch in diameter, for the cutter spindle. This spindle, with its shoulder and bevel gears, is all made in one piece. The driving bevel gear is provided with taper shank, and placed directly in the tapered hole in the milling machine spindle. The circular frame or flange is clamped on the milling machine column at any angle desired, the periphery being graduated in degrees; the milling machine table, meanwhile, remains in its normal position. This device may not add to the beauty of the machine, but it has saved money.

Los Angeles, Cal. S. Byron Welcome.

GRINDING REAMERS.

Having read several articles on relief of teeth of reamers and cutters, I thought the method I use would be of interest to the readers of Machinery. I have reference to taper reamers, being ¼ inch taper per foot, and from ¼ to ¾ inch in diameter at the small end. They are used for reaming cold-rolled stock, and are used in a drill press. They must produce true, smooth holes, free from chatter marks. This has been my great trouble, as all reamers manufactured for the market have either 6 or 8 teeth, and are inclined to chatter and produce holes that are not true. I have had a six-tooth reamer ream a hexagonal hole.

The work is held in a chuck, free to move, but not to rotate, thus allowing for the reamer not being held true in the drill chuck. To get rid of the chatter marks, which I have blamed to reamers having an even number of teeth, I have made them with seven teeth, and get the best of results with them. For a roughing reamer, I made one with seven teeth, and cut a No. 4 left-hand buttress thread on same, bringing the thread to a sharp point. I left the reamer above size for grinding, and ground off the sharp points, giving a flat tooth about 1/16 inch long. I use a Cincinnati Milling Machine Co.'s grinder, using a cup-shaped wheel, the tooth rest being adjustable. The centers that support the reamer are placed as near as possible in line with the emery wheel arbor, the tooth rest is dropped to give proper clearance, about 1/16 inch for a ¾ inch reamer, and the tooth is ground at the cutting edge first. Then the tooth rest is dropped about 1/16 inch, bringing the heel of the tooth up to the wheel, and a fairly good cut taken. After each revolution of the reamer the rest is raised slightly, which gives an eccentrically shaped tooth. Care should be taken not to feed on the same tooth every time, as this will not give a true reamer, because, if the feed is used on the same tooth each time, you will find that tooth will be shorter than the rest. By this method one does not require extra centers, and I think one gets just as good results as when they are used.

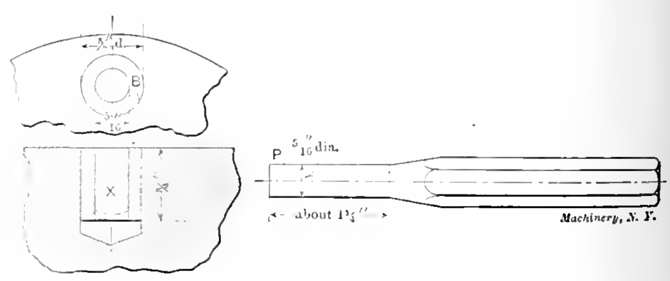
F. P. Hebard.

Muscatine, Iowa.

[The subject of preventing chatter in reamers is one that has caused many different opinions to be expressed. It seems certain, however, that if there is an even number of flutes in a reamer, if the cutting edges are unevenly spaced, the same satisfactory result should be obtained as with a reamer with uneven number of flutes. Spiral flutes have also been used as a remedy for chatter, but the expense of milling the spiral flutes, and the difficulty of grinding the cutting edges, have prevented reamers with such flutes from being used to any great extent. Why spiral fluted reamers do not chatter is because they are better supported all around the edges when cutting than are those with straight flutes. The increased support is also the reason for the superiority of the reamer with odd number of flutes, or with cutting edges irregularly spaced, over the reamer with equally spaced, even number of teeth. In the former case the reamer will always be supported at least on three edges, while in the latter case occasions may be conceived of where only two edges actually are in contact with the work. It is also certain that the proper clearance of the cutting edge has as much to do with the chatter of reamers as the spacing of the teeth. In fact, some mechanics believe that the clearance is the one important consideration. In March, 1897, we published a letter from Mr. F. W. Clough, in which this claim was strongly put forth. It is evident that any reamer will chatter unless the cutting edge is properly supported. An article, referring to proper clearance for reamers, by Mr. Fred Holz, former president of the Cincinnati Milling Machine Co., appeared in Machinery in June, 1904. It is safe to say that chatter can be avoided in as great degree as is possible by giving but a slight relief to the cutting edges, preferably an eccentric relief, and by at the same time spacing an even number of cutting edges at unequal distances around the periphery of the reamer.—Editor].

THE USEFULNESS OF HYDRAULIC PRESSURE.

The article by Mr. Calvin B. Ross in your issue of November, 1906, entitled the "Usefulness of Hydraulic Pressure," reminds me of an experience in which hydraulic pressure was used in a slightly more novel manner than the one



Simple Scheme for Removing Bushings.

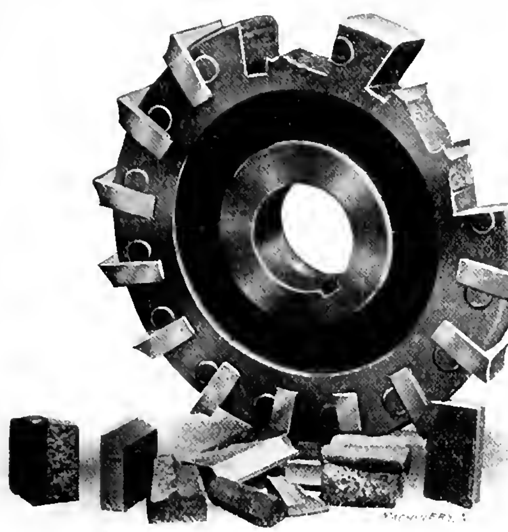
described by Mr. Ross, but with results equally effective. The occasion arose during the manufacture of some field gun mechanisms, when it was found that a number of hardened steel bushings *B* which had been driven very tightly into the breech blocks, as shown in the cut, must be taken out. The hole was too small to allow getting in anything in the form of a hook bolt strong enough to overcome the grip of the surrounding metal, and no other means of drawing out the bushings could be thought of at the time. After casting round for a short time for some method of overcoming the difficulty, the practical incompressibility of liquids suggested itself, and

we proceeded to remove the bushings in the following manner: A punch P was made, the round part of which was a close sliding fit in the hole of the bushing. Oil was then poured into the hole in which the bushing was driven, until it extended a small distance up into the bore of the bushing, the dotted line shown representing the surface of the oil. Then, by means of a few good solid blows on the head of the steel punch, while the punch was resting on the cushion of oil in the hole, the pressure of the oil on the under face of bushing was sufficient to start it out. It was only necessary to add more oil to that already in the hole, as the bushing was driven upward, so as to take up the increasing volume, and we soon had the satisfaction of being able to remove and replace any bushing at will. WALTER CANTELO.

Bridgeport, Conn.

A BROKEN MILLING CUTTER.

The half-tone shown herewith presents a view of a milling cutter made by one of the leading makers of such tools. The workmanship of this cutter was the best, but still it was not in service more than twenty minutes, milling cast iron at a



Inserted Blade Milling Cutter, too Weak in its Design.

feed of about one inch per minute and a speed of about 35 feet, before it broke as shown. The cutter was of a size of about 6 inches diameter by 1¼ inch wide. It seems to me that cutters of this size should have the teeth inserted in steel bodies instead of in bodies of cast iron, and, considering the slight difference in the cost, I fail to see why manufacturers do not make them this way. After this cutter had failed, I made a steel body to replace the broken one, and it has been in operation on the same class of work for a long time with a much coarser feed, but is showing no signs of weakness. M. H. W.

[Some manufacturers of inserted-blade milling cutters make a rule of using a steel body for small-sized cutters, say, up to about 7 inches in diameter; for larger sizes they use cast iron bodies whenever they use ordinary carbon steel blades, except if the width of the face of the cutter is less than 1½ inch, in which case machine steel bodies are used for all sizes. The Pratt & Whitney Co. make a rule of providing all cutters having high-speed steel blades with machine steel bodies.—EDITOR.]

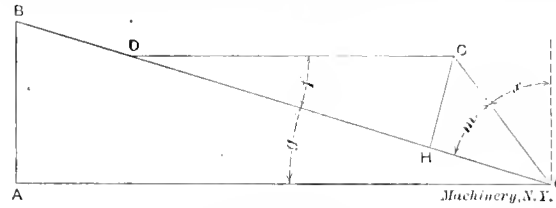
A BORING MILL PROBLEM.

I will attempt to give a solution of a boring mill problem, that I was called upon to solve, a few days ago. One of the "boys" had a job on a 12-foot mill, and in finishing this work, he was obliged to turn a taper of 1 inch in 3.25 inches. Now, the work was almost as large in diameter as the mill would turn, and he could not tip the boring head to the required angle and use the vertical feed, as the head would not go far enough out on the cross rail. Consequently it was necessary to use both the vertical, and the horizontal feeds. These feeds were geared up, so that their ratio was two to one, the tool feeding 2 inches horizontally to 1 inch vertically. It is obvious then, that if they were used simultaneously, the taper would be 1 inch in 2 inches. Now, the required taper was 1 inch in 3.25 inches; and the problem was to find the angle that the boring head should be set over to give this taper. This angle was found as follows: If $AB = 1$ inch, and $AO = 3.25$ inches, then the angle g = the angle that the surface of the work, when finished, makes with the mill table. Then, by the use of trigonometry, we find that

$$\tan g = \frac{AB}{AO} = \frac{1}{3.25} = 0.30769, \text{ and}$$

$$g = 17 \text{ degrees } 6 \text{ minutes.}$$

Now, the tool feeds 2 inches in one direction to 1 inch in the other; so let $DC = 2$ inches, and $CO = 1$ inch; then when



A Boring Mill Problem.

the boring head is set to angle x, the tool will finish the work to the required angle. It is obvious that the angle f equals angle g, or 17 degrees 6 minutes. Sin 17 degrees 6 minutes = 0.29404. Then $CH = 2 \times 0.29404 = 0.58808$.

$$\text{Sin } m = \frac{CH}{CO} = \frac{0.58808}{1} = 0.58808, \text{ and}$$

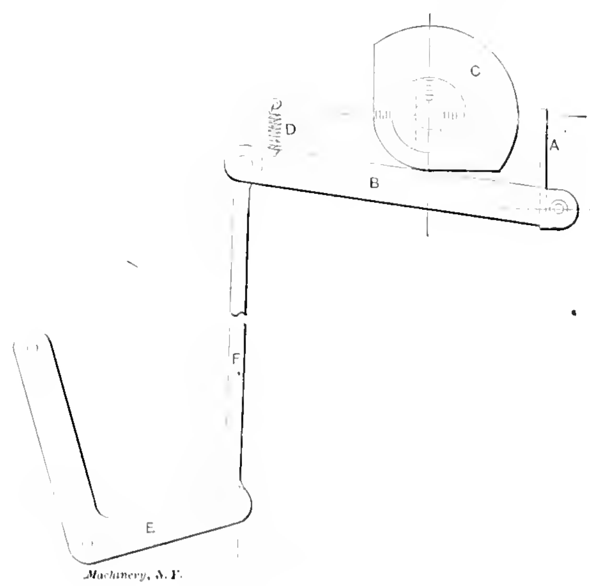
$$m = 36 \text{ degrees } 1 \text{ minute.}$$

Angle m plus angle $g = 53$ degrees 7 minutes, which, subtracted from 90 degrees equals angle x, which is the angle required. E. W. BEAN.

West Lynn, Mass.

AUTOMATIC STOP FOR DRILL PRESS.

The accompanying cut shows an automatic stop for a 20-inch Davis drill press used in connection with the hand feed. This automatic stop will start the drill when the feed lever is pulled down, and stop it when the lever is pushed back in position, the cam C being fastened to the feed shaft so that



Automatic Stop for Drill Press

its large diameter portion pushes the lever B down or permits it to spring up, according to the position of the feed lever. The piece A is of machine steel, 3/16 inch thick, and fastened in the slot provided for the clamping of the spindle sleeve The lever B swivels around the pivot at the end of A, and is held up to the cam C by a spring D. The foot lever is taken out, and the forged bell crank E operates the shifting rod for the belt. This crank is connected to the lever B by the connecting rod F. Both ends of the lever connecting rod and

bell crank should be case-hardened to prevent wearing too fast. The cam may be made of cast iron and fastened to the feed shaft by a set screw. S. OLIVER.

Great Barrington, Mass.

MANDREL BROKEN BY INTERNAL STRESSES.

The accompanying half-tones, Figs. 1 and 2, I believe, will be viewed with some curiosity by a number of MACHINERY'S readers. They show what was once a 1⅞-inch mandrel of standard form, manufactured by a well-known firm which has been putting them on the market for a number of years. The mandrel was purchased by us through a jobber, and when

Fig. 1. Mandrel Broken by Internal Stresses.

received was examined, and appeared to be all right in every respect. It was then wrapped in an oily cloth and put on a shelf in the tool-room. Five weeks later it was wanted, and on pulling the package out, the tool-room man was very much surprised to feel the package collapse in his hands. On unwrapping it, the mandrel was found broken in pieces as shown.

It had not been used in any manner, nor had it received any blows. It is therefore an interesting question what caused it to break so long after it was hardened, and why

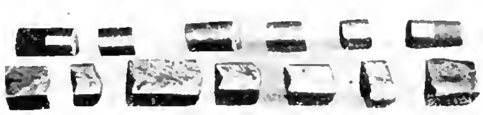


Fig. 2. The Pieces of the Broken Mandrel Arranged in their Natural Position.

it did not break when it was ground. We, of course, think that internal strain set up in hardening was the cause of the collapse. The grain of the fractures runs in various directions in the length, but none of the breaks show evidence of water cracks. I would be pleased to have any of the readers of MACHINERY explain the cause of such accidents, and how they can be guarded against by the purchaser, if such action is possible. C. W. M.

FAIR WAGES.

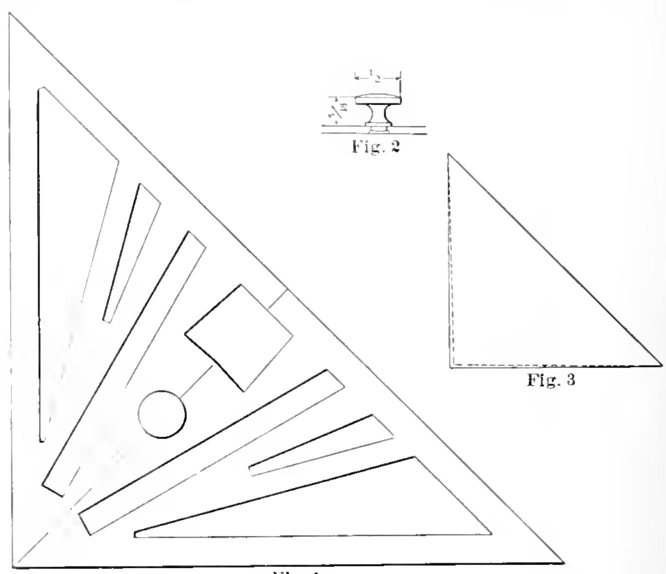
The question of wages has been uppermost with me lately. I have been working hard for some time, and it develops that my work is worth nothing. Not long ago I had a little job that I hustled through in good shape, and I made six or seven dollars an hour. What am I worth by the hour? What sense would there be in any one's gambling on my ability by hiring me by the hour? He would not know when I would be earning nothing, or when I would be at the top notch. Neither would I. I might make a suggestion to my employer some day that would save him hundreds of dollars, but if I am known as a machinist and am drawing 30 cents an hour, he would think I was a queer sort of a chap if I expected anything extra. There is a sort of inertia about this matter of wages. I tried to work in the premium plan in a shop once where I was superintendent. We had a lot of work on the big planer that we knew, from several years' work, just how long it took to do it. I offered the planer hand half his hourly rate extra for all he saved over the regular time. He said: "Do you mean it?" I said: "Yes. Why not?" He grinned and went to work. We had to hustle around to get the castings to him fast enough, and when the first pay day came around he drew more money than the foreman, and almost as much as I did.

Then there was trouble. The proprietor wanted to know what I was paying any planer hand such wages for, and the foreman wanted more pay. The proprietor said the foreman was no good, or he would have made the planer hand do the work as fast as it could be done on his old pay. He said he would fix that, so he went out and told the planer hand that he found that he had been cheated all these years, and now he was going to have those castings planed at the new speed for the old pay. So we lost a good foreman and a good planer hand. When the new men came I noticed that the castings were planed just as before, but the proprietor did not say a word. I guess he was too proud to say what he wanted to, but that was all the premium work that was done in that shop. ENTROPY.

DRAFTSMAN'S TRIANGLE.

The triangle is such an important tool for the draftsman that it should be made as convenient as possible. The Kelsey triangle was the first on the market that was provided with a knob for lifting about the board. This great convenience can only be used to advantage on a 45-degree triangle, and as I did not altogether like the Kelsey form, I worked out the design shown in the cut, which is the result of half a dozen experiments. The angles are 90, 75, 67½, 60, 45, 30, 22½, and 15 degrees, and each angle can be drawn from light edge. The angles of the opening near the center are the same as the angles of the head of a countersunk screw. A 45 degree line scratched on the under side is very convenient, but great care must be used to have it accurate. This triangle has been made by a number of draftsmen, and all prefer it to the old 60 and 45 degree combination. It is particularly useful to the designing draftsman. It has, however, a disadvantage for inking, as a line drawn by a slot opening is liable to be blotted when the triangle is slipped along.

To make such a triangle, get a piece of celluloid 0.070 inch thick. Make a drawing of the triangle full size and fasten the celluloid blank over it, so that the lines can be scratched as an aid to cutting. First, with a penknife start the openings, and, when large enough, use a hack saw. Finish



Draftsman's Triangle.

the edges with a file. After the slots have been worked out nearly to the finishing line it is a good plan to put the triangle away in a warm place for a couple of weeks, as it will shrink so as to impair the accuracy of the angles. The dotted lines in Fig. 3 show how the celluloid will shrink. After the celluloid has finally set, very little care is required to keep the angles accurate.

It is not necessary to tell a draftsman how to true up the outside edges. To true up the slot angles, the first thing to do is to draw with the T-square a base line. From this line lay off carefully all the angles that are on the triangle. With a file work out the slot edges of the triangle so that, when laid against the T-square, the edges will match the drawn lines perfectly. Any waviness or inaccuracy is clearly shown by this method.

The knob should be riveted in, but do not hammer hard

enough to buckle the celluloid. The hollow side of the celluloid should be down, as the triangle will then lay flat.

W. L. Breath.

Brooklyn, N. Y.

DRILLING CLEARANCE HOLES IN SOLID DIES.

The accompanying cut shows the manner in which I drill the clearance holes in solid dies. When I am through cutting the thread, I mark a circle *A* on which to locate the centers for the clearance holes of the dies. This I do before taking the die out of the lathe chuck. Then I divide this circle

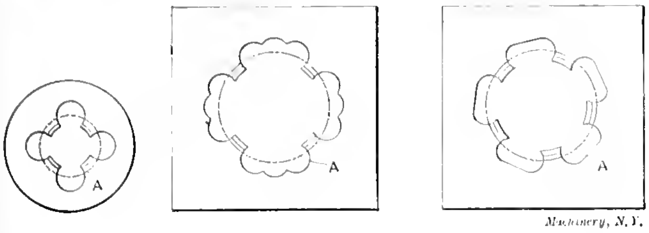


Fig. 1. Drilling Clearance Holes in Solid Dies.

according to the number of cutting edges I wish for in the die, and mark the division holes with a prick punch. I then drill the clearance hole first with a very small drill, say one that is 5/32 of an inch in diameter. After this I use a twist drill of proper size for the clearance hole, grinding the end down to a square-cutting face. This gives me a pilot in the center to fit the small hole originally drilled. In this manner I have no difficulty in drilling the clearance holes, and the drill has no tendency to run out. The way I grind the twist drill is shown in Fig. 2. In Fig. 1 are shown three examples of dies in which the clearance holes are produced by the method I have explained.

M. Schilling.

St. Paul, Minn.

[It seems as if the method of grinding down the twist drill so as to provide for a pilot and a square cutting edge is not a very good practice. In the first place, a counterbore with

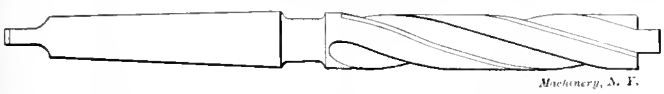

Fig. 2. Guide provided by Grinding Down Point of Twist Drill.

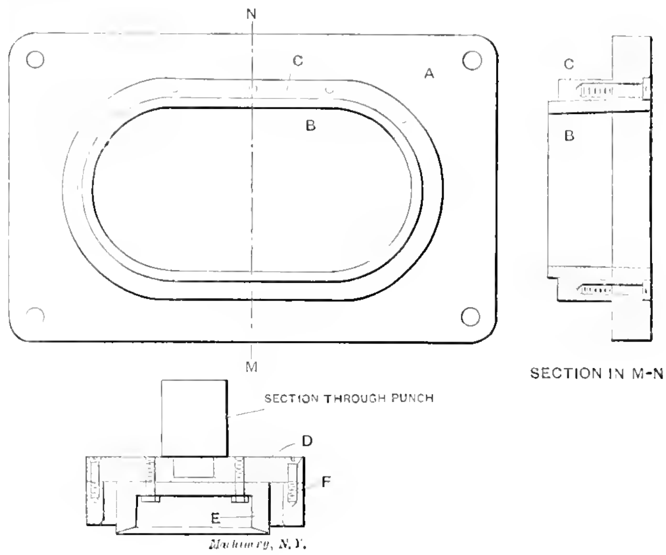
a pilot to fit the holes is not only better adapted for doing this work, but it is cheaper as well. In the second place, when the twist drill is ground down to a square face, it does not retain its efficient cutting edge, the twist drill being fluted so that its cutting edge is correct and most efficient only when the drill is ground to the usual angle of 59 degrees with the center line of the drill. For this reason, while the method itself of drilling the holes is recommendable, it would be best to substitute a counterbore for the ground down twist drill.—Editor.]

A COMBINATION CUTTING AND EDGING DIE.

The idea of cutting a hole and turning the edge up around it is old, and most die-makers are familiar with it, and with the usual methods of making such dies. It may still be that there is something new in the construction of the die shown in the accompanying cut. This die was made for cutting and edging the stove-pipe hole in range tops. The material which the die had to cut and edge was gage No. 18 soft steel. In the cut is shown a plan view of the die and a section through the center of it, and also a section of the punch. Referring first to the die, *A* is a cast iron die bed with a suitable hole cast through it for the punchings to fall through. At *B* is shown a tool steel ring which is planed at the top and bottom, and the inside hole at the top of which is the same as the size of the punched hole of the stove plate. This ring is tapered on the outside 10 degrees toward the bottom. The ring *C*, which is of machine steel, is finished to fit the outside of ring *B*. The ring *C* is about 3/8-inch lower than ring *B*. The inside of ring *B* is machined to have a taper of 1 1/2 degree toward the bottom for clearance, and is then hardened and driven into ring *C*. The die bed *A* is provided with screw holes and dowel holes, and the ring *C* is fastened to it.

The punch consists of a cast iron punch plate *D* with a punch shank screwed or riveted to it. The cutting punch *E* is made of tool steel and fastened to the punch plate. The punch, of course, fits closely to the ring *B* in the die, and should be provided with a slight taper on the outside, after which it is hardened and drawn. The forming ring *F* is made of hardened steel, and the inside is made to fit the outside of the cutting ring *B*, permitting, however, a space for the material, the edges of which are to be bent over. The inside corners of this forming ring are slightly rounded. This ring should be about 3/8-inch lower than the cutting punch *E*. It is screwed and dowelled to the punch plate. The punch plate with ring *E* is put onto the die with a strip of material of proper thickness between the forming edges of the punch and die. The cutting punch *E* is then put into the die and located, and is then drilled and tapped and fastened in place.



Combination Cutting and Edging Die.

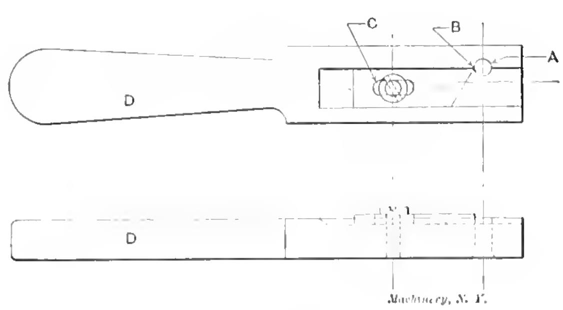
If the die is made in the above manner it will prove to be much stronger than if cutting ring *B* and ring *C* were made in one piece. The ring *B* will not have the same tendency to crack in hardening, as it sometimes does when made in one piece. If after long use the ring *B* is worn down, the machine steel ring *C* may be planed lower to make the cutting ring high enough. This applies to the punch also. In our shop we have made several of these dies, and they have given very good satisfaction.

Julius F. A. Vogt.

Buffalo, N. Y.

WIRE-TURNING TOOL.

I noticed a cut and description of a method for turning down very small diameter stock in the September issue of Machinery. In the accompanying cut is shown another device which answers the same purpose and has been used in our shops with entire satisfaction. This fixture can be put in the tool-post of a lathe, or may have a handle as



Wire-turning Tool.

shown at *D* for feeding along the work by hand on very small diameter rods. The hole *A* is of the same size as that of the stock before turning, and the tool *B*, adjustable at *C*, is set to turn the stock down to the required size; the work, of course, is chucked and revolved in the lathe as usual. This fixture is very simple to make and answers the purpose very nicely.

Tool Designer.

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

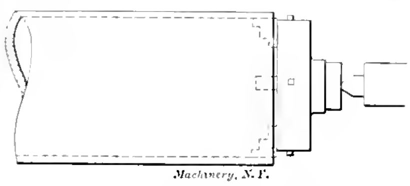
MILLING ON THE LATHE.

Our little shop cannot boast of a milling machine, so we have been accustomed to split the brasses and eccentric straps for the 5x5-inch vertical engines we manufacture on the shaper. This has made an ununiform job, since the parting tool would wear, and often necessitate the truing up of the surfaces after parting. Then, too, the babbitt in the straps would be pushed out in places, making a poor job. We now do this work on the lathe by clamping the pieces to be split on the compound rest, and running a slitting saw on an arbor between centers. This makes a very neat job in a fraction of the time taken by the old method.

Chattanooga, Tenn. E. R. Seiter.

HOLDING LARGE PIPE WHILE THREADING.

Coming in one morning, we had orders to thread a piece of 18-inch pipe several feet long, and a pair of flanges to fit; it

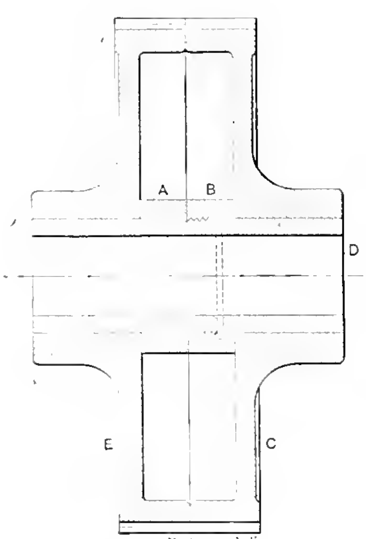


looked like making a spider, as the steady rest was too small, and there was no spider around. My pal, however, said no, and reaching under a certain bench, behind a certain post, brought forth a threaded plug which fitted any one of the three chucks for the lathe. With the plug screwed in, that chuck made an ideal spider, being just small enough to enter the pipe.

Sirius.

A KINK IN GEAR CUTTING.

A number of years ago we adopted a coupling bushing, as shown in the cut, to be used when cutting gears. The design of gears shown here is often used on milling machines, lathes, etc. In order to cut these economically, it is best to cut two at the same time. To do this we had first bushings *A* and *B* made in one piece, but this gave a lot of trouble when trying to get the gears apart. One man would be holding gear *C* on the face while another would be pounding at *D* to drive out the bushing, and thus force gear *E* away from gear *C*. This, however, caused lots of waste of time and sore fingers. The coupling bushing as shown in the cut was then adopted. It is simple and effective. Bushing *A* is put in one gear, and *B* into another; the bushings are then screwed together until the sides of the gears bind against each other. Now the two gears can be put on the gear cutter arbor as one gear, and it is easy to get the gears apart.



Gear Cutter.

FACING WORK ON CENTERS.

I think Mr. Leonard's kink, under the above title, in the August issue of Machinery, on grinding and using a side-tool is good. However, some trouble will be experienced at the extreme point. I have found when a good finish is required, or when facing a number of pieces, an extra lathe center with a recess milled in it to give clearance for the side-tool, to be of great advantage. Fig. 1 shows a top view of the lathe center, side tool, and a section of the work, the dotted lines showing the recess in the lathe center. Fig. 2 shows an end view of the center, with side tool in cutting position in the recess. An old discarded center will do, which after being annealed can be milled, or chipped with a good chisel, within 1/16 inch of the center line. It should then be hard-

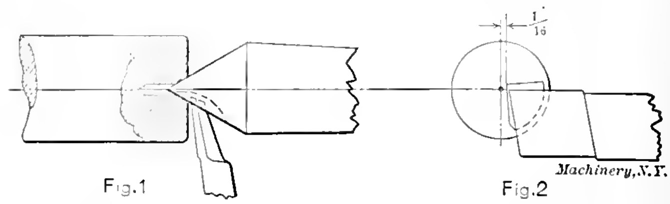


Fig.1 Fig.2

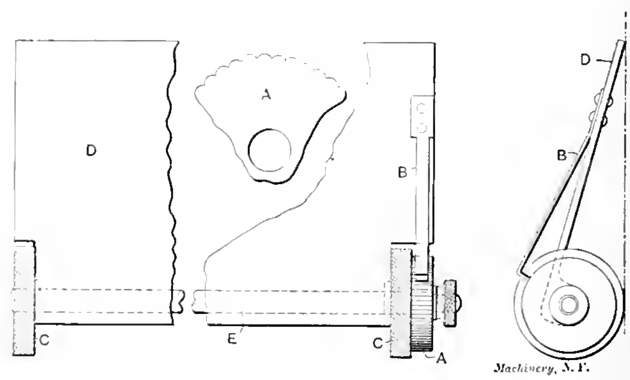
ened and ground the same as an ordinary center. Another advantage in using this tool is that any desired amount of stock can be removed, limited only by the depth of the center-drill hole, by facing close to the point of the lathe center and keeping this pressed into the drilled hole. Of course this center should be used only for facing, the ordinary center being put in for the succeeding operations.

Arthur Nichols.

DRAFTSMAN'S SECTION LINER.

The section liner shown among the Shop Kinks in the January issue made me think that the readers of Machinery might be interested in the device shown herewith, which has given excellent results. It is used on drawing paper entirely independent of a T-square. As seen from the cut, the device consists of a ratchet wheel *A*, a pawl spring *B*, two knurled rollers *C*, and the pen guide or ruler *D*. The teeth of the



ratchet are milled as shown in the detailed view. The ratchet and knurled rollers are fastened to the shaft *E*, and as the device is pulled back across the drawing paper for each line drawn, the ratchet pawl descends into each of the little grooves in the wheel, thus spacing the lines evenly. For different spacing, differently pitched ratchet wheels are used. By using thin rubber bands over the knurled rollers, the device would undoubtedly work well on tracing cloth, but I have not as yet tried it on anything but drawing paper.

Grand Haven, Mich. Charles A. Kelley.

ANNEALING NOVO AND BLUE CHIP STEEL.

The following method of annealing will give good results in the shortest space of time that I know of. Take the piece of steel, put it in a cast iron pot. Fill the pot full of lead, and put it in the fire. Bring it to a good heat, making sure that the steel is heated clear to the center. For the last few minutes before removing, hold the piece of steel down to the bottom of the pot with a piece of wire. Remove the pot from the fire and hold the piece down on the bottom of the pot by a weight on the top of a wire rod, leaning the rod against some support so that it does not fall over. It is important that the wire rod or the pot of lead be not moved while cooling off. When the lead has cooled, remove it from the pot and chop it apart with a cold chisel. It will be found that the piece of steel is well annealed in about two or three hours, according to the size.

P. W. Abbott.

SHOP RECEIPTS AND FORMULAS.

A DEPARTMENT FOR USEFUL MIXTURES.

This page is intended to be used only for the publication of such shop receipts as the contributors know from experience to be practicable. Receipts are solicited on the condition that the contributors personally know that they are reliable. The fact that a receipt is old and supposedly well-known does not bar it, provided it has not already appeared here.

385. LUBRICANT FOR CUTTING ALUMINUM.

A good lubricant for the cutting of aluminum in the lathe is kerosene oil. It will permit a better finish, and will materially reduce the liability of tearing the surface by the cutting tool. GREGOR.

386. SILVER WHITE BRONZE.

To prepare silver white bronzing powder, melt together one ounce each of bismuth and tin, adding one ounce of mercury. When cool, pulverize into a fine powder. R. P. PERRY.
Hoboken, N. J.

387. IMPREGNATING CAST IRON WITH ZINC.

Use 1 pound of pulverized zinc to each 50 pounds of iron. Scatter the zinc well over the bottom of the ladle, and fill with melted iron. Stir the mixture well with an iron rod, and pour it at once. W. B. STAUFFER.
Scottdale, Pa.

388. LUBRICANT FOR TURNING COPPER.

Referring to receipt No. 359 in the June issue, which says gasoline is a good lubricant for copper, would state that a solution of sal-soda mixed with lard oil is a lubricant I have seen used on copper in turret lathe work with good results.
Bridgeport, Conn. S. H. SWEET.

389. RUST-PREVENTING MIXTURE.

Melt 4 ounces of rosin in 1 quart of linseed oil and mix with 2 gallons of kerosene oil. The mixture is readily applied with a cloth or brush, and can be easily removed. So far as concerns absolute protection of metal surfaces from rust however, it perhaps is no better or worse than many other compounds recommended for the purpose. M. E. CANEK.

390. TO CLEAN RUSTY PIECES OF STEEL.

Put the pieces in a solution of chlorate of tin, not too strong, or it will attack the metal, and let them stay there about 24 hours or less. Take the pieces from the bath, wash them in water, then in ammonia, and then dry them quickly. They will have an appearance almost of silver, but will take the natural color by rubbing them. J. M. MENEGUS.
Los Angeles, Cal.

391. METHOD OF REPAIRING CRACKED WATER JACKETS.

The following method of closing up cracks in castings will be found to produce good results: Prepare a dry mixture of 17 parts of cast-iron filings, 2 parts of sal-ammoniac, and 1 part of flour of sulphur; add twenty times the weight of new iron filings; put in a mortar and add water so as to obtain a paste. This paste is applied to the crack, and in a short time becomes as hard as the metal itself. M. E.

392. TO JOIN TOGETHER TWO PIECES OF IRON THAT CANNOT BE HEATED.

I have used a compound consisting of sulphur, 6 parts; white lead, 6 parts; and borax, 1 part. These substances are dissolved in concentrated sulphuric acid, and the surfaces to be united covered with the mastic, and pressed very hard together. In about six days the two pieces are so well joined that even hammering will not part them. J. M. MENEEUS.
Los Angeles, Cal.

393. TO UNITE METALS OF ANY KIND.

The following mastic may be used to unite metals of any kind. It becomes very hard. First, mix well together 4 parts of iron filings with 4 parts of chloride of ammonia. Then dissolve 100 parts of arabic gum and 20 parts of sugar in 100 parts of water and add 1½ part of nitric acid. Boil this, and put the first mixture into it. When the mastic has to be used, mix one part of it with ten parts of new iron filings and some water, and heat it until a paste is formed, which is applied well heated to the pieces to be united.
Los Angeles, Cal. J. M. MENEGUS.

394. TO COPPER BRASS FOR LAYING OUT WORK.

To apply a copper coating on brass for laying out purposes, apply the ordinary copper solution in the same manner as used on iron or steel. Then, while the brass is still wet with this solution, cover the entire surface with a thin layer of fine cast iron dust from the drill press. Brush off the cast iron dust, and the surface will have a nice copper coating. This works much better than the receipt No. 34, reprinted in the booklet 150 Shop Receipts and Formulas, in which an iron rod is recommended. C. S.

395. TO TEST GALVANIZED WIRE.

The Western Union Telegraph Co. subject their wires to the following test in order to ascertain that they are well galvanized. The wire is plunged into a saturated solution of sulphate of copper (blue vitriol), and permitted to remain in this for one minute, after which it is wiped clean. This process is repeated four times. If the wire appears black after the fourth immersion, it shows that the zinc has not all been removed, and that the galvanizing has been well done; but if it has a copper color, the iron is exposed, showing that the zinc coating is too thin. O. G.

396. INVESTIGATING ADULTERATIONS IN BELTS AND LEATHER.

Some manufacturers make their belts and leather heavier in the following way: The leather is kept in a current of steam at low temperature until its pores are well open. Then it is put in a solution of glucose. The leather absorbs the liquid, and in drying the water evaporates and the pores close, retaining the glucose. To find out whether belts or leather have undergone this operation, put a piece of the suspected leather in some distilled water, and when it is well soaked, half fill a glass tube with some of the water, add a few drops of sulphate of copper, and fill the tube with a solution of caustic potash. Stir the liquid well and let it boil on an alcohol lamp. If the leather is natural, no change will take place in the liquid, but if it contains glucose, a characteristic precipitate of copper will form, due to the action of the glucose on the solution of sulphate of copper and potash.
Los Angelus, Cal. J. M. MENEGUS.

397. CAST IRON BRAZING.

The ingredients for this cast-iron brazing may be had at any first-class drug store and should cost no more than about 50 cents. They consist of 1 pound of boric acid, 4 ounces pulverized chlorate potash, and 3 ounces carbonate of iron. These ingredients should be thoroughly mixed, and kept perfectly dry (a glass jar or bottle answering the purpose), and when wanted for use, a small amount should be taken and mixed with grain spelter. In trying this brazing for the first time, take a piece of cast iron of say one square inch cross section, hold the broken parts together by clamps, and fit the break closely in order to form a strong joint. Use a gas forge if possible, but an ordinary blacksmith's forge will do if no gas forge is available. When a blacksmith's forge is used, use charcoal, and be sure to get a high heat. When the pieces of the casting are in place, heat the joint to a good bright red before applying the flux. Then apply it liberally with an iron rod, flattened on the end, and work along the fracture, gradually raising the heat to almost a white heat. Then shut off the heat and allow the casting to cool slowly. If this work is done carefully, the joint will be as strong or stronger than the original casting.

Another formula is: 1 pound of boric acid, 3 ounces of caustic soda, and 3 ounces of carbonate of iron. This is mixed with spelter in the same way as in the first formula, and must also be kept dry. The main points to keep in mind when brazing cast iron are to have the metal clean and free from grease; not to apply the flux until a bright red is reached; and then be sure to raise the heat high enough to make the mixture flow nicely. ETHAN VIALL.
Decatur, Ill.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

BROWN & SHARPE NO. 3 VERTICAL MILLING MACHINE.

This description and the accompanying cuts relate to a new vertical milling machine made by the Brown & Sharpe Mfg. Co. of Providence, R. I. In describing it, it is not necessary to call attention to the advantages which the vertical miller possesses over the horizontal machine for a large class of work, since these advantages have in recent years come to be well recognized, so that the use of the vertical miller has become standard practice. Of the general construction of the machine it only needs to be said that it has been designed and made with the three cardinal points of accuracy, rigidity and convenience in mind. The following detailed description will tend to show that these three features have been realized to a high degree, without requiring that any one of them should be sacrified for the sake of the others.

General Features of the Design.

The front elevation, Fig. 1, and the sectional line drawing, Fig. 2, will serve to give an idea of the general arrangement of the tool. The power is delivered to the machine through a single speed shaft, *C*, driven either by a pulley, or from a direct-connected constant-speed motor, as in Fig. 1. The spindle motion is transmitted through a gear mechanism giving eight changes of speed to the bevel gears and reversing clutch shown at *B*. From here a vertical driving shaft leads to a train of gearing at the top of the column, where another change of speed is provided, giving sixteen in all. The feed gearing, also having sixteen positive geared changes, is driven by a Renold chain from the constant speed shaft; from the feed gearing the motion is carried to the knee, where it can be applied to either the vertical, cross or longitudinal feeds, automatic and positive stops being provided for all of these in either direction, as well as fixed automatic stops to prevent over-running. This variable feed can also be applied to the axial movement of the spindle, as well as to the circular milling attachment shown in Fig. 6, when the latter is furnished.

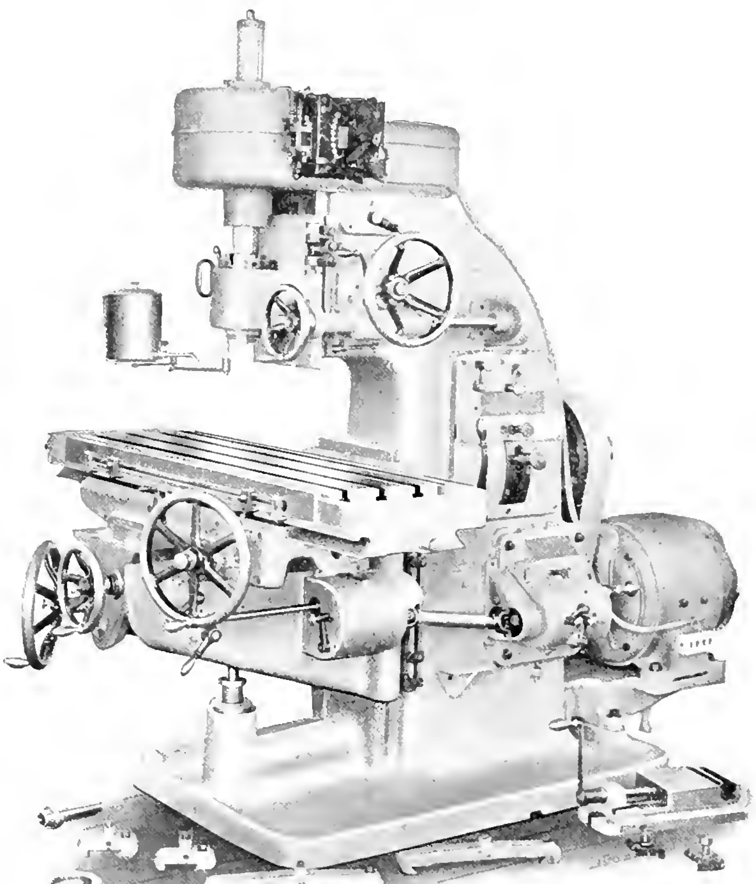


Fig. 1. The Brown & Sharpe No. 3 Vertical Milling Machine.

Spindle Speed Change Gearing.

A driving pulley of the plain flanged type as shown in Fig. 2 (or a wide-faced sprocket wheel, if the machine is motor-driven, as in Fig. 1) runs loosely on the driving shaft, and may be clutched to it or released from it at will by operating the vertical lever shown at the side of the column in Fig. 1, and connected to reach rod *A* in the line drawing. This serves regularly to start and stop the machine. In the case of a belt drive, no countershaft is needed or ordinarily furnished, the belt leading directly to the main line shafting. The spindle speed change mechanism (also shown removed from the machine in Fig. 3) operates very simply, giving four changes by the shifting of an idler from the driving pinion on *C* to mesh with either of the gears in cone of four gears. This number of changes is multiplied by two, by shifting a double gear on the sleeve on the upper shaft. This mechanism is similar to that used in varying the feed, which will be explained more in detail later, the only difference in design between the two being the different arrangement of the handles necessitated by the location of the shafts. As shown in Fig. 3, a speed plate is provided, giving definitely the revolutions per minute obtained by shifting the various handles to either of the sixteen combinations it is possible for them to take, ranging in geometrical progression from 17 to 374 revolutions per minute. The lever for operating the reversing mechanism *B* is shown just at the left of the speed plate.

The vertical shaft *E*, Fig. 2, leading to the top of the column, carries a gear *F* meshing with the wide face gear *G*. A sliding gear *H*, with an attached pinion, may be shifted along the face of *G* so that either the gear or the pinion may be connected with the corresponding diameters of the double spindle gear *I*. This change is effected by a lever seen in Fig. 1 over the hand-wheel for the spindle feed. The spindle is of crucible steel with ground bearings, running in bronze boxes. The lower end is threaded and has a No. 11 taper hole, with a recess milled across the end for driving an arbor or collet with a clutch collar.

Feed Change Mechanism.

The feed change gearing is driven from the constant speed shaft *C* by the sprocket pinion *J* on its end, Fig. 2, through a "silent" chain to the driving sprocket *A* shown in Fig. 4. The same mechanism is shown in the half-tone Fig. 3 separated from the machine. Through the keyed hub on this sprocket *A* passes the shaft *B*, carrying gears *C* and *D*; by the shifting of the lower lever seen in the feed box in Fig. 3, either of gears *C* or *D* may be shifted to engage with the corresponding ones on pinion shaft *E*, opposite them. Two speed changes are thus provided for. Pinion teeth are formed on *E*, as shown. Meshing with this is an intermediate gear which does not appear in the cut. This intermediate gear may be shifted to engage either one of the four gears on shaft *F*. Lever *G* at the side of the gear box serves to adjust the intermediate about the axis of *E* to suit the different diameters of the gears on shaft *F*, while the knob shown just under the feed plate in Fig. 3 shifts it to the proper station on the cone of gears for the speed desired. A further doubling of the eight feeds thus obtained is effected by the shifting of double gear *H* on the delivery shaft *J*. This is effected by the movement of the upper of the two short levers on the front of the gear box, which may be shifted to either of two positions. The sixteen feeds desired are thus provided for.

Arrangement of Automatic Feeds.

The telescope shaft carries the motion to a gear box on the side of the knee, in which the feed may be reversed to act in either direction as desired. This reversing box is shown removed from the machine in Fig. 3. From here the feed movement is either led through splined shafts and gearing to the table screw or to the cross and vertical feed mechanisms, as required. The latter two are operated by the handles and clutches encased in the cross and vertical feed box, shown removed from the machine in Fig. 3. It will be seen attached to the machine in Fig. 1 at the side of the knee. The table feed is operated in either direction by the lever at the front of the saddle, the reversing box at the side of the knee not being used for this purpose. Either a slow feed or a quick hand feed may be given by the hand-wheel, or this may be disconnected from the mechanism entirely, the clutch on the center of the hub being used to make these changes. All the movements of the table, saddle and knee are controlled by fixed hand-wheels which may be disengaged so as to hang free on their shafts, thus preventing accidental disturbances of the settings. Graduated dials reading to 0.001 of an inch are provided for all these movements. The hand-wheels do not interfere under any circumstances, and can be used simultaneously without difficulty.

The vertical feed of the spindle head is operated from the same change gear mechanism as the table, saddle and knee feeds. In Fig. 4 a gear K will be seen on the hub of the fork of the universal joint. By operating the knob provided, gear L may be brought into mesh with K, thus driving sprocket M. A chain runs from sprocket M back into the column over two pairs of idlers and out again to a sprocket at N in Figs. 3 and 5. A lever O operates a clutch for connecting this sprocket with the worm shaft on which hand-wheel P is keyed. This clutch is also operated by the automatic stops, adjustably clamped in the T-slot at the side of the spindle head. A worm on the hand-wheel shaft meshes with worm-wheel Q on the pinion shaft R. Q may be connected to it, or disconnected from it at will, by the lever S. Hand-wheel T, when Q is disconnected, may then be used for a rapid hand movement of the spindle head; at other times, hand-wheel P gives a slow movement. The pinion on the inner end of R meshes with a rack on the spindle head. This pinion also meshes with a gear U on the hub of a disk V, to which is connected a chain which runs over an idler W and down through the column to a counterweight shown in Fig. 2. A channel walled in on all sides is provided for this, preventing it from swinging against other parts of the mechanism, and stiffening the frame of the machine as well. The connection of the counterweight of the head through the gearing described makes it possible to use a lighter counterweight having a greater movement than would be the case otherwise.

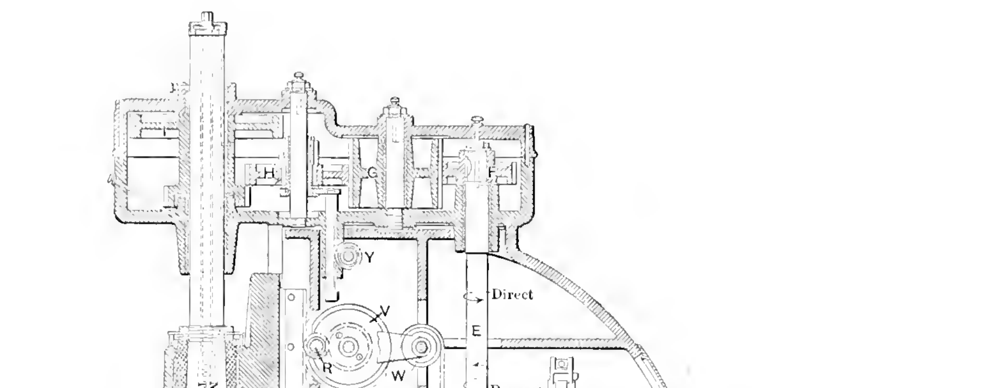

Fig. 2. Vertical Section through Spindle-head and Column, showing Spindle Driving Mechanism.

Circular Milling Attachment.

The circular milling attachment shown in Fig. 6 is furnished for work requiring the finishing of parts on the arc of a circle. The feed for it is taken from the splined shaft which drives the longitudinal feed screw of the table. For this purpose this screw is disconnected from the splined shaft by the simple means provided, so that the table feed applies to the circular table only. For making longitudinal adjustments of the table under these conditions, a crank is applied to the squared end of the table screw at the left end of the table. At the back of the table, at the right end, is provided a finished pad to which may be bolted the bracket shown, carrying the sprocket wheels and chain conveying feed motion from the table feed shaft to the circular milling attachment. These connecting parts are made interchangeable, so that the milling attachment may be purchased at any time subsequent to the purchase of the machine, and applied without requiring any fitting.

The automatic stop and feed controlling devices used for the circular table are similar to those used on the main table. The feed is reversed, started and stopped by the same lever. The dogs for the automatic stop are held in a circular T-slot in the periphery of the face-plate. This latter has three T-slots in one direction, and a third crossing in the center of the plate at right angles to the other three. The periphery of the face-plate is divided in degrees so that the table may be used for indexing the work for taking straight cuts, as well as for circular milling pure and simple. By the movement of a small lever, the hand-wheel may be disconnected from the feed motion.

Recurrence of Identical Details of Design.

The large number of line cuts and photographs shown of this machine furnishes a good opportunity for studying the methods of design followed by a firm which has a high reputation in this regard. One of the things that is noticeable is the recurrence throughout the machine of certain details of design, wherever similar movements have to be performed. For instance, note the use made of the rack and pinion principle in operating the various sliding gears, clutches, etc., in the feed and spindle feed mechanisms. Examples of this occur twice in Fig. 2, once at X, where the double gear of

the spindle speed changing mechanism is shifted, and again at Y in the back gear shifting mechanism. In the first case the rack teeth are turned in the lathe on the hub or shell of the double gear, so that they have a circular form. This allows the part to be rotated freely through the teeth of the pinion, which still controls its endwise movements. The pinion is attached to the shank of the operating handle on the outside of the machine.

will show that it accomplishes the movements desired with about as few parts and as little machining as could be obtained in any possible way.

Another feature also noticeable from a study of the photographs is the carefulness with which the design of the main castings have been worked out. Looking at the side of the machine in Fig. 1, it will be seen that a great many separate parts are bolted onto the sides of the column, knee and

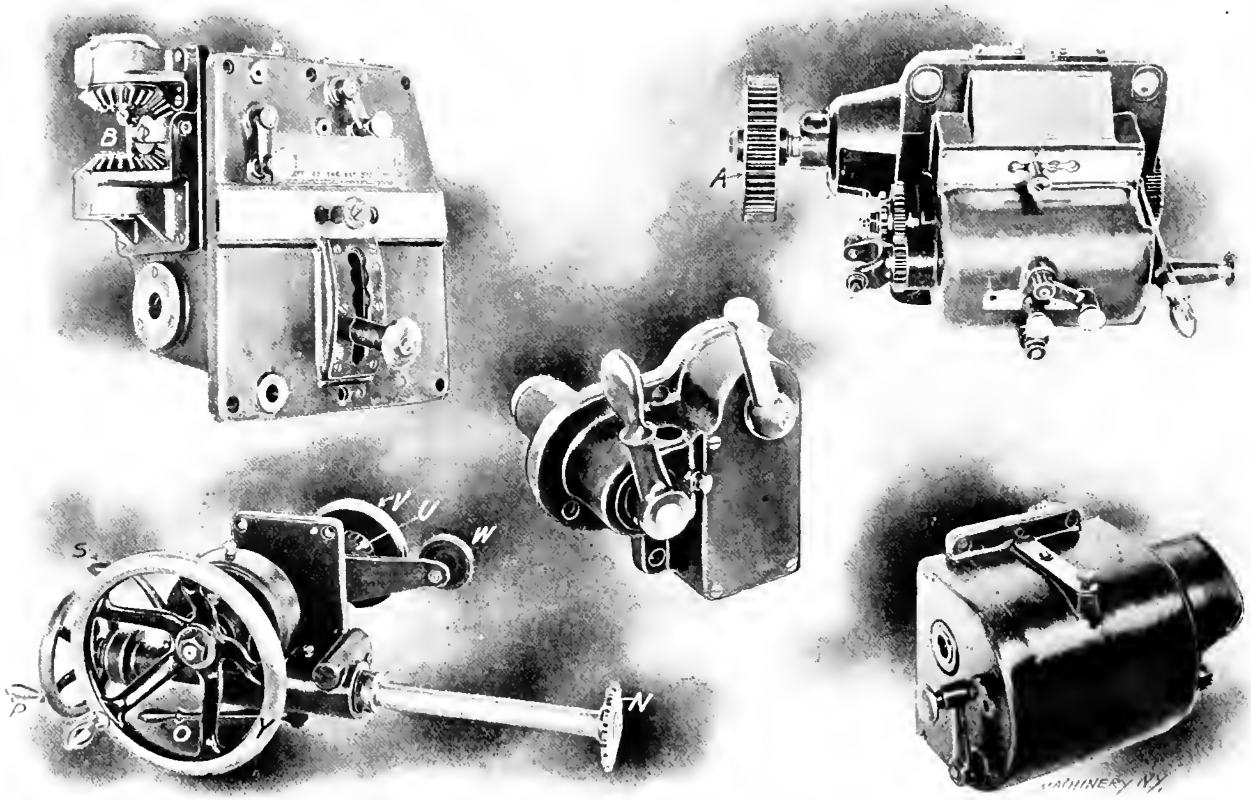

Fig. 3. A Group of Assembled Units of the Brown & Sharpe Vertical Miller.

Spindle Speed Change Mechanism. Feed Change Mechanism.

Cross and Vertical Feed Control.

Vertical Spindle Feeding Mechanism. Feed Reversing Mechanism.

In Fig. 4 the same form of control is used for shifting the double gear H. In Fig. 5, lever O is connected to a pinion actuating a rack, which connects or disconnects the vertical feed clutch. Lever S in the same manner meshes with circular rack teeth in the hub of wheel T, throwing it in or out of engagement with worm-wheel Q. The same device is freely used in the movements controlling the vertical, cross

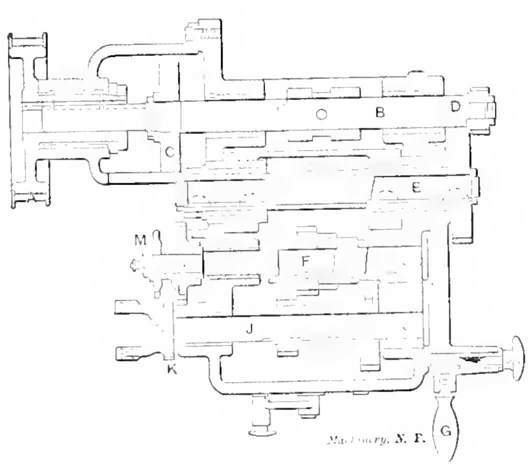

Fig. 4. Arrangement of Gear Feed Changing Device.

and longitudinal feeds. These rack teeth appear to be all of the same pitch, and made of substantially the same form in either of two ways, by being turned in the lathe on the cylindrical surfaces of gears, hand-wheel hubs, etc., or by being milled across the top of round rods seated in drilled holes in the casting. A consideration of this detail of design

saddle. For all of these, however, suitable pads and bosses have been prepared on the main casting, so that to the eye they seem naturally to fit into place, instead of having the appearance of being stuck on afterwards as an after-thought, as is the case with many examples of machine tool design. This requires castings somewhat more elaborate than would otherwise be required, yet it is doubtful if the final cost of producing such work is much, if any, greater than the cost of poorer design.

Unit System of Design.

Perhaps the most noticeable featnre of the machine so far as concerns the matter of design, however, is that best illustrated in Fig. 3. For want of a better name it may be called the "unit system" of grouping the mechanism. It will be seen that the speed changing mechanism, feed mechanism, the feed reversing gearing, and the cross and vertical feed mechanisms, are each grouped in separate independent units, which may be made and assembled as a whole, without reference to the machine in which they are to be used.

This had its advantage, not only as regards manufacture, but from the standpoint of design and use as well. In making changes and improvements in the drafting-room, these mechanisms may often be considered as separate machines, to be altered as occasion may require without affecting the remainder of the structure. This is made possible by the fact that they are so self-contained. Where the different parts are attached to the main frame of the machine at many different points, changes cannot be so easily made. From the standpoint of manufacture there is the advantage of being able to finish much of the assembling at the bench, making the erecting of the machines on the floor a comparatively short and inexpensive process. Not only is it costly to have the erect-

ing space taken up by half-completed machines for weeks at a time, but there is a greater expense as well in fitting small parts to heavy columns and bed castings, remote as they usually are from the tools in which the fitting is done. In addition to all this, the purchaser has the advantage of being able to take the machine apart quickly and easily. The removal of the driving shafts, for instance, allows the spindle speed change mechanism to be removed from the machine in its entirety, so any trouble that may have occurred there may

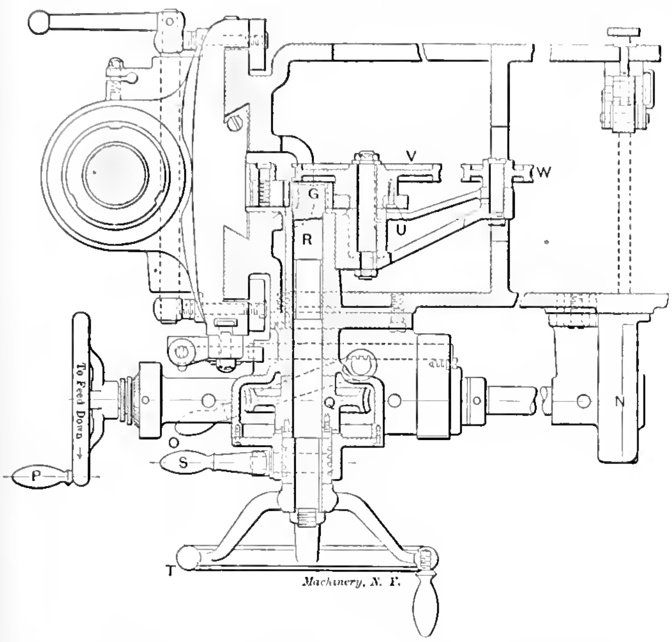

Fig. 5. Arrangement of Hand and Power Feeds for the Spindle.

be easily remedied, the part being carried to the bench or lathe for the purpose. The same thing applies to the other separable units of which the machine is constructed.

It is entirely possible to design machine tools that are commercially and mechanically successful without refinements of the kind we have just been considering, but the fact that wide and insistent markets are found for such machinery as this, where thought and time have gone to the perfecting of the small details, indicates that there are many users who believe that such matters are decidedly worth the time and money spent on them.

Range of Feeds, Dimensions, Etc.

This machine is known as No. 3 in the builders' line of vertical millers. It has a table with a working surface of $49\frac{1}{2}$ by $16\frac{1}{2}$ inches, having three T-slots, $\frac{3}{4}$ inch wide. The longitudinal feed is 34 inches, the transverse feed $13\frac{1}{2}$ inches,

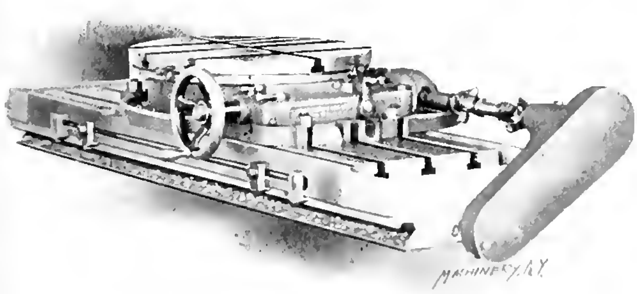

Fig. 6. Circular Milling Attachment.

the vertical feed of the knee 15 inches, and of the spindle head 8 inches. The distance from the center of the spindle to the column is 18 inches, and the maximum distance from the top of the table to the end of the spindle is 23 inches. The net weight of the machine is about 6,100 pounds.

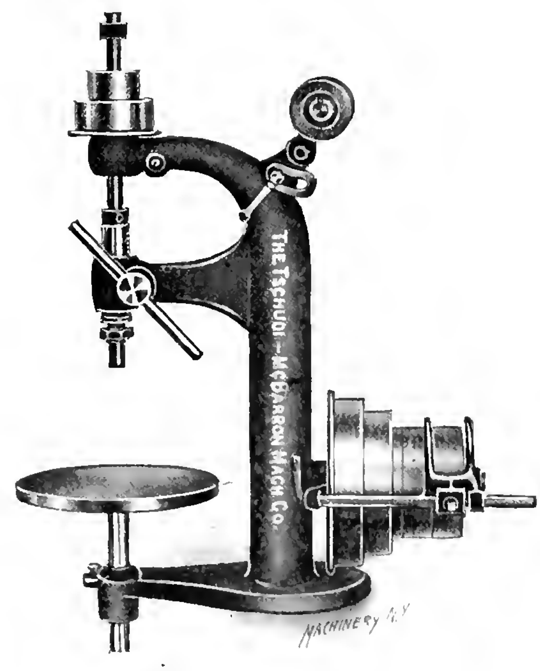
GASOLINE ELECTRIC GENERATING PLANTS.

The Buffalo Mechanical and Electrical Laboratory, Erie County Bank Building, Buffalo, N. Y., furnishes complete gasoline engine and dynamo sets for temporary or permanent electric generating plants. The engines are adapted to either gas, oil, or alcohol, in sizes to carry 10, 20 or 30 lights, according to the candle power and voltage. When operated at a speed of 850 revolutions per minute the engine develops $1\frac{1}{2}$ horsepower, and the dynamo supplies a current of 101 volts pressure. The electrical generator has a capacity of 7.5 amperes at normal load and will carry a maximum load considerably above this amount. For a constant load with a definite number of lights, no regulator is necessary, as the outfit runs at practically constant speed. For a variable load, a storage battery is provided having 50 cells, giving an 8 or 10 ampere hour capacity, this being sufficient to give good regulation and supply a reserve current for night lamps, and extra current during a heavy over-load.

This set is particularly useful for boat lighting, charging automobile batteries, store lighting and other places where isolated plants are required. In places where fire underwriters object to gasoline being used as a fuel in insured buildings, a portable house is provided to protect the engine and dynamos, and the storage batteries as well, if the latter are used. Besides the $1\frac{1}{2}$ horse-power size mentioned, larger sizes are provided, up to double cylinder engines generating 6 horsepower. The latter are especially devised for charging automobiles and similar work. Similar sets have been on the market for some time in Europe, but they are of considerably more costly construction, heavy cast iron bases and complicated governing mechanism being used. These engines are muffled to give results as good as those obtained in the best automobiles.

EXCELSIOR SENSITIVE BENCH DRILL.

The Tschudi-McBarron Machine Co., Dayton, Ohio, is building the bench drill shown in the cut. It is called the "Ex-



Tschudi-McBarron Sensitive Bench Drill.

celsior." As may be seen, the spindle is driven by a 2-step cone, carrying a 1-inch belt. The speed variation thus obtained gives from 1,000 to 2,000 revolutions per minute of the spindle when the driving pulleys are connected to give 800 revolutions per minute. In changing from the large to small diameter on the cone pulleys, the idler shown is swung about its pivot to accommodate the new position of the belt. Bronze bearings are used throughout.

The table is 8 inches in diameter. The front end of the machine is arranged to over-hang the work bench, allowing the stem of the table to drop over the edge as much as is required for the adjustment for height. The distance from the column to the center of the table is $5\frac{1}{8}$ inches, so that the tool may be classed as a 10-inch drill. The vertical travel of the table is $1\frac{1}{2}$ inches and the vertical feed of the spindle is $1\frac{3}{4}$ inch, and the greatest distance from the spindle to the table is $7\frac{1}{2}$ inches. The floor space required is 9 x 7 inches.

STURTEVANT STEAM TURBINE.

The B. F. Sturtevant Co. of Hyde Park, Mass., has been working for some time past on a steam turbine of the impulse type, adapted for direct connection to high-speed machinery, especially for the fans and blowers and electrical apparatus which this firm manufactures. The experiments have resulted in the machine herein described, and illustrated in the accompanying half-tones. It is the invention of Mr. William E. Snow, of the firm's engineering staff, and is built

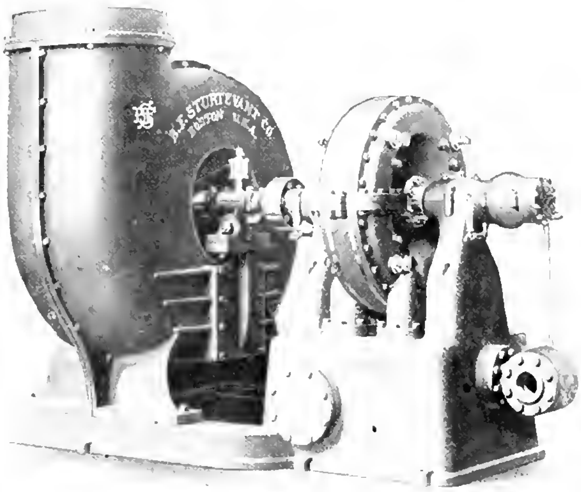


Fig. 1. Sturtevant Steam Turbine, Driving Gas Blower.

under his patents. The experimental work was begun in 1889, soon after the modern practical form of the steam turbine appeared, so that in its present design it is the result of a long period of development.

General Description.

This turbine works entirely on the impulse principle, the steam expanding completely in the stationary member, the rotor only serving to absorb the velocity of the fluid without

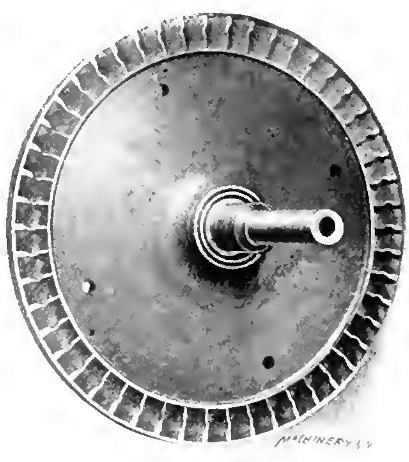

Fig. 2. Runner of the Sturtevant Turbine.

changing its pressure (see article "Impulse and Reaction Turbines Defined," Engineering Edition of MACHINERY, October, 1906). Fig. 1 shows a general view of a 75-horse-power machine attached to a gas blower—a service to which it is particularly adapted. It will be seen, by comparing it with the blower, that it is much more compact than a reciprocating engine for the same purpose, and that it is neat and simple in design. Fig. 2 shows the runner and Fig. 3 the guide plate or stationary member, containing the nozzles and return buckets. One of the side pieces is seen just behind it. So far as can be judged from photographs, the machine is double, the runner having buckets on each side, with two reversing or guide rings, one for each side of the casing. A guide ring and casing are shown assembled in Fig. 4.

As shown in Fig. 1, the diameter of the wheel, as compared with the driven blower, is so small that the base is of considerable size, allowing room for steam passages and a water separator to provide dry steam—a very necessary feature for a steam turbine, if the wear of the blades is to be kept at a minimum. This also reduces the clumsy and complicated outside piping that would otherwise be necessary. The live steam enters the casing through the four small outside ports shown in the base casting in Fig. 5, going up through the side of the frame of the casing into the annular steam chest formed around the side. The passages for this can be traced from the outside contour of the casting in Fig. 1. From this annular steam chest four nozzles lead to the wheel. Samples of these nozzles, disassembled, are shown in Fig. 6. The oval opening which they form in the reverse guide ring will be seen at four points in the face of the ring in Fig. 3.

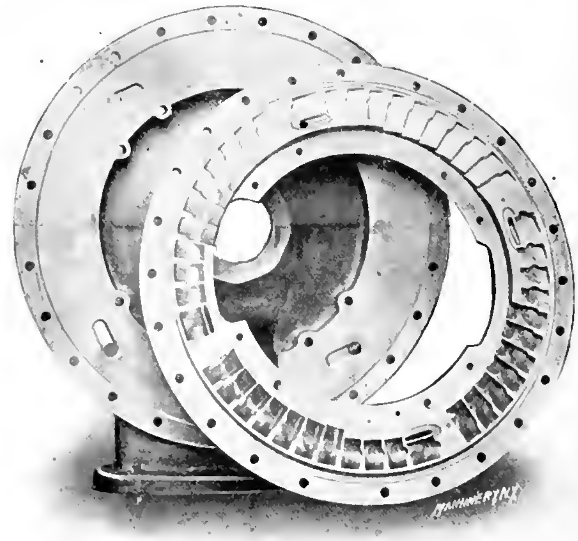

Fig. 3. Guide Plate for Returning the Steam to the Runner.

The steam (having expanded in these nozzles and transformed the dynamic energy, due to its pressure, into kinetic energy, due to velocity) enters one of the side buckets of the runner in Fig. 2. Delivering a portion of this velocity to the runner, and being returned by it to the reverse pocket shown in the guide ring in Fig. 3, opposite each of the nozzles and openings, the curved bottom of this pocket again returns it to the buckets of the runner, where it again gives up another portion of its velocity at a slower rate of speed, and is reverted to the three following guides of the guide plate. This increase in guide area is necessitated by the increase in the volume of the fluid due to its slower velocity.

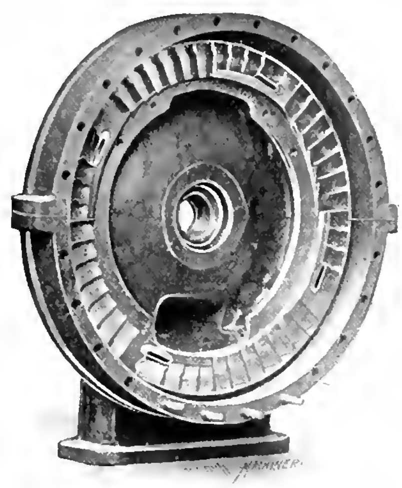

Fig. 4. Guide Plate and Casing Assembled.

From these three pockets the steam again returns to impart its velocity to the runner, which finally carries it around to be discharged into the last seven openings in each of the four series in each guide plate. From here, instead of being returned again to the wheel, it is discharged towards the center through the side openings shown, at a velocity of practically zero, having given up most of its energy to the moving wheel. It is a little difficult to understand just what path the steam takes in traveling through the nozzle to the runner, back to the reverse guide, and so on, until it escapes into the center space of the casing; but it is doubtless done,

so far as can be judged from the photographs, in substantially the manner described. From the center of the casing, the exhaust steam is led down to the center of its support, and through the large central holes of the base in Fig. 5, to the exhaust pipe.

It will be seen from the foregoing that while the Sturtevant turbine shown in Fig. 1 has but one wheel, it is not of the single stage type in the usual accepted meaning of the word, since the steam acts in the buckets over and over again until

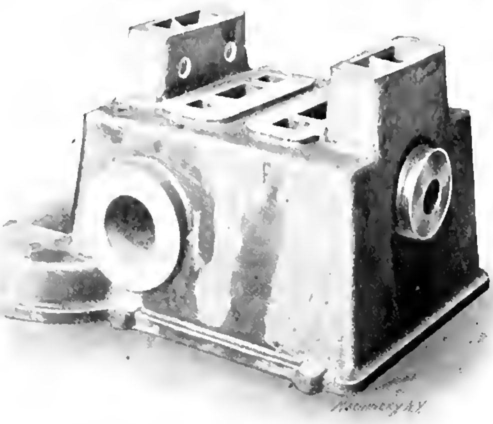

Fig. 5. Base Casting, showing Steam Passages.

all the available energy is extracted. This not only results in a high efficiency, but also permits the use of very moderate speeds of rotation as compared with other types. This speed ranges from 1,600 to 3,000 revolutions per minute, permitting direct connection with blowers and high-speed machinery, and avoiding the use of gears and other reducing devices.

The description shows plainly the simplicity of the machine. It is composed in the form shown of seven principal parts: the bucket wheel, the shaft, the reversing guide rings, casing, bearings, base, and governor. The only parts subjected to actual wearing contact are the two main bearings, and as the load upon these never exceeds four pounds per square inch of bearing surface, they last indefinitely.

Details of Construction.

The bucket wheel is a single forging of the best grade of open-hearth steel, with buckets worked out in the solid

Fig. 6. Steam Nozzles.

metal, as shown in Fig. 7. Here the wheel is mounted in an indexing fixture on the table of the vertical milling machine, having recesses milled out in a way which is obvious from the cut. This process insures a wheel of great strength, and also does away with all possibility of the breaking of the blades of the buckets, as sometimes occurs with wheels of the inserted blade type. If the bucket wheel of the Sturtevant turbine should get out of line and touch the casing, the result would be merely a rubbing together of two steel plates, which could not produce the slightest injury to the guiding surface for the steam. The steam is admitted to the buckets in such a manner that the wheel is always in perfect balance, and end thrust is eliminated. The method of cutting the buckets and the form of the cutter used insures a high degree of accuracy and smoothness of finish. The reverse guide rings are of forged steel, having the buckets milled in them similar to those in the wheel, as described. In the size shown, four steam nozzles are inserted at intervals between the buckets. These nozzles are made of the best phosphor bronze of a shape to give the proper curve for the degree of expansion desired. They are easily removed from the reversing guide rings at any time.

The casing is so made that no packing boxes have to be used on the shaft, steam tightness being secured with a short "labyrinth" or "water" packing. There is no contact between the rotary and stationary parts of this packing, so it requires no adjustment and will wear indefinitely without leakage. The bearings are of self-oiling ring type, with linings of phosphor bronze. Both the governor and the regulating valve are of great simplicity, and the form of the latter does away with all belts, gears and speed-reducing devices. It is

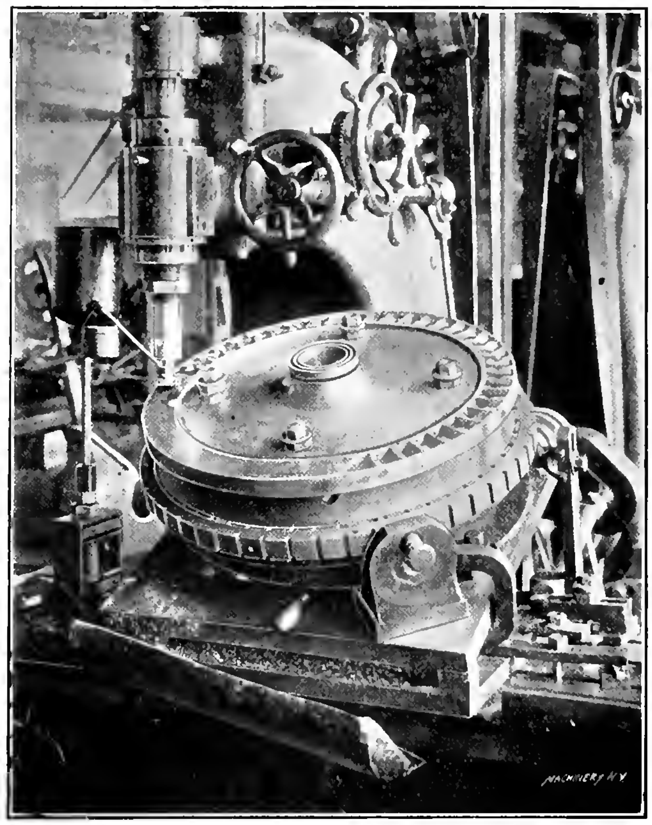

Fig. 7. Cutting the Buckets in the Runner on a Vertical Miller.

composed of but five parts, and is located in the end of the outboard bearing, enclosed in a dust-proof case. The connection between it and the throttle valve is direct, the latter being located directly under the governor.

The extreme simplicity of the turbine makes it comparable to the blower rather than to the engine. The only attention

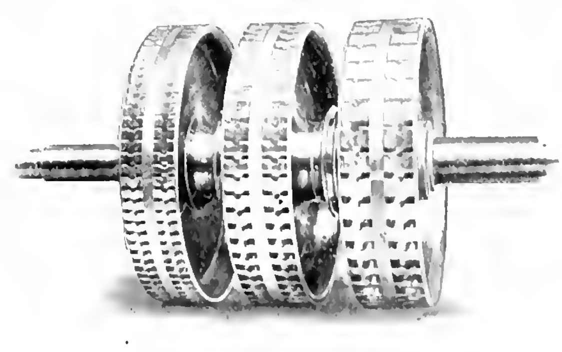

Fig. 8. Multiple Stage Runner, with Peripheral Buckets.

the Sturtevant turbine requires when in continuous operation is a weekly filling of the oil wells in the two main bearings. Since the whole machine is enclosed in a dust-proof case, it is absolutely protected from injury.

Range of Size in the Single and Multiple Stage Forms.

Turbines of the form just described are made in powers ranging from 10 to 200 H.P., and furnished in three sizes, so far as their outside dimensions are concerned. Intermedi-

ate horse-power and speeds range according to the arrangement of the nozzles and buckets. In sizes larger than 200 horse-power, two to four bucket wheels are used, the runner having a somewhat different form, as in Fig. 8, where three of them are shown mounted on a single shaft. This same runner is shown, mounted in its bearings, and placed in the lower half of its casing in Fig. 9, this machine being a 250-horse-power, 3-stage turbine. In this case the steam is directed from nozzles into the first row of buckets on the left-hand wheel, from which it escapes into the pockets in the reversing guide ring shown surrounding it in Fig. 9. These

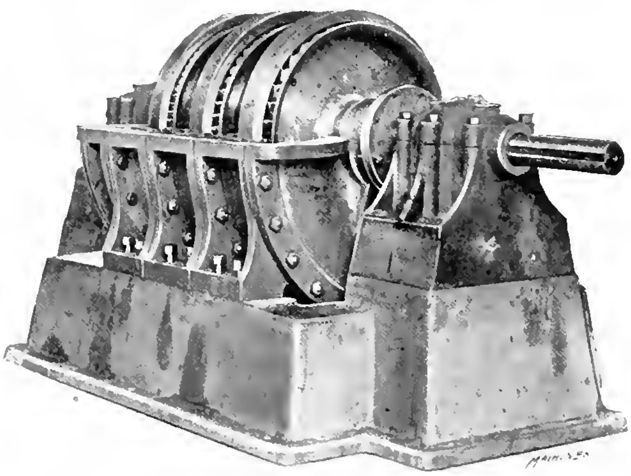

Fig. 9. Multiple Stage Turbine with Runner Exposed.

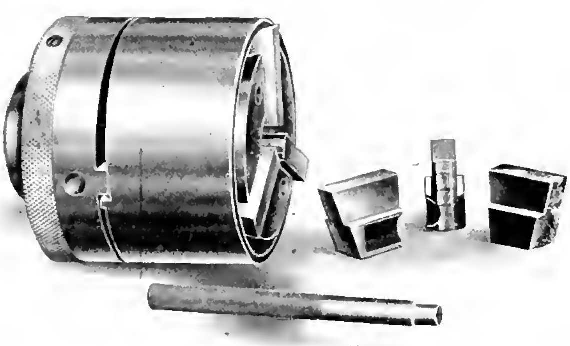
direct it into the second row on the same wheel, from which the steam is led to the second wheel, where the same operations are repeated. Following as above through the third wheel, it escapes, having given up all its velocity in the meantime. It will be noted that the buckets are progressively larger from the first to the third wheel, thus giving the larger space required by the decreasing velocity of the steam.

The advantages claimed for the Sturtevant turbine over the reciprocating engine for the same work are: greater simplicity; decreased weight; less space; greater reliability; less vibration; decreased cost of maintenance; and noiselessness of operation. As compared with other turbines for the same service, the builders claim for their machine greater durability, greater capacity, lower speed, larger clearance, better balance, less floor space, and higher economy.

QUICK ACTION ADJUSTABLE COLLET CHUCK.

This device is designed to be used in engine lathes, speed lathes, grinding machines, gear cutters, etc., in fact, in any



Quick Action Adjustable Chuck of Wide Range.

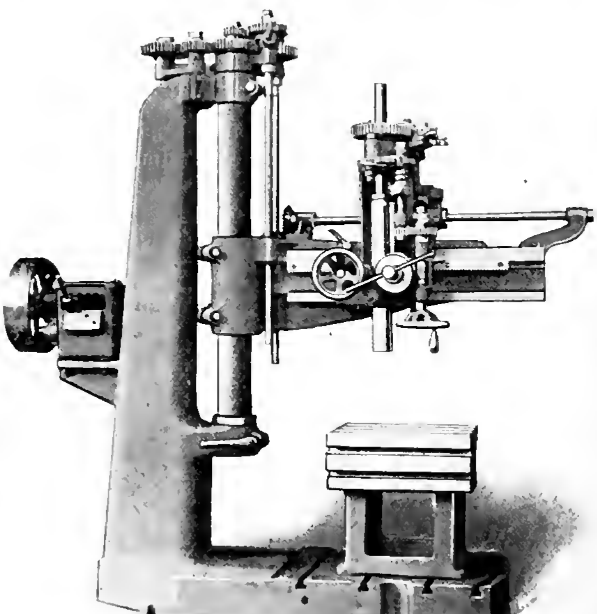
machine having a rotating spindle in which it is desired to hold work or tools of comparatively small diameter. It replaces a full set of draw-in collets, draw-in bar and hand-wheel on the lathe at less than half the cost.

As may be seen, it consists of a solid body, slotted to receive the jaws, which may be either plain (as shown in place in the device) or stepped (as shown dismounted). These jaws have tapered outer surfaces to match the cone shape inner surface of the outer sleeve. This sleeve may be adjusted forward or back, to suit the diameter of the work to be held, by rotating the knurled nut, threaded to the rear end of the body. When this adjustment has been made, the jaws can be quickly opened or closed by inserting the pin, shown in the cut, in the cam ring located between the nut and the sleeve. This latter has cam surfaces engaging projections on the cam ring in such a way that it is forced to move outward or inward, in accordance with the movement given the cam ring by the operator. All working surfaces are hardened and ground.

This device is made in four sizes: for bar stock with plain jaws from 1/4 to 1 inch, or from 1/2 inch to 1 1/2 inch; and with extra capacity stepped jaws (as shown in the cut) to give from 1 to 3 inches or from 1 1/2 to 4 inches capacity. The chuck is made with 2, 3 or 4 jaws as required, and will also be furnished with jaws for stock of special shape. Chucks of the same design for larger capacity will be made to order. The Adjustable Collet Co., Cleveland, Ohio, are the makers.

THE HILBERT 2 1-2 FOOT RADIAL DRILL.

The Hilbert Machine Co., 2116 Colerain Avenue, Cincinnati, Ohio, are placing on the market the radial drill shown in the accompanying half-tone. This machine will do the work of a radial drill of its capacity, but is arranged in addition to have such quick handling and operating features as to allow it to do the work of the ordinary drill press. The driving mech-



Hilbert 2 1-2 Foot Radial Drill.

anism consists of a speed box, having four changes, which, with the addition of the back gear on the spindle, gives eight spindle speeds. The back gear can be thrown in and out while running. All the changes in the speed box are controlled by one lever. The spindle is made from high carbon steel, has four changes of feed, an automatic stop, and a counterbalance weight. A tapping attachment is provided for the head, operated by a lever within convenient reach of the workman. The head can be securely locked in any position.

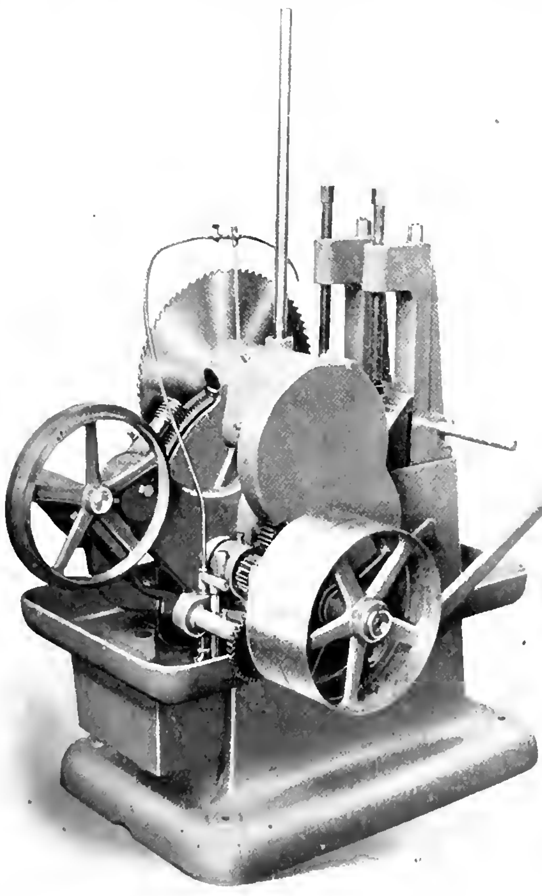
The arm is of rigid design, and is raised and lowered by power. For extra heavy and accurate drilling, a tie-rod arrangement is used to connect the outer end of the arm to the base of the machine, a circular slot being provided in the base for the T-head of the tie-rod. This may be seen in the cut. The maximum distance of the spindle from the base is 49 inches and the minimum extension of the spindle from the column is 11 inches. The rail has a vertical adjustment of 30 inches. The movement of the head on the arm is 24 inches. The machine will drill work on the base to the center of an 82-inch circle, or on the table to the center of a 70-inch circle. The total height of the machine is 80 1/2 inches, and the weight is 2,600 pounds. It will drill 2 1/2 inches diameter in cast iron, 2 1/4 in steel, and drive a 2-inch pipe tap in cast iron.

COCHRANE-BLY METAL SAWING MACHINE.

This tool, made by the Cochrane-Bly Co., Rochester, N. Y., is known as their No. 4 machine, and is designed for cutting rapidly and accurately bar stock in all sizes up to 6 inches round, 5 inches square, and I-beams, channels, etc., up to 12 inches wide.

The saw arbor is carried in a swinging frame, pivoted directly below the axis of the saw. The feed is accomplished by swinging the saw inward about this pivot, a segment of a worm gear being formed on the frame for that purpose, engaged by a feed worm. This feed worm is itself driven by a worm gear receiving its motion from a large cone pulley belted to a cone pulley on the driving shaft, giving two feeds. It is thrown into mesh with the worm-wheel segment by a hand lever, and is held in place by a pawl, which is thrown out by an adjustable automatic stop when the cut is finished.

The spindle is hardened and ground and fitted into a solid bearing on the carriage. It is driven by accurately cut spur gears, mounted on round shafts, insuring a high degree of durability. The vise for holding the work is adapted for either round or square stock, and the large table on which it is mounted may be used with movable clamps for making angular cuts on structural steel, etc. An oil pump supplies the blade with oil from the reservoir, and a large drip pan surrounding the bed provides for chips and oil drainage.



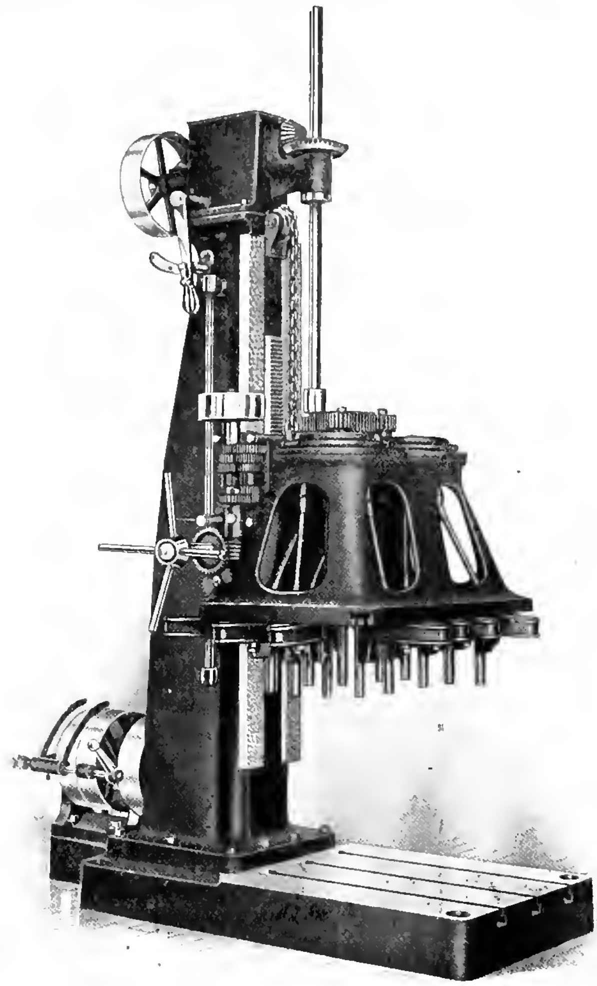
Cold Saw for Bar Stock and Structural Shapes.

This machine takes a saw 18 inches in diameter and 5/32 inch thick. The work table is 15 x 18 inches in area, with a vise having a capacity for stock 6 inches by 12 inches. The floor space occupied is 30 x 43 inches, and the net weight of the machine is 1,150 pounds.

WESTERN HIGH-SPEED MULTIPLE SPINDLE DRILL.

This machine, as may be inferred from the half-tone shown herewith, is built with massive proportions and strong drive, to adapt it to the use of high speed drills. So well has this been done that it will drill simultaneously any number of ½-inch holes up to 20, in a circle, square, or any irregular lay-out within the capacity of the head. If ⅝-inch drills are used, 16 of them may be driven, or twelve ¾-inch drills.

The head is provided with both hand and power feed, with quick advance and return and automatic stop, there being three changes of feed for each of the spindle speeds. It is also counterbalanced by a weight inside the column, through the connecting chain shown. In order to lose as little as possible of the power in transit between the driving pulley and the point of the drill, the spindles have been provided with ball thrust bearings. They are provided with check nuts at the upper ends to take up all end play, and run in bronze bearings which are adjustable vertically to compensate for varying lengths of drills. The arms which carry them are, of course, adjustable horizontally to any desired lay-out.



Heavy Duty Multiple Spindle Drill.

All of the fast running bearings are provided with bronze bushings. The loose pulley and countershaft bearings are chamfered to form reservoirs to hold the oil for their automatic lubrication. The speed gears mounted in the box at the top of the column are submerged continuously in a bath of oil. The driving pinions on the gear box, and the intermediate gear on the head are made of raw-hide, thus insuring a quiet running drive. The size of the head and the number of the spindles can be varied in building the machine to order. In the size shown in the cut, the largest lay-out for the centers of the spindles is 16 x 30 inches. The machine weighs, net, about 6,800 pounds. It is built by the Western Machine Tool Works, Holland, Mich.

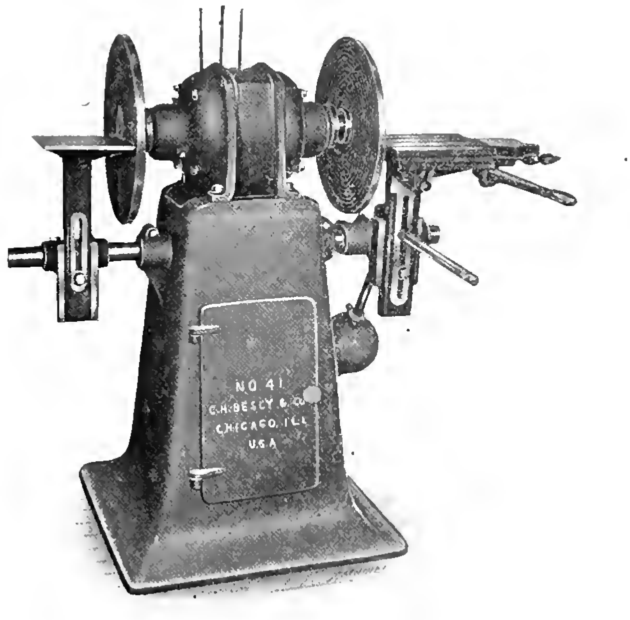
NEW BESLY SPIRAL DISK GRINDER.

Charles H. Besly & Co., of 15-17-19-21 So. Clinton St., Chicago, Ill., have added two new designs to their line of spiral disk grinders, one of them belt-driven and the other motor-driven. The general arrangement of the work holding and feed mechanism is the same in each case. The motor-driven machine, known as the No. 11, is shown in the cut. This tool is intended for general manufacturing purposes on a variety of work.

This machine has one tilting table and one geared level feed table, the latter having T-slots and a keyway for attaching angle plates or other work holders. The disks are 18 inches in diameter and are driven by a 5 horse-power al-

ternating current motor, wound for either two- or three-phase current with voltages of 110, 220, 440, or 550. The spindle, which is of crucible machinery steel, runs at 1,800 revolutions per minute. The journals are 5 inches long and 1⅝ inch in diameter, running in boxes of phosphor bronze, lubricated by the ring oiling method.

The machine covers a floor space of 28 x 28 inches. The length of the spindle over all is 23¾ inches. The height to



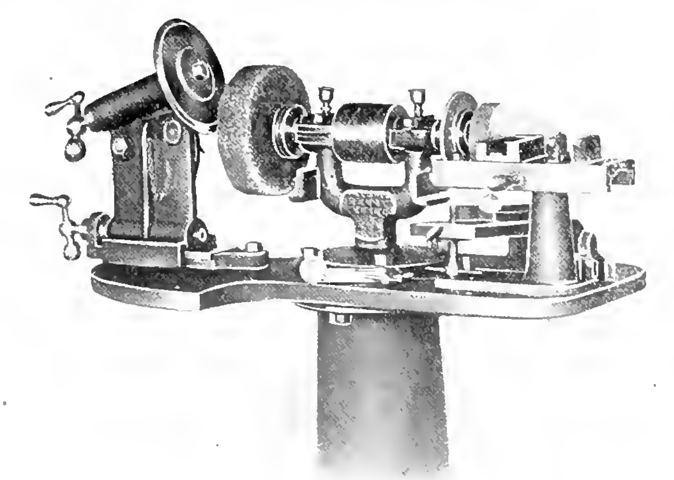
No. 41 Besly Disk Grinder.

the center of the spindle is 40 inches. The net weight of the machine as described, with two extra disks, is 1,400 pounds. All necessary accessories are provided, such as setting up press, cement, lubricating oil, glue pot and brush, wrenches, etc., and a large assortment of "Helmet" spiral paper and cloth circles.

SPECIAL GRINDER FOR PIPE THREADING DIES AND CUTTER DISKS.

This device has been built to fill a need found by the makers, the Murchey Machine & Tool Co., Detroit, Mich., for grinding the tools used in pipe cutting and threading machinery.

The grinder shown in the cut is particularly useful for grinding the disks used in rotary pipe cutters, and the chasers used in pipe threading machines. In the illustration, a cutter



Grinder Specially Designed for Sharpening Thread Chasers and Cutting Rolls.

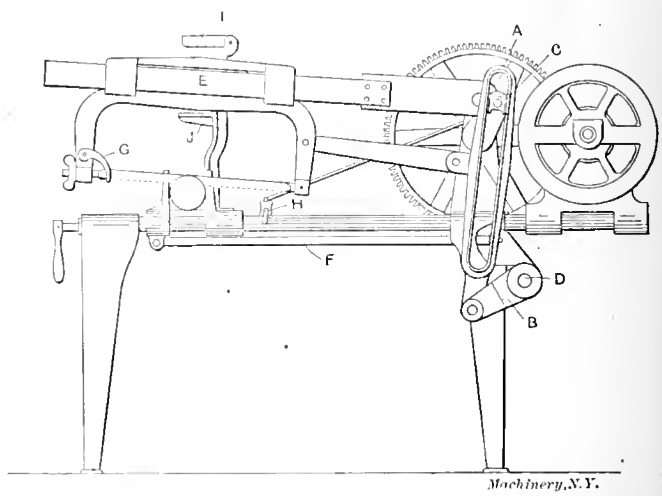
disk is shown in position for grinding on the left-hand side of the machine. It is fed against the side of the cup emery wheel by the movement of the lower screw of the fixture. The upper crank is then used to revolve the roller until its edge has been brought to the proper degree of sharpness. The fixture is then swung around out of the way, the emery wheel removed, and replaced with a felt wheel coated with emery. This gives a fine finish, and is said to increase the strength of the cutting edge.

The chasers are ground on special cone-shaped wheels shown in place at the right-hand end of the spindle. They are held in a suitable holder having stops to locate it squarely, and at the right position in relation to the grinding wheel. The purpose of the cone-shaped emery wheel is to grind the throat of the chasers to the required diameter to agree with the diameter of the pipe or hole it is to thread. After the throats of the chasers have been ground, the holder in which they are mounted is removed to the lower slide, where the face of the thread is sharpened by passing it under the small emery wheel in back of the cone wheel. These operations are all done quickly without removing the individual chaser from the holder. Suitable adjustments are provided to compensate for the wear of the wheels. An emery dresser is furnished attached to a moving slide, to dress the cone-shaped wheel to the proper angle.

VARIABLE STROKE QUICK RETURN HACK-SAW.

It is generally rather difficult to say anything of startling interest in describing a new hack-saw. The movements involved are so simple that no great scope is allowed the designer for the exercise of ingenuity in design. In the machine shown in the cut, however, two features are added which we have not seen before applied to this machine tool.

One of the novelties of the machine lies in the mechanism by which the saw is reciprocated. The crankpin block *C* enters the groove of slotted link *A*, which is pivoted to bell crank arm *B* at the bottom as shown. The other end of this arm is connected to a rod *F*, running back under the machine



Variable Stroke Quick Return Hack-saw.

to a connection with the front vise jaw. By this means the whole link is bodily raised or lowered with the closing or opening of the vise. To the side of link *A* is pivoted the connecting rod by which the saw is driven. By following the action of the mechanism through, it will be seen that when the jaws are adjusted for a large piece of stock, the stroke will be shortened to correspond, and when a small piece of stock is in place, the stroke is lengthened to the proper degree, so that the full length of the saw blade is always in use, without any danger of the saw frame striking the vise jaws.

The arrangement of slotted link *A* pivoted in *B*, and crank pin *C*, forms a quick return motion which gives the saw a back stroke occupying only about one-third of the time taken by the cutting movement. This is owing to the fact that the crankpin is at the lower end of its travel nearest the fulcrum when the saw is returned, so that the motion is very rapid. The quick return movement is a valuable feature. In fact it allows about ten strokes more per minute than would otherwise be the case, without increasing the cutting speed.

An automatic device is furnished for stopping the machine when the stock has been cut in two. A friction drive is used which is disconnected at *H* by the dropping of the saw carrier and the arm. The saw carrier slides in babbitted bearings on the machined rectangular surface of the arm *E*. This gives a guiding surface which will wear for a long time without

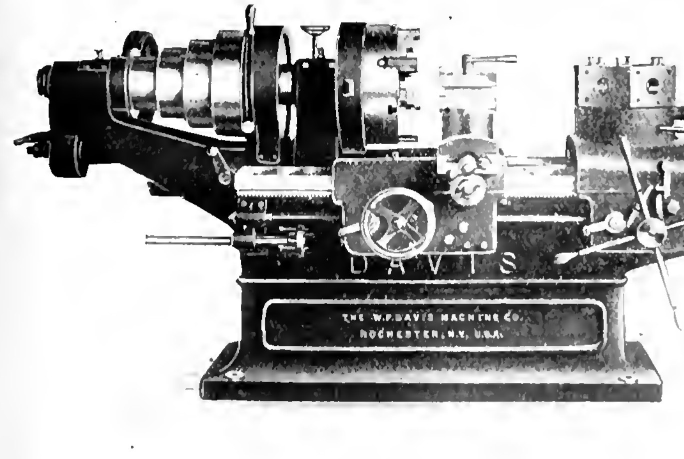
becoming worn or roughed up. The makers of this machine, E. C. Atkins & Co., Indianapolis, Ind., furnish it in three sizes, to cut stock 4 x 4 inches, 5 x 5 inches, and 8 x 8 inches.

DAVIS TURRET LATHE FOR BORING, FORMING AND TURNING.

This tool, built by the W. P. Davis Machine Co., Rochester, N. Y., will be found useful for work done in the large quantities required for the making of duplicate parts for interchangeable manufacture. Six or more operations may be performed on a piece without removing it from the chuck.

As may be seen from the half-tone, the lathe has an unusually strong and massive bed, with the head-stock cast in one piece with it. The spindle is driven directly, or through a quick acting triple back gear mechanism, from a 4-step cone. The front spindle bearing is 4$\frac{1}{2}$ inches in diameter and 7 inches long; the hole through the spindle is 2 inches in diameter. The cone pulley has steps of suitable width for a 4-inch belt. The back gear arrangement provides for a friction drive for connecting the cone directly with the spindle, and a positive clutch drive for engaging the back gears. The triple gear connection provided is not shown plainly in the cut, owing to the fact that the faceplate gears are covered with a guard. With the 2-speed countershaft provided, this gives 24 speeds to the spindle.

The feed connections for the carriage and turret slide are located inside the bed. A shaft is carried in the head-stock, connected with the spindle through the gearing shown at the left-hand end of the machine. A sliding key may be shifted by means of the lever shown at the end of the head-stock to give two changes of speed. The lever shown beneath the large step of the cone operates a sliding key controlling three speed changes given by a cone of gears beneath the main bearing. Six changes in all are thus provided for. The feed rod runs through the center of the machine to change gearing at the rear end of the bed, which may be set to give threads from 2 to 32 per inch, with the gears provided. These gears connect the central shaft with the splined leadscrew at the front of the machine. Either a screw feed or a rod feed may be used, for either the carriage or turret slide. The movement of the screw feed or rod



Turret Lathe of Rigid Design.

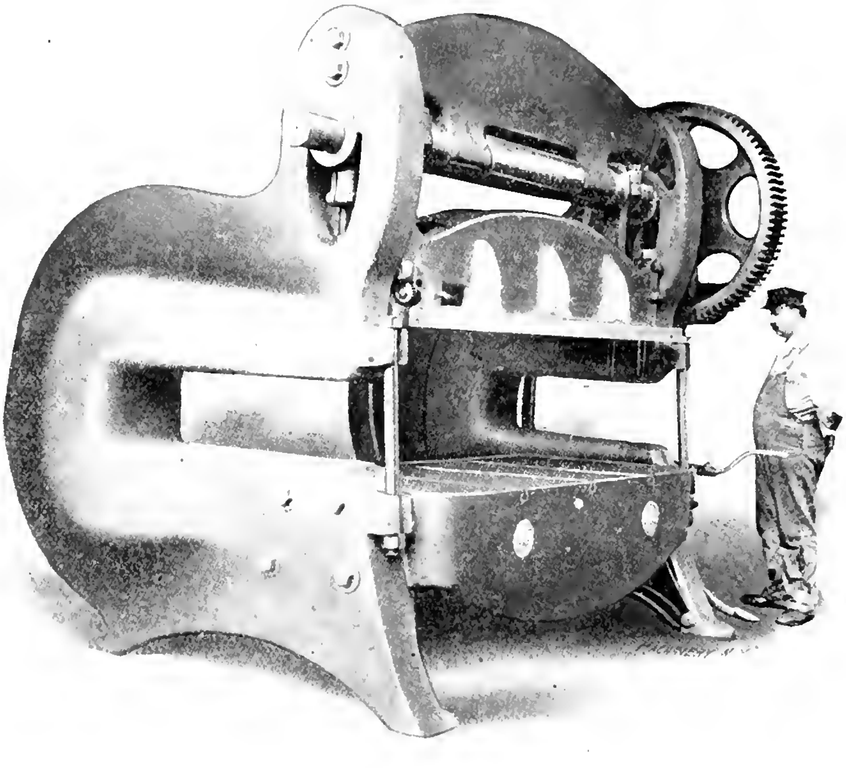
feed is reversed by bevel gears and clutches operated by the lever shown projecting from beneath the bed at the right of the apron. A later design provides for a foot treadle to control this movement at the front of the machine.

The turret has an open center, so that a mandrel can be passed entirely through it. The separate stops provided in the bed for each of the six faces of the turret act automatically, so that the feed may be tripped at any desired point. The carriage, which may be operated independently of the turret slide, has a 4-sided turret for carrying tools, which may thus be used for either turning, forming or facing. Separate stops for each face are provided on the rotating stop carrier on the front of the bed beneath the head stock.

This machine is regularly provided with a special heavy 4-jawed independent chuck, and with a friction countershaft having self-oiling pulleys lined with bronze bushings. The machine swings 26 inches, and its net weight is 7,000 pounds.

FERRACUTE PRESS FOR HEAVY CUTTING.

The heavy cutting press shown in the accompanying halftone was built by the Ferracute Machine Co., of Bridgeton, N. J., from designs of Mr. Oberlin Smith, president and mechanical engineer of the company. This machine is used for



Cutting Press of Great Capacity.

cutting shoe sole blanks from the largest and heaviest sole leather hides, 32 soles being cut at each stroke of the press. As it is run from 20 to 30 strokes per minute, the great capacity of the machine is apparent. It has a width of 7 feet between the columns, and a depth in the center of the ram to the throat of 3 feet, so it is adapted for work of large area.

The columns are well proportioned and calculated to withstand all ordinary stresses, the tie-rods at the front of the press being used only for exceptional work, where extra stiffness is required. The press is capable of safely exerting a pressure of 84 tons. All machines of this type now being built by the Ferracute Machine Co. are fitted with a multiple-disk friction clutch of new design, the result of much study and experience.

The dimensions of the press are as follows: Height, bed to ram when up, 14$\frac{1}{2}$ inches; stroke of ram, 2 inches; adjustment of ram, 3 inches; fly-wheel, 40 inches diameter and 7 inches face, weighing about 1,100 pounds. The total height is 9 feet. The floor space occupied is 11$\frac{1}{4}$ feet right to left, and 8 feet front to back. The total weight of this machine is about 20 tons.

The design of the press can be adapted, of course, to any line of manufacture requiring the cutting of heavy sheet material.

GOULD & EBERHARDT GEAR HOBBING MACHINE.

The accompanying half-tone and line cut illustrate a new machine designed by Gould & Eberhardt, Newark, N. J., for cutting spur, spiral and worm gears by the hob-generating process. In this process a hob is employed whose teeth have a normal section corresponding in outline to the rack of the interchangeable series of the gears which are to be cut. This hob is mounted in a swiveling head on a slide which can be fed downward along the face of the column of the machine. In cutting spur gears, the spindle is inclined to the same angle as that made by the teeth of the hob on the pitch line. This presents the normal section of the hob squarely with the axis of the blank to be cut, with the outline of the interchangeable rack, as previously described. The hob being set to the proper depth, and being connected with the blank by change gearing so as to give the proper speed ratio between the two, the hob and the work are rotated together, and the former is fed gradually down through the latter. When the hob has passed entirely through the work, the teeth will be all cut, of the required number, shape and depth. It will be seen that the continued rotation of the hob with its worm-like series of teeth, as it is gradually fed down through the work, generates the proper shape of teeth in the gear, the same as would be accomplished by meshing a rack of similar shape with a blank of some plastic substance like wax or clay.

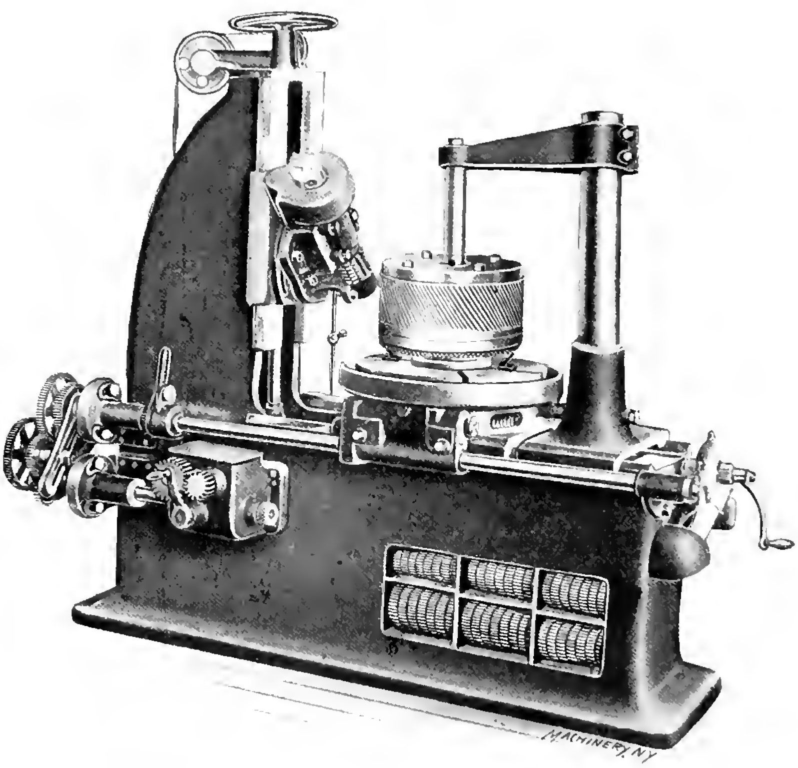


Fig. 1. Automatic Gear Hobbing Machine for Spur, Spiral and Worm Gearing.

The Spindle and Work Table Driving Mechanism.

The mechanism by which this is accomplished will now be described. In Figs. 2 and 3, *A* is the four-step driving cone. This is geared through a reversing mechanism (comprising the usual set of bevel gears and toothed clutches) to the vertical shaft which transmits the motion to the cutter head. Handle *B* operates the reversing clutch and gives the desired direction to the spindle *D*. A splined bevel gear carried by the head, and moving with it on the vertical shaft, acts in turn on a train of gears, and drives the spindle. As stated the hob is carried by a head *E*, which can be swiveled on the slide to any desired angle, the arrangement of the driving gears being such as to permit this. The hob can be adjusted endwise to bring any portion of its length central with the work, so that the wear may be evenly distributed along its cutting face.

The driving shaft, on which the cone pulley is keyed, is continued to the gear casing shown in front of Fig. 1, where it is made to drive the lower shaft running to the change gears back of the column. These change gears connect the spindle movement with a long shaft running along the front of the bed as shown, and geared to a worm, driving what may be called the "index" wheel of the work table *F*, although, strictly speaking, there is no "indexing" in this form of machine. These change gears are the ones which are set to give the proper ratio of movement between the hob and the work. If, for instance, the hob is double threaded, and the gear is to have 84 teeth, the ratio of movement between the hob and the work would be $84 : 2 = 42 : 1$, and the proper change gears for giving this ratio will be put in place.

Near the left-hand support of the long shaft driving the index worm in Fig. 1, will be seen a vertical handle operating a pair of tumbler gears, meshing with a larger gear almost concealed in the frame of the machine. This larger gear drives the feed mechanism, and the handle serves to reverse it for feeding in either direction. At the back of the column, not plainly seen in either of the cuts, change gears are provided for varying the feed, which is applied to cutter slide *C* by a vertical screw *G*, running the length of the column and terminating in the horizontal hand-wheel shown at the top. The slide is carefully counterweighted as shown, so that the only strain put on the feed mechanism is that due to the pressure of the cut. The feed screw is arranged to pull the slide when feeding, instead of pushing it, so that it is not at any time in the condition of a long slender column supporting a heavy load. This provision is markedly effectual in giving steadiness of action.

The gear casing with the vertical handle shown at the front of the machine in Fig. 1 provides a rapid traverse of the cutter head either upward or downward, as desired, and in accordance with the movement given to the handle. This rapid movement is directly connected to the driving shaft. At the rear of the machine is a vertical rod carrying an adjustable dog *H* which is struck by an arm on the saddle at the completion of the working travel of the cutter slide. This throws out the automatic feed.

The work table *F* is directly connected with the index worm-wheel instead of having the latter below the bed, as was usual in previous machines of this type. A double bearing is provided for the table and the gear, the latter being located centrally and supported near its rim, while the table itself has a second bearing under its outer periphery and directly below the work. This insures a rigid support to the gear blank. The cutter arbors are forced into place or withdrawn from their tapered seats by a differential screw arrangement, which does away with the necessity for driving them out from beneath. The table is supplied with a central aperture, so that pinions with long hubs can be inserted and held with suitable chucks. The chip guard is stationary and does not rotate with the table. By this means the carrying of the chips around the whole periphery of the work table is avoided. They are discharged, instead, into an opening in the bed directly beneath the cutting point. As in the regular automatic gear cutters made by this firm, the index worm is arranged to be thrown out of mesh with the worm-wheel, when so desired, so that the work may be rotated freely, as well as allowing the wear to be taken up. A fine adjustment of the worm is also provided, which is useful in setting gears accurately with the hob for recutting. The speed ratio between the worm and the worm-wheel is 60 to 1. This gives a strong and durable drive under the pressure to which the gearing is subjected when cutting, and does not require a high rate of speed when cutting small pinions.

Provisions for Hobbing Worm-wheels.

The machine, as so far described, will be seen to be adapted to the cutting of spur gears. To the machine as described, certain additions have to be made to adapt it to the cutting of spiral and worm gears. In cutting worm gears, for instance, the hob is fixed in the same position that the worm will occupy with relation to the finished wheel, and the hob and blank are rotated together with the same ratio that the worm and wheel will have. This ratio is obtained in the same way as in the case of spur gear cutting, by using the proper change gears. The additional mechanism required is for feeding work table *F* along the bed toward the hob. For this purpose, the screw by which the table is adjusted on the bed is provided with a worm-wheel driven by a drop worm, both being concealed in casing *J*. This worm is connected by bevel gears with a shaft running back to the feeding mechanism at the column end of the bed. A stop rod *K*, see Fig. 3, is provided with an adjustable dog which is engaged by the work slide when the desired depth of cut has been reached. This releases the drop-worm and stops the feed. Scale *L* is read by a vernier carried by the work table, and serves to give accurately the center distance between the work spindle and the hob spindle. This is useful in setting for spur and spiral gears as well as for worm gears. When cutting worm-wheels by this method, it is obvious that preliminary nicking of the blank is not necessary, though it may sometimes be advisable.

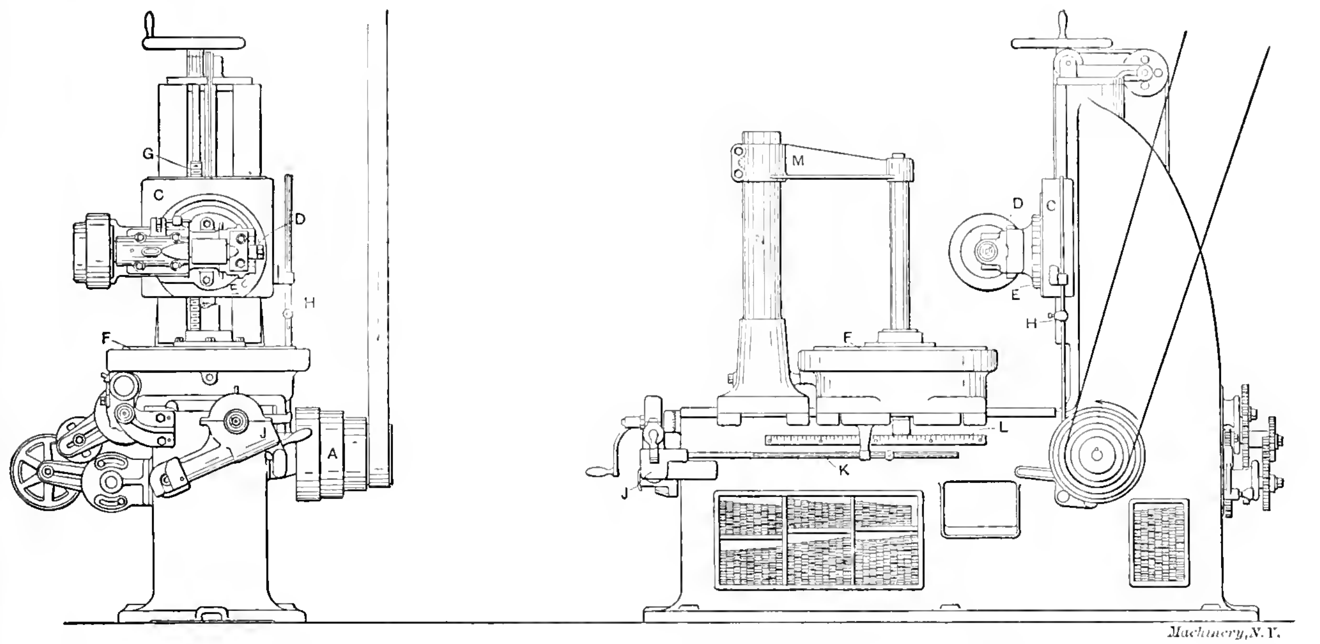
The Spiral Cutting Mechanism.

For cutting spiral gears additional mechanism has to be introduced. In this operation, the head is set so as to bring the teeth of the hob at the same angle as the teeth which are to be cut on the work. A movement of the work relative to the hob, or *vice versa*, is needed, such as would have to be given were the rotation of the spindle stopped, and the hob moved down through the work. It will be seen that in this case, owing to the inclination of the teeth of the work, if the teeth are to clear those of the hob, either the work or the hob would have to be rotated or shifted sideways. The mechanism for taking care of this requirement is not plainly shown in any of the cuts, as it is located at the column end of the bed. It is controlled by a train of change gearing, which is set to agree with the lead of the spiral being cut. With proper change gears for the lead and for the ratio between the hob and the wheel, the machine may be set to work cutting a bank of spiral gears as in Fig. 1, and will make a continuous operation of it, the same as when cutting spur gears.

All the various movements entering into this operation may be reversed at will, to accommodate right- and left-hand spirals, etc. In addition to this, the cutter head *E* may be swung around to the other side, above the horizontal, through an angle of 180 degrees. With this arrangement, the driving gear is always above the center line of the head, so that less clearance is required below the work. This means that the blanks can be held down closer to the table, giving less overhang and greater rigidity.

Rigidity in Design.

This matter of rigidity is of special importance in a machine working on this principle. The number of teeth at work at a given instant is much greater than is the case with a disk cutter in an ordinary automatic machine. This means that the pressure of the cut is much greater, with a corresponding increase of the strain on the machine. Under these circumstances, the number of joints between the cutter, spindle, and work must be reduced to a minimum, and the amount of overhang, as well, must be looked out for. In the present machines, for instance, the column is cast solid with the bed. The cutter is brought as near the face of the column as is possible with the various adjustments required. Mention has been made of the support afforded to the work table immediately beneath its outer rim, and above the worm gear by which it is driven. In addition to this, an outboard support is provided for the upper end of the work arbor. As shown, this support consists of an arm *M*, carried at the upper extremity of a vertical post *N*, which is seated in a base clamped to the ways on the top of the bed. This base may be fastened by a through bolt to the work slide, so that it is adjusted in and out with it.



Figs. 2 and 3. End and Side Elevation of the Gould & Eberhardt Gear Hobbing Machine.

Development and Scope of the Hobbing Process.

This process of cutting spur and spiral gears with a hob is not a new one, as it has been done since about 1850 in various ways, and by different people in Great Britain and continental Europe. The first step taken in this country of which we have any record, was the taking out of a patent by Mr. Geo. B. Grant, about eighteen years ago. This one as well as a number of others relating to this art have been acquired, or have been taken out, by Messrs. Gould & Eberhardt. In spite of the comparative oldness of the idea, however, it is only within the past four or five years that it has been applied commercially. Barring the Grant Lees machine, described in the October, 1907, issue of MACHINERY, there have been but two or three isolated cases of machines acting on this principle, none of them built for the trade. A number of considerations have stood in the way of the development of the idea. Perhaps the most important was the general satisfaction with the work of the automatic machine using a rotary disk cutter. Another factor was the necessity in the hobbing machines for unusual rigidity, only made possible with modern knowledge of machine tool designing

The development of the hobbing machine has also been seriously hampered by a difficulty in giving the proper shape to the teeth of the hobs. It has been found by experience that what would seem to be the theoretically correct tooth will not produce correctly shaped and noiselessly running gears under ordinary conditions. It is commonly found, for instance, that the teeth of such gears are unsymmetrical, even though the hob with which they are cut appears to conform in all particulars with the rack tooth which it is supposed to represent. The builders of this machine have investigated the matter thoroughly, and have arrived at a method of forming the hob which produces in the gear a tooth of the required shape. This feature has been covered by domestic and foreign patents.

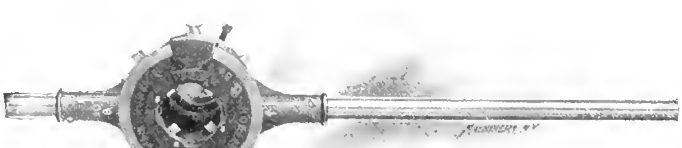
A strong factor tending to develop the hobbing machine in the past few years has been an increased appreciation of the merits of the "twisted-tooth" or "herring-bone" spur gear, for high speeds and smooth action. A largely increased use of this form of gearing has awaited a convenient means of manufacturing it. The making of helical gears in the universal milling machine is a comparatively slow and costly process. Numerous attempts have been made to manufacture them in better ways—such, for instance, as by making an automatic gear cutter, following the lines which have proved so successful for plain spur gearing. This involved the addition of a differential gear mechanism to the indexing parts (somewhat similar to that required on the hobbing machine), and in addition some device for dropping the cutter away from the cut on the backward or quick return movement, to prevent the cutting edge from striking on the finished sides of the tooth spaces. These conditions so complicated the already somewhat complicated machine as to render its commercial success doubtful. In addition to this, it involved the introduction of a number of joints, which tended to reduce the capacity of the machine for taking heavy cuts. A comparatively simple hobbing machine, however, will cut spiral gears as readily as spur gears, and seems to be the correct solution for this problem.

When it comes to the matter of cutting spur gears, its field has not yet been definitely determined. In some work it appears to have certain advantages over the usual type of automatic gear-cutting machine, while in other cases it falls behind. It will doubtless require continued use, with a variety of work, and for a considerable length of time, to determine just what cases are best suited for the hobbing machine, and what for the machine with the rotating disk cutter. It is not probable that in the future either of them will occupy the field to the exclusion of the other.

This machine will cut gears 24 inches diameter and 10 inches face. A larger and smaller size are in preparation.

HOEFER PIPE-THREADING DIE STOCK.

This device, made by the Hoefer Mfg. Co., corner Chicago and Jackson Sts., Freeport, Ill., is believed by its makers to solve all the difficulties connected with the operation of die stocks of ordinary construction. It is so arranged as to require but one set of chasers for a given pitch over a wide range of diameter. In addition to this, a thread may be cut



Improved Die Stock for Pipe Threading.

with this tool with a great deal less exertion than is ordinarily required. The reasons for this will be understood from an examination of the cut and the following description.

The chasers are very narrow instead of being wide and covering several threads. After starting them onto the end of a pipe, they are automatically withdrawn as the cut proceeds, giving the required taper. Owing to their narrowness, the great friction met with in the wide chasers of other dies is obviated, and the cutting is comparatively easy. The first three chasers divide the cut evenly between them, while the fourth takes a thin shaving cut, leaving a smooth thread similar to that which would be produced in a lathe.

The No. 8 size, shown herewith, is instantly adjustable from 1 to 2 inches in diameter. The dies can be set to the desired size by shifting a plate on the stock. This plate is then firmly clamped by a thumb screw which cannot slip, after which the stock is ready for immediate use. By simply relieving the dies, the tool can be taken off the work without fear of injuring the cutting edges of the chasers.

MULTIPLE TOOL BORING HEAD.

This tool, made by Melvin & Hamaker, of Meadville, Pa., embodies a number of novelties in its construction. Six blades, presenting six cutting edges, are used; and owing to

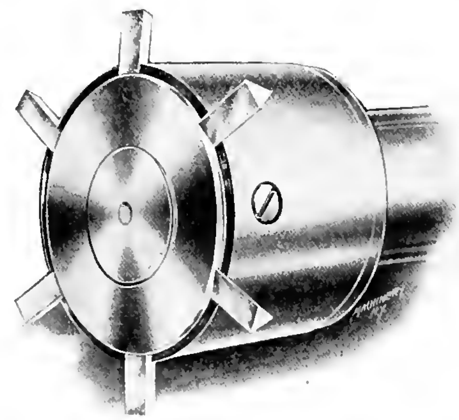


Fig. 1. Melvin-Hamaker Adjustable Boring Head.

the triangular shape of these blades, they may be reset in different positions to give new cutting edges when the old ones are worn. The tool is made in either of two styles, with blades adjustable for diameter, or fixed.

The blades are formed from steel having an equilateral triangular section, and are seated in grooves of corresponding shape in the body of the tool, which presents them to the work at the required cutting angle and with the required clearance. When one cutting edge is dull, the blade may be turned in its seat to present a new one. Three cutting edges are thus provided for each end of the tool, so that reversing it gives six cutting edges in all at one grinding. When the point of the tool is rounded to give a smooth finishing cut, four positions are provided for.

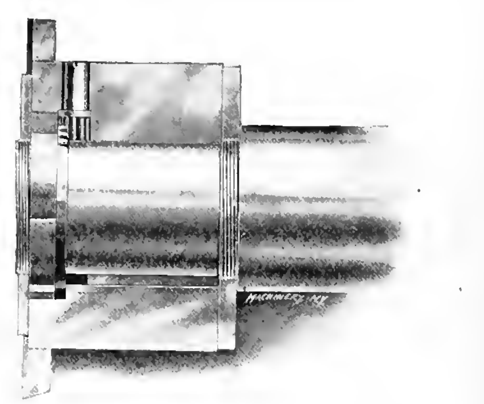

Fig. 2. Section of Adjustable Head, showing Construction.

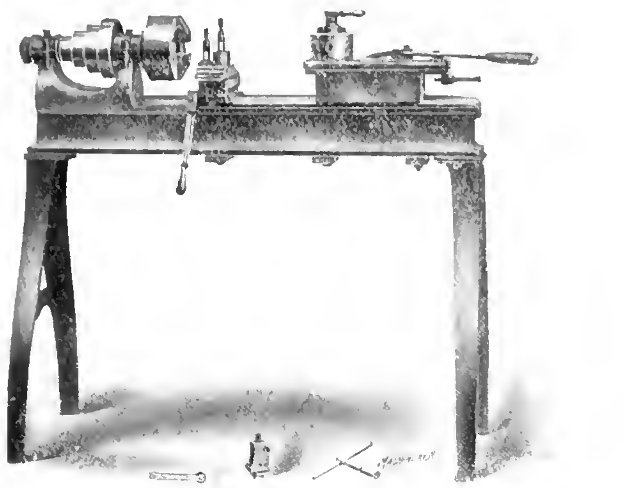
The adjustable form of the tool is shown in cross section in Fig. 2. The bottoms of the blades seat against the corresponding faces of a cam. This cam is rotated by teeth on its left side, engaging with an adjusting pinion, operated by a screw driver slot in its upper end. A nut, threaded to the front of the shank, has to be loosened to make this adjustment, and is tightened down again after the required size has been reached, as determined by calipering over the outside diameter of the blades. This adjustment is furnished in the shell form of the boring head in sizes above 6 inches, and in the solid or machine type of head in sizes above 4 inches in diameter.

WELLS CHUCKING LATHE.

This chucking lathe is one of a line of turret machines which F. E. Wells & Son Co., of Greenfield, Mass., has recently designed. Like the other machines of the line, the head-stock and bed are cast in one piece, this being a distinctive feature of the machines made by this firm. This chucking lathe is intended for doing the machine work on small brass and iron castings, being adapted for doing work



Simple and Inexpensive Chucking Lathe.

which is generally done on much more expensive machines. The lathe is ordinarily furnished with a 4-hole hand-operated turret, but either a 4-hole or 6-hole automatic turret can be furnished if desired. Any kind of a 2-jaw scroll or geared chuck can be used, and if the customers work requires it, a 3-step cone for a 2-inch belt, or a 2-step cone for a 3-inch belt can be furnished in place of the 4-step cone shown. The bed is made in 3½, 4 and 5 foot lengths.

DOWN-FEED FOR STOCKBRIDGE SHAPER.

The advantage of the automatic down-feed on the shaper for work for which it can be used, is obvious. It enables

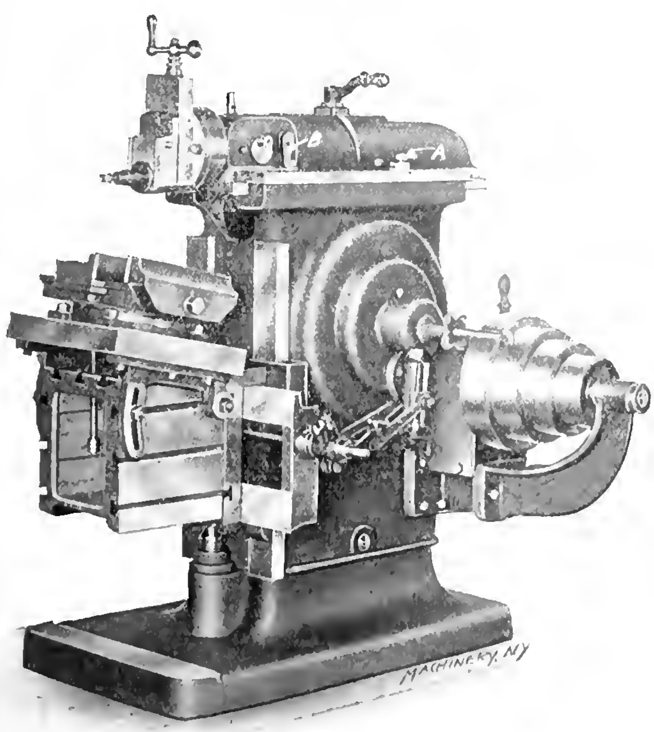


Fig. 1. Stockbridge Shaper with Patented Automatic Down-feed.

the operator to attend to other matters while the actual cutting is in progress, and it enables the tool to be used at its maximum efficiency, by giving it, uniformly, the heaviest cut it is capable of standing safely, at each stroke. With hand feed, this latter requirement is especially not met, since the amount which the handle is turned is bound to vary more or less with each stroke.

The attachment is shown applied to the machine in Fig. 1, and separated from it in Fig. 2. An adjustable dog A, is mounted in a T-slot on the upper surface of the holding-down gib for the right side of the ram. This dog engages with the lever B on the ram at the end of the return stroke, giving B a greater or less movement depending on the position in the slot at which dog A has been clamped. If, by mistake, it has been set too far toward the front, so that the backward movement carries lever B entirely over it, no harm results on the forward movement, owing to the fact that the acting portion of the dog is formed by a catch, pivoted and held in position by a spring. As the lever is going back over it under the circumstances just described, it is forced to one side, snapping back into place again ready for action as soon as the ram again returns.

Fig. 2. Mechanism of the Automatic Down-feed

Lever B, which receives an adjustable swinging motion by the means just described, is keyed to a short shaft having a bearing in the plate, and carrying at its inner end the disk D, having teeth cut in a portion of its periphery. This latter mechanism is best seen in Fig. 2. Disk D meshes with a similar one E, located on the stud C. An internal ratchet in E engages teeth on gear F, so that the positive movement given to lever B by the dog is transmitted through to this latter gear. A coiled spring about the axis of lever B and disk D returns these parts to their original position as the ram starts its forward stroke. It will be seen that this action gives to gear F an intermittent rotation, continuous in direction. By the pinion and bevel gears shown, gear F is connected to G, the down-feed screw of the machine. The ratchet connecting E and F may be engaged or released by a knob on the outside of the machine.

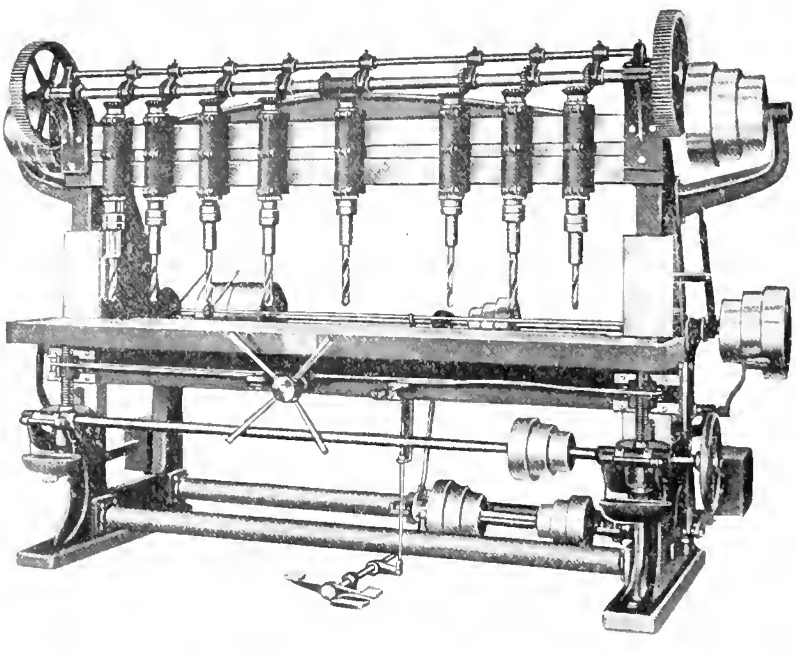
This machine will be seen to be practically fool-proof, positive in action, and simple and compact in construction. It is built by the Stockbridge Machine Co., Worcester, Mass.

ANDREW MULTIPLE DRILLING MACHINE.

This tool, as may be seen from the accompanying half-tone, is of the type in which the drill spindle heads are adjustably mounted on a long cross rail, and are spaced the distance apart required by the work in hand. The work is supported by a table, which is raised by a power feed to perform the operation of drilling.

This machine has been given unusual strength and rigidity by the judicious use of cast iron in the uprights, cross rail and table. The rail, in particular, is so designed as to prevent any

springing or twisting from the thrust of the drills, thus insuring true and accurate work. The spindles are driven from both ends of the machine by large 3-step cone pulleys, driving raw-hide pinions meshing into large spur gears, fitted to the main driving shaft. From this shaft cut steel miter gears transfer the movement to the vertical drill spindles. These spindles, mounted in heads adjustable along the rail, have each four inches vertical adjustment to allow the use of different lengths of drills, and to accommodate off-sets in bars and irregular work. This adjustment is made with a screw sleeve, which may be securely locked when set to the proper length. All the spindles are fitted with ball thrust bearings to reduce the power required to drive the machine. This is



Heavy Duty Multiple Drilling Machine.

especially important when it is being worked to its full capacity with eight 1¼-inch drills.

The table is carefully counterbalanced with levers and adjustable weights, and has a rapid movement by means of a steel rack and pinion which is operated from the pilot wheel shown in the front. This is independent of the feed movement, which is given to the table by vertical feed screws at each end, acting on split nuts of a construction similar to those used in the lathe apron. These nuts may be opened and closed by the action of a foot lever at the front of the machine. The screw feed is very powerful and also easily operated, ball thrust collar bearings being provided for each feed screw. The makers state that six changes of feed are provided, though the two sets of 3-step cones shown in the cut would lead one to the belief that nine changes are possible. An automatic stop is provided for stopping the feed when the desired depth of hole has been reached.

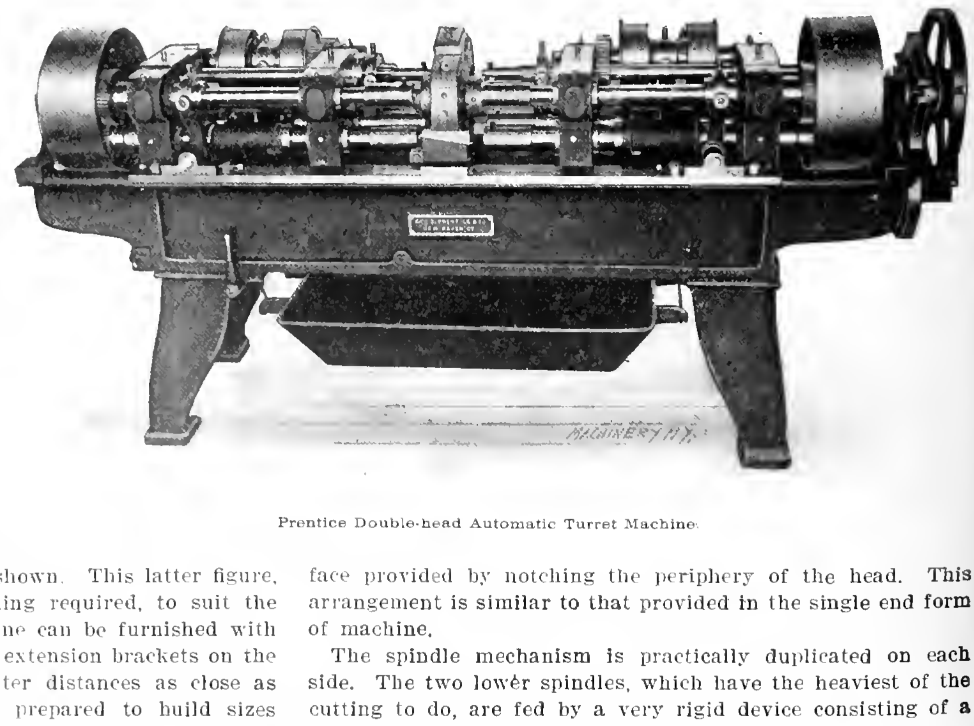
This machine is regularly built with eight spindles, having sufficient power to drill eight 1¼-inch holes in steel at one time. The spindles may be adjusted to a minimum center distance of 4 inches apart and a maximum center distance of 72 inches, in the machine shown. This latter figure, however, may be made most anything required, to suit the needs of the purchaser. The machine can be furnished with a sliding compound table; also with extension brackets on the rail to drill staggered holes at center distances as close as may be desired. The makers are prepared to build sizes both larger and smaller than the machine shown. It is built by M. L. Andrew & Co., 2850-2852 Spring Grove Avenue, Cincinnati, Ohio.

PRENTICE DOUBLE-HEAD MULTIPLE SPINDLE AUTOMATIC TURRET MACHINE.

In the December, 1905, issue of MACHINERY, we illustrated and described an automatic multiple spindle turret machine built by Geo. G. Prentice & Co., of New Haven, Conn. This machine comprised a head, carrying work holding chucks, and arranged to be indexed to as many positions as the design of the machine provided for. Facing each of these positions (except the upper one, which was left blank for inserting and removing the work) were placed rotating spindles, carrying the tools needed to perform the required operations for the work. The feed was effected by cam movements actuating the work carrying head, moving it slowly toward the spindles for the cutting stroke, and returning it rapidly to be indexed for a new position. It will be seen that this design made possible the performance of 3 to 5 operations, depending on the number of spindles, in the time that would ordinarily be taken by the longest of them on an ordinary chucking machine.

In the machine shown in the accompanying half-tone, this idea has been extended to adapt the principle to work requiring machining operations to be performed from each end. To accomplish this, the work holding head is stationary, so far as feeding movement is concerned, and is located in the center of the bed. At the right and left of it are carried the spindles, each opposite a station of the index head. These spindles are operated by cams on the cam shaft in the bed of the machine, for the feed and quick return movements. It will be seen that the principle of the machine is the same as before, except that the spindles have been duplicated at the right-hand side of the head, and that the feed movement is given to the spindles instead of to the work.

In the 5-station form of machine, as shown in the cut, the top position is left open for removing and replacing the work in the head, which latter is shown in the center of the machine. This head is supported against the rotative tendency, given to it by the cutting of the tools, by a wedge-shaped slide, which comes under it from the front, and bears on a surface provided by notching the periphery of the head. This arrangement is similar to that provided in the single end form of machine.



Prentice Double-head Automatic Turret Machine.

The spindle mechanism is practically duplicated on each side. The two lower spindles, which have the heaviest of the cutting to do, are fed by a very rigid device consisting of a yoke connecting each pair on each side of the head, and carry-

ing a cam roll bearing on the cam directly beneath it. This connection is so direct that there is very little side strain or cramping action set up. The first spindle, the upper one at the front of the machine at each side, is fed from the cam by a forked lever arrangement as shown. The fourth and last spindle on the back of the machine is for threading. This is driven separately from the countershaft, tight and loose pulleys with friction clutches being provided for the forward and reverse movements. A cam in the bed of the machine starts the die or tap properly for the first two or three revolutions. The continued forward movement of the threading spindle continues the threading or tapping operation until the proper depth has been reached, when the reversing clutch is thrown by the cam, and the die or tap is backed off or out.

The plan of the mechanism of the machine is simple. The first four spindles on each side are connected together by gearing, each side being driven by a separate pulley. The cam shaft of the machine is driven by a worm and worm-wheel operated by a pulley at the back of the machine, separately driven from the countershaft. Change gears are provided to give different rates of feed, depending on the material and length of cut on the work to be handled. A fast and slow movement for this cam shaft is provided, similar to that used in automatic screw machines of some makes. The right-hand end of the cam shaft carries the roll member of a Geneva stop motion, which is used to index the work-carrying head, whose spindle extends through the machine to the right and carries the slotted disk member of the mechanism. An index wheel of large diameter provided with a locking lever, also operated by the cam shaft, is used for definitely locating the head in position.

This machine is made in 6- and 8-spindle forms, both of which are furnished in three sizes—one for light work, one for ¾-inch pipe size threads and smaller, and one for work having pipe threads from ¾ to 2 inches. These machines vary in weight from 2,300 to 7,500 pounds. The machine is obviously useful in the finishing of pipe fittings, valve bodies, injector parts, etc., as well as in the general run of manufacturing work involving chucking operations, such as bicycle hubs and other work of a similar nature. Manning, Maxwell & Moore, Inc., New York, are selling agents.

THE BICKFORD UNIVERSAL RADIAL DRILL.

The machine illustrated in the half-tone, and described in the following paragraphs, represents a radical departure in design from the standard universal radial drill. The greatest novelty lies in the construction of the arm and the saddle. The changes introduced in the construction of these parts give the machine a rigidity of structure and power of driving mechanism which its builders, the Bickford Drill & Tool Co., Cincinnati, Ohio, believe have not been hitherto attained in any radial drilling machine.

A cross section of the arm is shown in the line cut, Fig. 2. As may be seen, it is composed of a double pipe section, each entirely enclosed, and thus capable of resisting great torsional stresses. The saddle has a bearing on the inner side, the front and outer angular face of a way on each member of the double arm. When the two handles *M* and *N* are tightened, gibs *X* and *Y* are drawn in, clamping the saddle firmly and independently to each of the two sections, and tying them and the saddle together in one solid structure. It will be readily seen that this construction offers possibilities in the way of rigidity not attainable with the older form of arm, usually made in U-form, as shown in Fig. 3, with an opening at the front through which the short intermediate shaft *D* passes, to lead the power from the arm shaft to the spindle. The cutting of this opening in an otherwise circular arm practically nullifies the ability of the circular section to resist torsion.

As is most clearly seen in Fig. 2, the back gearing and the reversing mechanism are located behind the arm. This allows the use of much stronger driving parts, and permits placing the back gears close to the spindle. The tapping attachment, also, is not subjected to so much strain, since the back gears can be located between it and the spindle, so that it is running at a comparatively high speed and transmitting a small turning movement. Besides this, the shafts can be made long enough to provide adequate bearings for them, insuring long life. This point will be particularly noticed in com-

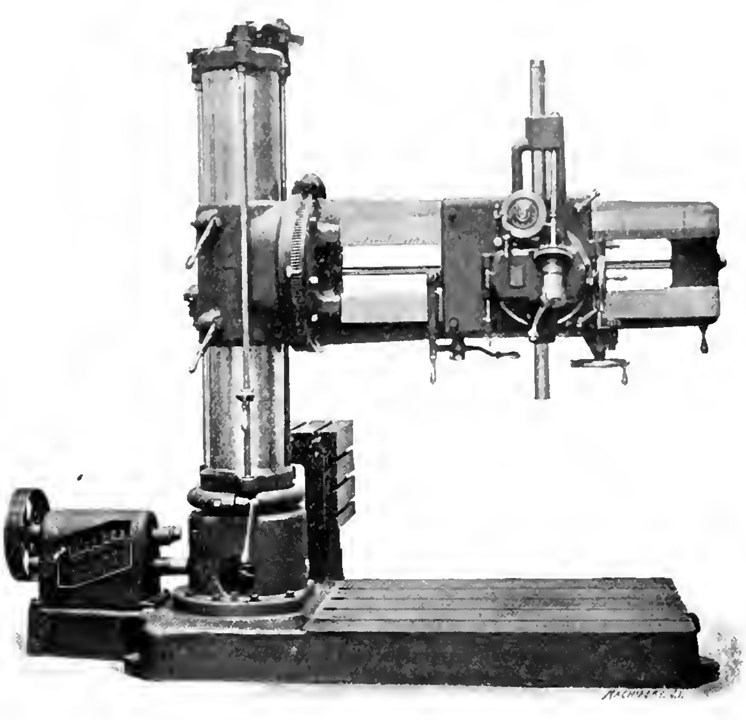


Fig. 1. Universal Radial Drill, with New Design of Arm and Other Features.

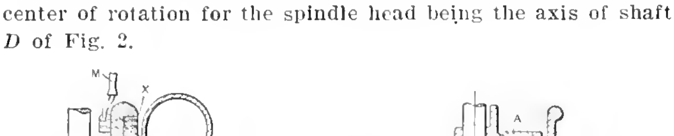
paring the new and old constructions in Figs. 2 and 3. The short shaft *D* in Fig. 3, as used in the old construction, will be seen to be very poorly fitted to perform its function continuously under severe duty for long periods of time. This is replaced, in Fig. 2, by shaft *D* working under conditions which could scarcely be bettered. The removal of the heavy back gearing and reversing mechanism from the top of the spindle makes the swiveling part very much lighter and less top heavy. It will be seen that the gear frame work does not revolve when the spindle is adjusted for angular position, the center of rotation for the spindle head being the axis of shaft *D* of Fig. 2.



Figs. 2 to 5. Improvements in Detail. Figs 2 and 4 show New Designs, Figs. 3 and 5 the Usual Construction.

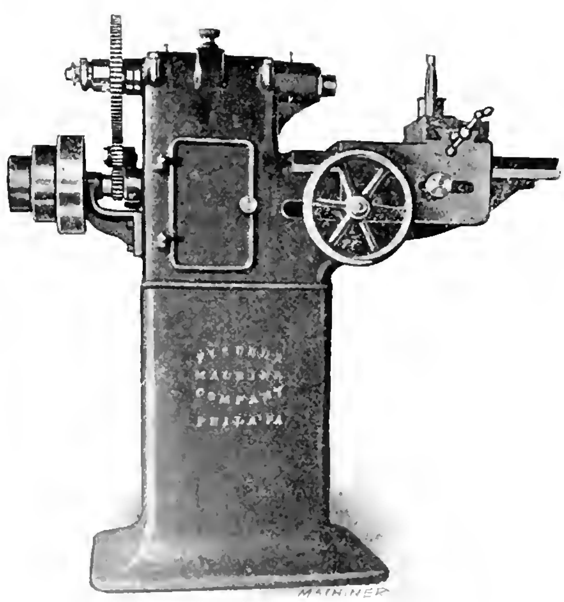
Improvements have also been made in the manner of leading the drive from the vertical shaft at the back of the column to the driving shaft in the arm. These are shown in Figs. 4 and 5, the former being the new arrangement, and the latter that previously used. In Fig. 5 conditions were such that the arm shaft *H* could not be located in the axis around which the arm was adjusted for the angular position. This necessitated the use of an extra shaft with gears *J* and *K*, to

bring the movement down to the axis. From J, an intermediate idler I on a stud completed the connection to the shaft carrying the bevel gear which meshes with the vertical shaft G at the back of the column sleeve. A glance at Fig. 4 will show the simplification effected. The intermediate shaft and gears I, J and K of Fig. 5 have been eliminated, by bringing the arm shaft and the axis of rotation of the arm to coincident positions, and the new design of arm permits this without destroying its balance.

Aside from the points mentioned, this tool appears to follow in its details the general practice of its builders. The facilities for handling the spindle movements, for instance, are retained. A depth gage is provided which enables the operator to read all depths of holes from a datum point at zero, doing away with the usual delays attending the operations of scaling or calipering. This also supplies a convenient means for setting the automatic trip provided, since the graduations show exactly where each dog should be located in order to disengage the feed at the required points. The automatic trip operates at as many different points as there are depths to be drilled at one setting of the work. In addition, it leaves the spindle free after any intermediate tripping to be advanced, raised or traversed its full length, without disturbing the setting of the dogs. It also automatically throws out the feed when the spindle reaches its limit of movement. Eight rates of feed are provided, ranging in geometrical progression from 0.007 to 0.640 inch per revolution of spindle. These may be instantly obtained by positive geared changes. The tapping mechanism permits backing out the tap at any speed with which the machine is provided, regardless of the speed used in driving it in. It is operated by a friction clutch, controlled by a lever whose handle extends around under the arm, within convenient reach of the operator, as shown in Fig. 1. The driving mechanism, positive geared spindle speed changing device, etc., are essentially the same as in previous designs. For a description of the speed changing arrangement, see MACHINERY for January, 1906. The speed box of this machine is similar to the one described in that issue, though a greater number of changes are provided for. Twenty-four speeds in all are obtained, each of which is instantly available. This machine is furnished either as a half or full universal, in three different sizes, with 4, 5 or 6 foot reach.

FISCHER OIL GROOVING MACHINE.

This machine is adapted to cut oil grooves automatically in bearing boxes, the lines of the groove forming a double letter O. The design of the machine is simple. The spindle



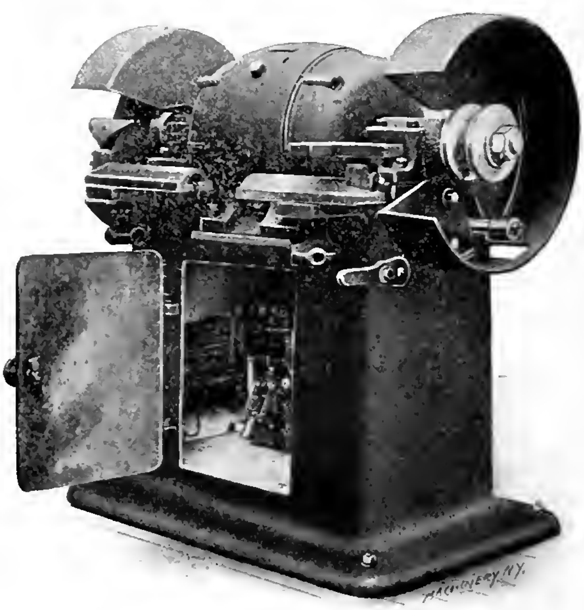
Machine for Cutting Oil Grooves in Journal Boxes.

is geared to the driving pulley, so as to give a slow movement to the work, which is held on a chuck or faceplate on the end of the spindle. The driving pulley is also connected with a crank, inside the column of the machine, whose connecting rod operates the slide. When the work is rotating, a boring tool placed in the tool post in the carriage, and properly adjusted to the work, will automatically cut out an oil groove of the shape desired, the controlling mechanism being such as to give the necessary movement. The resulting groove is made with a clear, clean cut, without the ragged edges and distortion of the soft bearing metal that often result from chipping. The operation is, as well, much more rapid than the hand process, while it can be performed by a "handyman" instead of requiring a skilled mechanic.

The spindle may be locked with a lever provided for the purpose, and the intermediate gear connecting it with the driving pulley disengaged, in which case the machine is adapted for cutting keyways on either side of the bearing. The crank connecting rod and gears driving it are enclosed within the machine, making a dust-proof and compact arrangement. The maximum limit of its adjustment, both as to diameter and length, is for boxes 5 inches in diameter by 5 inches long. This machine is built by Fischer Machine Co., 1217 Race St., Philadelphia, Pa.

SPEED CONTROLLER FOR ELECTRICALLY-DRIVEN GRINDERS.

The Ransom Mfg. Co., of Oshkosh, Wis., has devised a remarkably ingenious device for regulating the speed of elec-



Grinder provided with Device for Graduating the Speed to Suit the Diameter of Wheel.

trically-driven grinders to conform with the requirements for a uniform surface velocity for the wheel as it wears to a smaller diameter.

The device operates on the electrical speed controller, enclosed in the base of the machine. The contact lever for this is connected by link work to a rod passing through the base, parallel with the grinding wheel spindle. This rod carries at either extremity, on the inside of the column, arms having fixed to them studs with rollers extending through slots in the base, bearing on the periphery of the grinding wheel.

The operation of the device is obvious. By means of the handle at the right hand side of the machine, the roller is brought up until it touches or almost touches the grinding wheel. This movement, through the connecting link work, adjusts the speed of the spindle to correspond to the diameter thus gaged. It is evident that with wheels at each end of the spindle varying considerably in size, the speed should be adapted to the requirements of the larger of the two. This is automatically taken care of from the fact that in that case the roller bearing on the larger wheel determines the setting of the controller, it being impossible to bring the other roller into contact with the smaller wheel, since both arms are connected rigidly together.

This device can be attached to any of the motor-driven grinders for direct current made by the builders.

GARVIN AUTOMATIC TAP FLUTER.

This machine, built by the Garvin Machine Co., Spring and Varick Streets, New York, is an example of the way a standard machine tool may be adapted, with comparatively slight changes, to the automatic performance of repetition work, with a great saving of time and cost. As intimated by the name, the purpose of the machine is the milling of straight flutes in small tools, such as taps, reamers, etc. The modifications introduced comprise quick acting work holding apparatus, automatic index, automatic feed with quick return by a spring piston checked by air cushion, and automatic stoppage of the machine when the work is completed.

The machine itself is a No. 11 plain milling machine, with a rack feed. The rack pinion shaft is driven by a clutch on the rear end, from the power shaft inside the column. It is movable endwise, so that the clutch can be disengaged, being normally held in engagement by a spring. The handle shown at the front of the knee in Fig. 1 is clamped on the pinion shaft, and can be set in any position according to the travel desired. Its hub carries a small roller, not plainly shown in the cut, which engages a cam block fastened to the knee. With the handle adjusted to suit the length of feed desired, when this roller reaches the cam block, the rack pinion shaft is withdrawn and the clutch disengaged. A catch holds the clutch in the disengaged position. The table, being now free from the power feed, is returned to the other extreme of its travel by a spring enclosed in a tube shown at the rear of the table in Fig. 2. This rapid motion is checked before the table reaches its fixed stop, by the air cushion shown at the right in Fig. 1. This allows the motion to be reduced to a comparatively slow rate for the last fraction of its travel.

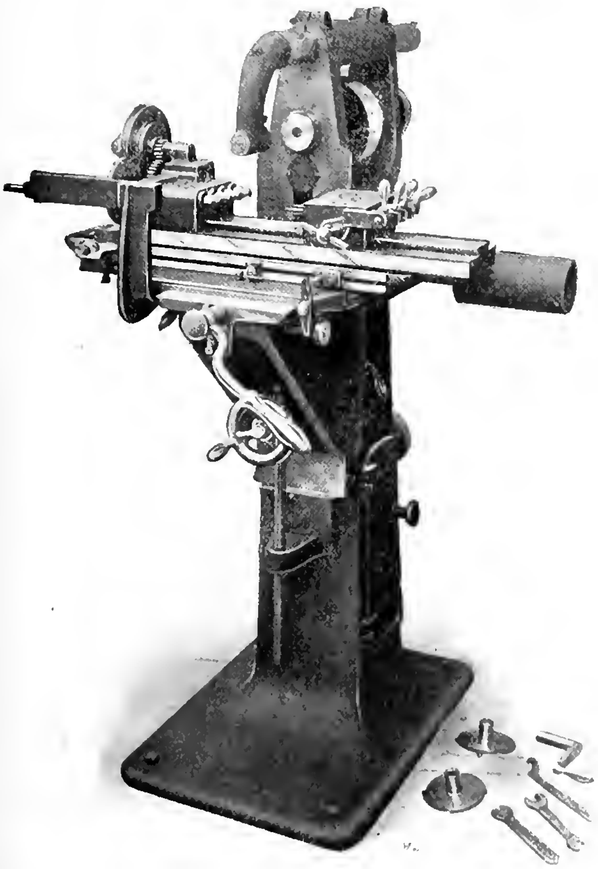


Fig. 1. Small Miller, arranged as an Automatic Tap Fluting Machine.

As the table approaches its extreme return position, the dog shown in the slot at the front engages the horizontal arm of a bell crank lever, whose other arm forms a detent engaging one of the teeth of the indexing ratchet, seen in both cuts. This ratchet is friction driven through the gearing and the pulley shown, a round belt leading to the latter from the countershaft for that purpose. The raising of the detent allows the work to be revolved one step. The attachment shown has four spindles, all geared together to move in unison. The foot stock has a corresponding number of spindles separately adjustable to suit slightly varying lengths of work. They are all clamped by a single handle. Just before reaching the fixed stop formed by the middle of the three dogs in the slot at the front of the table, the dog at the right releases the catch which held the feed clutch out of engagement. The feed is thus thrown in at the same instant that the movement of the table is arrested, so that there is no shock thrown on the clutch. The table again feeds forward and the same cycle of operations takes place.

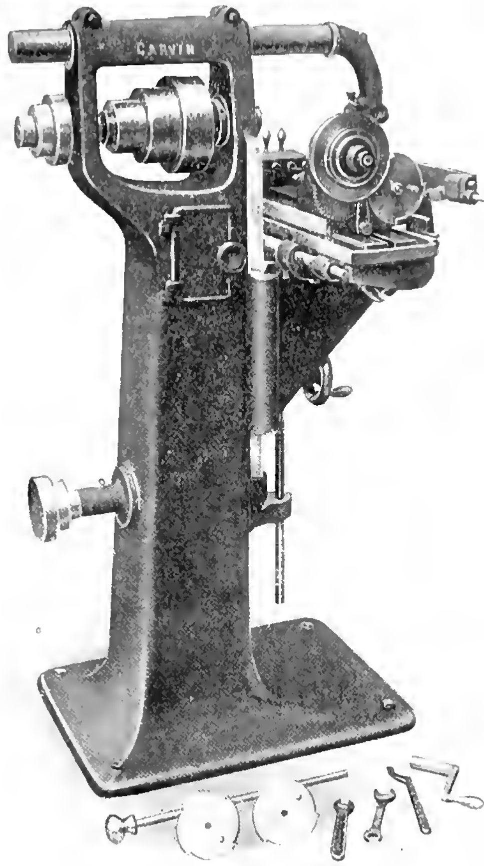

Fig. 2. End View of Tap Fluting Machine, showing Indexing Mechanism, Etc.

The countershaft is shifted by a spring, and a rope controlling this is attached to a pin on the left-hand end of the machine. There is a corresponding pin on the face of the index dial, and when the dial has made one complete rotation, it comes in line with the rope pin on the return stroke, pushes off the rope, and releases the countershaft so that the machine stops. This mechanism is seen mounted on a bracket attached to the left side of the saddle.

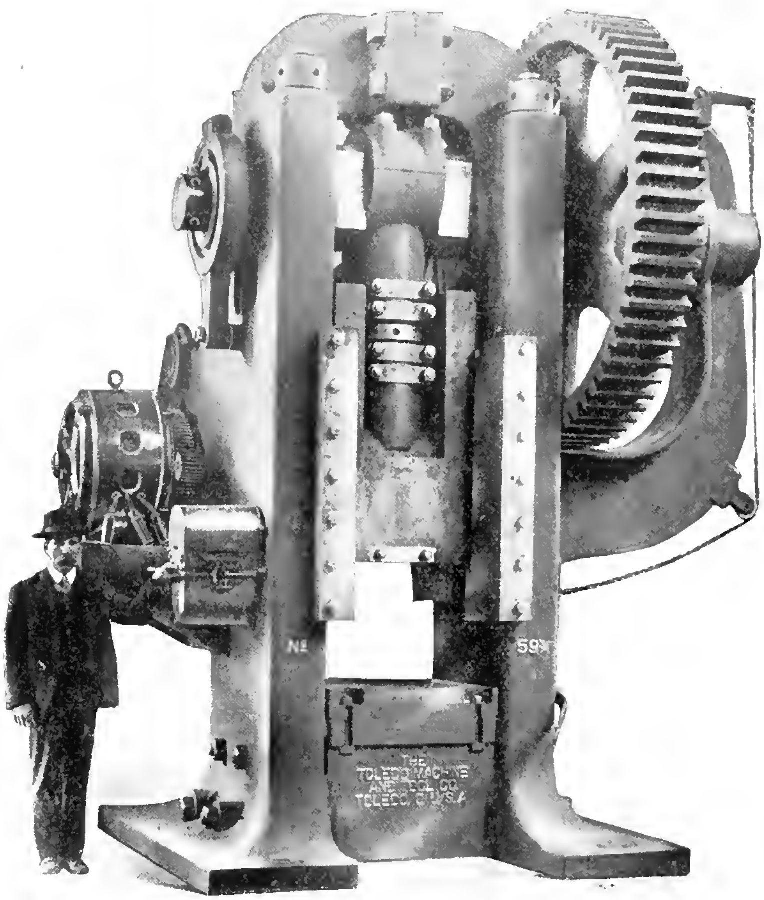
The four spindle centers are set $1\frac{1}{4}$ inches apart. The table has a feed of $3\frac{1}{2}$ inches, adjustable, as described, by dogs. The knee has a micrometer adjustment for depth of cut. The weight of the machine is about 690 pounds.

HEAVY TOLEDO STRAIGHT-SIDED PRESS.

This single pitman straight-sided press is built by the Toledo Machine & Tool Co., Toledo, Ohio. The massive proportions of the frame, connecting rod, and slide at once strike the eye. The construction of the frame is particularly interesting. This frame is made in three pieces, there being two side pieces and a separate bed, which rests on ledges planed on the inner faces of the side pieces, as may be seen in the cut. The bed and side pieces are held together by bolts closely fitted in reamed holes, passing through from side to side. At the top, over the crank, the side pieces are joined together with a tongue and groove fit, carefully made. The side pieces are reinforced for tensile strains by heavy steel rods, passing through from top to bottom inside of the housing and shrunk in position. It will be seen that this whole design is admirably fitted for the taking of heavy strains, the thrust due to the pressure of the die on the work being

transferred from the journals of the heavy crank, down through the straight side piece, to the ledges which support the bed.

The machine is intended for making steel stampings for automobile parts and similar work. Brake drums, ¼-inch plate, and similar flanged automobile parts are made with this machine. It has a capacity for working cold steel plate as heavy as ⅜-inch in thickness. By using cupping and reducing dies constructed to suit the work, the use of blank holders (which are commonly used and necessary on thinner metal) can be entirely avoided, thus doing the work to better advantage than other forms of presses used to make stampings from heavy plates



Heavy Electrically-driven Straight-sided Single Crank Press.

The machine can be furnished with a stroke as great as 24 inches. The one illustrated has a slide movement of 14 inches. It is fitted with a three-contact block clutch having automatic releasing mechanism with gravity control, eliminating entirely the use of spriugs, and giving a safer and more positive action. The motor shown attached to the machine is of 50 horse-power size. A large proportion of heavy tools of this class are now furnished with individual electric drive.

This press is one of a great number of sizes ranging in weight from 2,000 to 110,000 pounds, the latter being the weight of the machine shown. The weight of the flywheel is 2,000 pounds, and it has a diameter of 62 inches. The bed has an area of 38 x 38 inches. The extreme height of the machine is 196 inches.

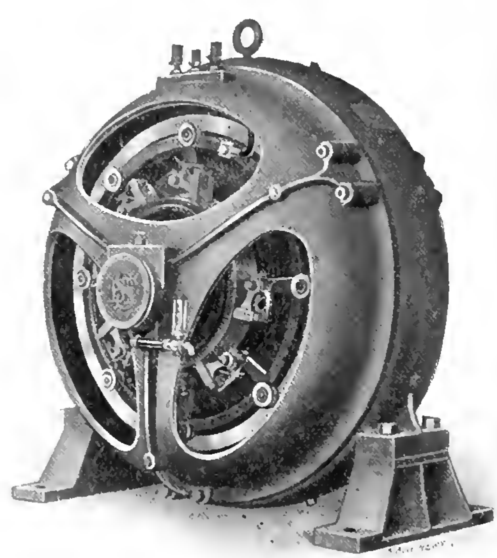
STURTEVANT TWO, FOUR AND EIGHT-POLE MOTORS.

The B. F. Sturtevant Co., Hyde Park, Mass., has recently developed a complete line of 2, 4 and 8-pole motors especially adapted to the driving of machine tools, fans, etc. The bi-polar motors are adapted to the driving of small high-speed machinery, and may be furnished either in the semi-enclosed or enclosed style. The frame (which forms the magnet ring) and the end casings are of cast iron, machine fitted together. The pole pieces are built up of steel plate, energized by field coils of double cotton covered copper wire, well insulated, and made oil and water proof by a special treatment, including baking for 24 hours at a heat of 212 degrees Fahrenheit. The bearings are ring oiling, self aligning, and are cast in the end casings, which are so designed that the motors may be placed on the floor, wall or ceiling.

The armature is of the toothed drum type having a core of thoroughly insulated soft steel plates slotted to receive form-wound coils. It is water-proofed by the same process as used for field coils. The commutator segments are of hard drawn copper, insulated with selected mica. The brushes are of carbon mounted in brush holders of approved form. The starting box provided with these motors is furnished with a "no-voltage release" which serves to automatically open the circuit when the supply of current is interrupted, thereby preventing possible damage when the current is again turned on.

The 4-pole motors are designed for a machine requiring greater output than can be obtained from the bi-polar machines. They are made in the enclosed, semi-enclosed or open type. The enclosed type can be operated continuously at full load, or temporarily at an overload of 50 per cent without undue sparking or heating. The temperature rise does not exceed 90 degrees Fahrenheit. The magnet frame of the 4-pole motors is of special steel with cast field cores having laminated pole shoes. Helical air ducts provided between the laminæ of the armature core act like the arms of a centrifugal fan, cooling and ventilating the windings. The same provision for water-proofing, and the same high grade of commutator construction as in the smaller machines, is used.

The cut shows an 8-pole machine. These have a lower rotative speed than those of the 4-pole type, and are well suited to the driving of large machine tools and for direct connection to blowers and exhausters. For this latter service they may (in the smaller sizes) be supported in a special annular plate bolted to the side plates of the fan, the fan wheel being overhung on the end of the motor shaft. The larger sizes are placed on a suitable steel plate base. They are built in nineteen sizes, having a maximum of 75 horse-power, when the motor rating is based on the horse-power delivered at 100 revolutions per minute. The smaller sizes may be furnished in the



Sturtevant Motor for Direct Driving of Fans, Machine Tools, Etc.

enclosed style by attaching three doors to the end casings. Special attention has been given to ventilation. Air is forced through and about the windings by specially shaped brass

blocks with radial arms, which act like the blades of a centrifugal blower. The air is drawn into the spider and exhausted through the core. For low speeds and high voltage the armatures are wire wound, while bar winding is used for other conditions. The same general methods of water proofing, commutator construction, etc., are followed as with the smaller sizes.

SAFETY SLIPPING DEVICE FOR MACHINERY.

The device shown in the two accompanying half-tones is intended to be used as a safety device in machines of various kinds in which it is required that there be some point in the mechanism which will yield before other parts break. It thus replaces shearing pins, friction slips and similar devices.

The construction is quite evident from Fig. 2, in which the device is shown taken apart. The shaft has keyed to it a body containing four holes, in which are seated springs, contained within hollow bushings which they force outward. These hollow bushings have at their outer ends spherical seats for four corresponding balls, which are thus pressed against the face of the gear mounted on the same shaft. Twelve seats for these balls are formed in the gear. In operation, the shaft will drive the gear or *vice versa*, so long as the force required is not so strong as to force the balls out of their seats in the web of the gear against the pressure of the springs which hold them to their work. This pressure can be regulated by means of the knurled nut shown on the back face of the body, which bears against plungers on which the springs are seated, and increases or decreases the compression which they furnish.

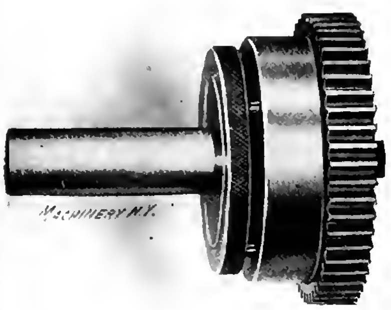


Fig. 1. Safety Slip Gear.

Simplicity and reliability are claimed for this safety device. It has the advantage over the shearing pin of not requiring to be repaired whenever it operates. It has the further advantage of being adjustable, by means just described, so that it may be set to agree with new conditions when conditions change. It is much more reliable than any friction device can be, since it is independent of the condition of the air as to moisture, temperature, etc. It is applicable to any mechanism liable to shock or sudden over-load, such as quick change feed and speed devices for machine tools, automobiles, etc., and will be found useful, as well, for electrically driven and automatic machinery of all kinds. It has been thoroughly tested and experimented with for over a year, in a great variety of uses. It is applicable to any machine without requiring radical change in design, and when once installed, requires no further attention. It is the subject of patents in this country and Europe. The device is made by the Yieldable Gear Company, Springfield, Ohio.

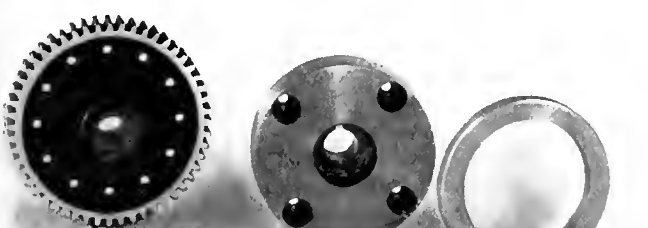

Fig. 2. Slip Gear Disassembled, showing Construction.

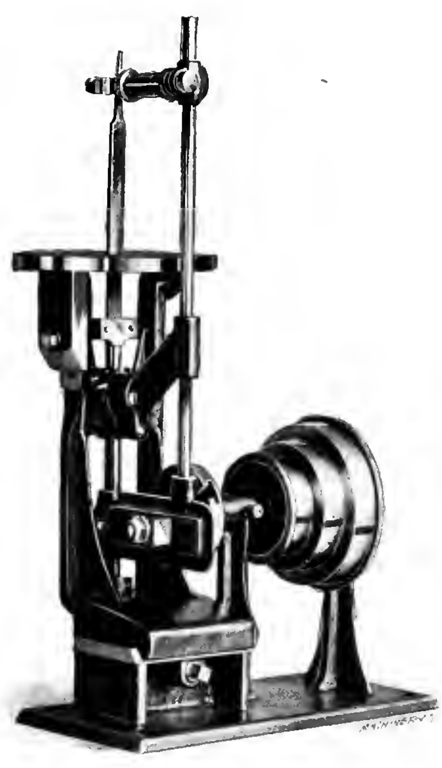
HARDINGE FILING MACHINE.

Hardinge Bros., 1034-1036 Lincoln Avenue, Chicago, Ill., are making the neat filing machine shown in the accompanying cut. One novel feature of the design is that the device may be used either as an attachment for the bench lathe, or as a machine by itself in the form shown in the cut.

As here shown, it is mounted on a base and driven from a cone pulley by slotted yoke and adjustable crank-pin. The square block on the crank-pin engages the slot of the yoke attached to the main plunger of the device. It also gives motion to a back rod extending up above the table of the machine and carrying an arm in which the tang of the file is clamped. The lower end of the tool is held by a clamp on the upper end of the plunger. The table is mounted on a pivot, and may be adjusted by graduations provided to swivel 20 degrees either side of the horizontal position. When used as an attachment for the lathe, the table supporting frame, with the plunger, back yoke, etc., is bolted to the ways, instead of to a special base as in the cut. The adjustable crank is mounted on the spindle of the lathe in the same way as the faceplate, and the whole machine is driven from the lathe spindle. In this way it may be used with Cataract, American Watch Tool Co., or Pratt & Whitney bench lathes.



Hardinge Filing Machine.

The table is 6 inches in diameter, and the maximum stroke is 2 inches. The device is made in a substantial manner, with adjustable take-up boxes properly protected from dirt, the same as with the Cataract lathe head. Besides being useful for a filing machine, it may be used with a jig saw in any experimental work with brass, or for jeweler's use with a fine saw, to cut out open gold or silver work.

FLATHER SIXTEEN-INCH GEAR-DRIVEN SHAPER.

This shaper, recently designed by the Mark Flather Planer Co., of Nashua, N. H., has a number of features which make a study of its design worth while. Aside from the quick return mechanism used, which was described in the March, 1907, issue of MACHINERY, other points of interest are the quick change gear device for varying the speed, the novel shape given to the bearing surface of the ram, and the design of the automatic down-feed.

The geared speed changing device will be readily understood from an examination of the half-tones, Figs. 1 and 2. The driving pulley has but a single diameter for a 4-inch belt and is keyed to a driving shaft having at its other end a long 16

tooth pinion. The change gear lever encircles this pinion, and carries an intermediate, meshing with it. By shifting the change gear lever from one to another of the holes provided for its index pin, the intermediate may be made to engage with any one of a cone of five gears, thus giving five speeds. This cone of five gears is connected to the shaft, on which the driving pinion of the crank disk is mounted, by two sets of gears, either of which may be engaged by shifting the lever shown at the top of the gear box. By this means ten changes in all are provided. This is more than ordinarily obtained from back geared machines driven by cone pulleys, and the drive is stronger as well.

All the gears in the gear box are of steel, cut from bar stock, each gear being cut with a cutter made for its exact number of teeth. As ordinarily equipped, the machine can be furnished with tight and loose pulley belted directly from the main line to avoid the necessity of mounting a countershaft on the ceiling. Another advantage of the gear box arrangement is that the machine may be changed to motor drive at any future time by simply attaching a motor to the rear of the column, and connecting it to the driving shaft with the proper chain or spur gearing.

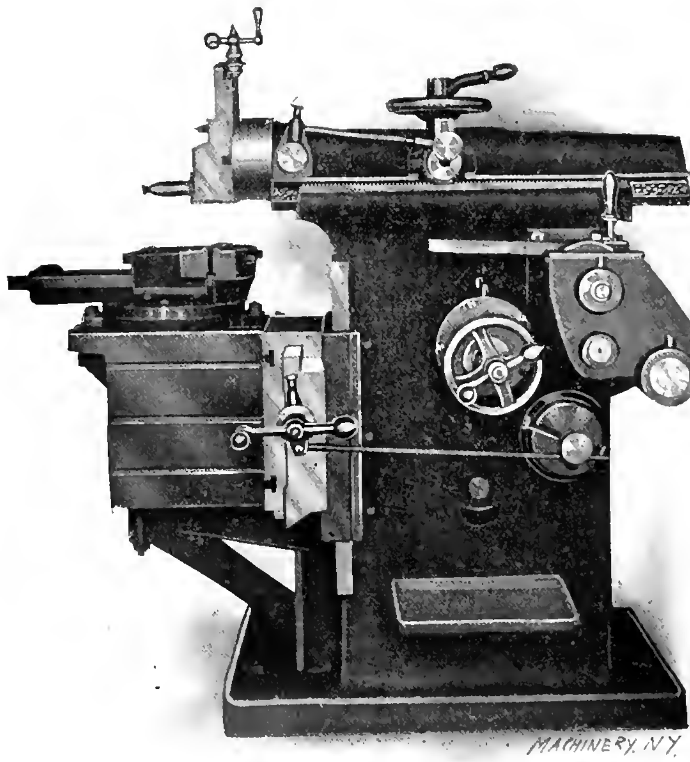


Fig. 1. Flather Quick-change Gear-driven Shaper.

The shape of the ram bearing surfaces is best seen at *A* in line cut, Fig. 3. They are formed to rectangular shape, but set at an angle of 45 degrees, so that the two under surfaces form Vs. The angular straps *B* bear on the third or upper surface, holding the ram down to its work. The advantages of this arrangement are that the alignment is kept by means of the V-way, and that gibs for preventing side motion are entirely eliminated, provision being made for taking up this motion by the simple tightening down of the straps on top. Ample provision has been made for oiling the ways by means of rollers at *C*, similar to those used for oiling the ways of planer tables. These run in oil pockets and are forced against the bearing surface by springs. Wipers are furnished at both ends of the ram bearing.

The automatic down-feed provided is also worthy of note. The strap *B* for holding the ram on the right hand side of the column has rack teeth cut in it, engaging with a pinion *D*, revolving loosely on a stud seated in a recess of the ram. By means of a friction device, held to its work by a spring as shown at *E*, this pinion gives motion to a slotted arm *F*, moving between fixed stops. The movement is given at the beginning and end of the stroke, and in the same way as the regular friction feed for the planer. The adjustment for the feed is also similar to that of the planer, the fulcrum moving in or out from the center to give a less or greater movement. From this fulcrum a rod leads to a ratch lever carrying a pawl, which may be set to give either an upward or downward feed to the head, through connecting gearing not shown in the cuts.

The table support shown in Fig. 1 is peculiar to this shaper. It is always in position and needs no adjustment. This makes it one of the most convenient and satisfactory table supports on the market. It is furnished with each shaper.

BLISS DOUBLE CRANK PRESS.

This press is one of specially massive design, necessitated by the growing needs of the manufacture of articles made from sheet steel. It is one of eight, built for heavy punching, shearing and forming operations. Aside from the magnitude of the press, (which will be appreciated from the dimensions given later) there are a number of details of construction which are worthy of note. The clutch is mounted on the main crank-shaft, and is of the automatic draw type with a positive lock, having three locking faces of hardened

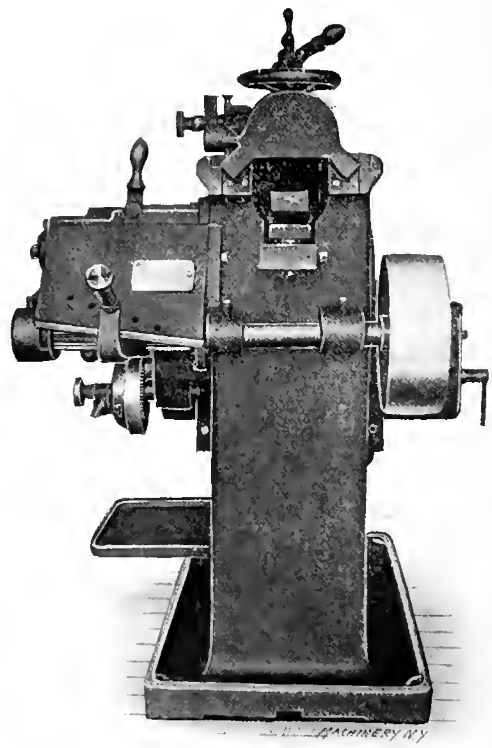

Fig. 2. Rear View, showing Speed Change Mechanism.

tool steel. It is positive in its action, and silent whether engaged or disengaged. The driving pulley is located at the back of the press in such a position as to decrease by a considerable amount the floor space required for the machine. The bottom knock-outs, shown beneath the bed of the press in the cut, are operated from the slide by two connecting rods, screw adjustment being provided for setting them at the proper height. The slide has an unusually long bearing in the frame and is adjusted simultaneously by means of the two threaded connecting rods operated by double pinions on the shaft connecting the two cranks. This insures at all times a perfect alignment of the slide in relation to the bed. A safety coupling, connecting the main driving pinion with its shaft, is provided to prevent the great damage that would ensue in the case of such accidents as the careless leaving of a bar or wrench on top of the die, an improper adjustment of the cross head, or the tripping of the clutch when the work has not been properly placed in the die. These accidents are liable to occur, and without the safety device shown, they would almost certainly result in a broken press body or broken tools.

The crankshaft of this press is 7½ inches diameter, and it gives a stroke of 8 inches. The fly-wheel is 60 inches in

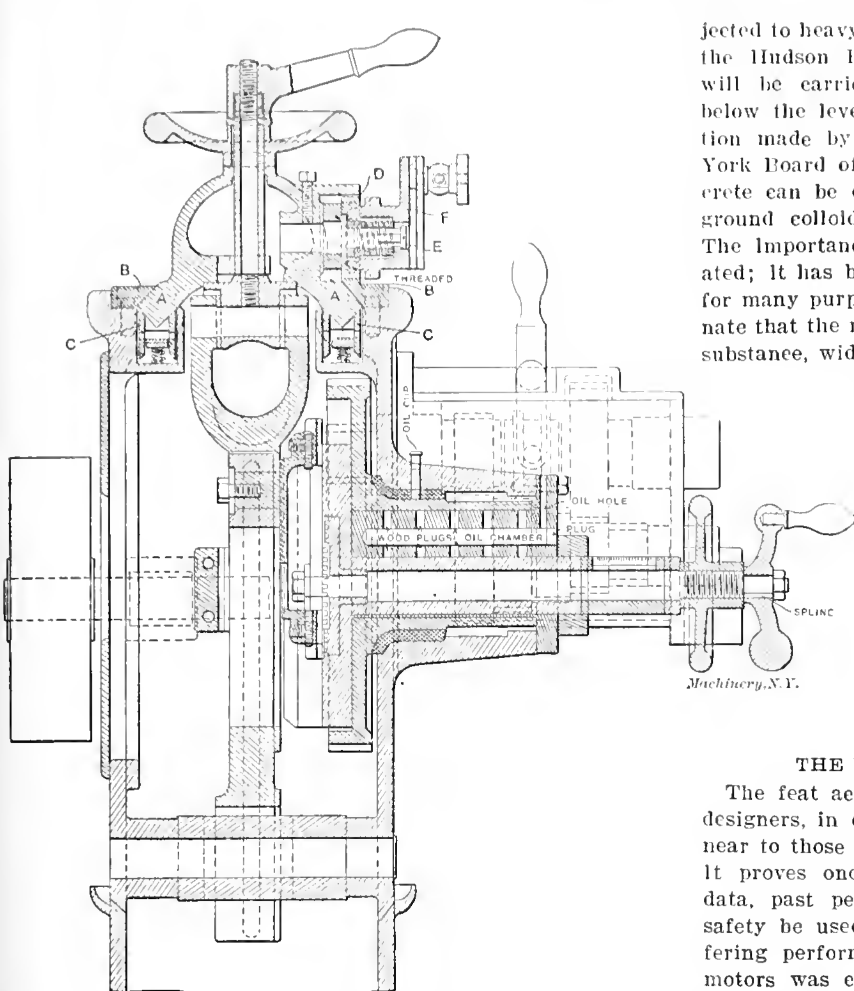

Fig. 3. Section through Ram Driving Mechanism of Flather Shaper.

diameter with an 8-inch face. It weighs about 2,000 pounds, and makes 195 revolutions per minute. The over-all height of the press is 137½ inches, and its total weight is 47,000 pounds. The bed is 24 inches wide by 97 inches long. This press is built by the E. W. Bliss Co., 5 Adams Street, Brooklyn, N. Y.

CARR REVERSIBLE CUTTING-OFF TOOL HOLDER.

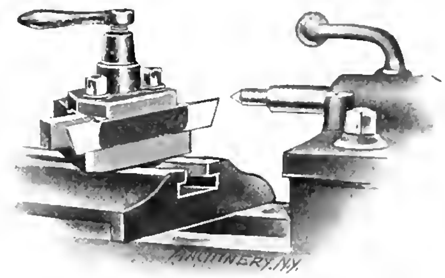
The cutting-off and side-tool holder shown in the cut is made by Carr Bros., Syracuse, N. Y. The construction followed is novel, and provides for holding the blade very rigidly. This is especially necessary in the case of the cutting-off tool.

As may be seen in the cut, the regular tool post of the lathe is used for holding the tool. The ring and rocker are removed, and the body of the holder is dropped down over the post. A key is then inserted through the holder into the slot of the tool post, and the set screw tightened down with a wrench as usual. This clamps the holder firmly in position. The cutting-off tool blade, after being set to project the proper amount for the work in hand, is clamped by a strap held down by two cap screws as shown. In changing from a right- to a left-hand tool, the holder is merely swung around 180 degrees to use the other end of the blade. For a right- or left-hand side-tool, the same device is used, but with the cutting-off tool blade replaced with a side-tool blade.

* * *

WATERPROOFING CONCRETE.

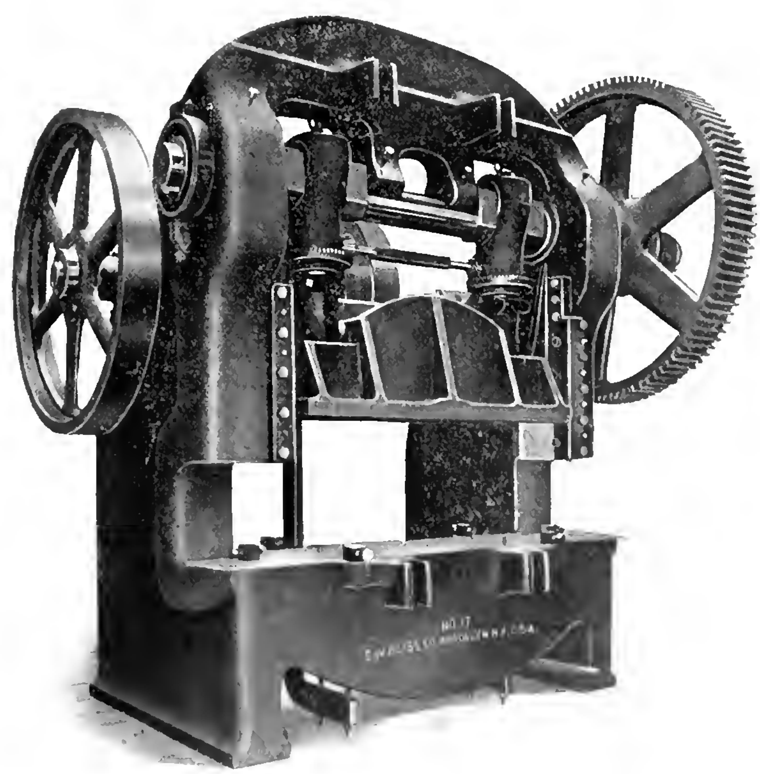
The great water supply system which New York City is constructing in the Catskills will cost about $161,000,000, and it will require years to complete it. Concrete will be used very largely in the construction of the immense dams and aqueduct, and it is highly important that the concrete be made waterproof, especially in the portions which are subjected to heavy pressure, notably in the inverted siphon under the Hudson River at Highland, N. Y. Here the aqueduct will be carried to a depth of something like 1,000 feet below the level of the river. It appears from the investigation made by Mr. Richard H. Gaines, chemist of the New York Board of Water Supply, that the waterproofing of concrete can be done by the use of 5 to 10 per cent of finely ground colloidal clay, intimately mixed with the concrete. The importance of this discovery will be generally appreciated; it has been a serious drawback to the use of concrete for many purposes, that it is permeable to water. It is fortunate that the material required for waterproofing is a common substance, widely distributed.



Cutting-off and Side-tool Holder for the Lathe.

THE PERFORMANCE OF THE LUSITANIA.

The feat accomplished by the *Lusitania*, or rather by her designers, in enabling her to make a speed within limits so near to those calculated, is one of great interest to engineers. It proves once more that, without access to experimental data, past performances of a similar character may with safety be used to accurately determine new and widely differing performances. In the first place, a class of driving motors was chosen for this vessel which had never before been applied to so large a ship, nor had any type of engine



Double Crank Press of Unusual Size.

ever been built with such enormous dimensions for ship propulsion. Notwithstanding the absence of information on the working of these machines, the engineers who designed them were able to determine the horse-power developed, as well as the speed with which this developed power would propel a ship of hitherto unequalled dimensions, within a limit of error, at the trials, of less than 2 per cent, the error being on the side of more, rather than less, power and speed.

INDUSTRIAL NOTES FROM EUROPE.

BRITISH TRADE TOPICS.

Though, taking the country through, the value of goods imported and exported still increases, in the engineering and allied industries the peak of the upward tendency would appear to have been reached, the present indications pointing to gradual retrogression. For the month of August, 1907, the imports show an increase of $2,037,240 over the corresponding month in 1906, and of $12,199,180 over those of 1905. The exports increased during the same period by $19,312,150 as compared with 1906, and $39,186,040 over that of 1905. Iron and steel, and manufactures directly connected, show, during the month, increased exports to the extent of $2,078,925. Cotton machinery, for which there is an unprecedented demand, contributed considerably to the increase.

Trade Union Activities and Labor Conditions.

As previously mentioned, a prominent topic here, for some time, has been the question of recognition of the official representatives of trade unions in a number of industries. At the moment, a movement is on foot among organized railway servants to insist on negotiations on matters of wages, working conditions, etc., being conducted by their accredited representatives in place of individual application and discussion. The directors of the principal railways are strongly opposed to the suggestion, but apparently this attitude is not to the liking of many shareholders and prominent business men, who have found collective bargaining to answer well in their private business. A ballot is being taken among the men as to whether they will strike as a protest against the refusal of their demands. For the time being, questions of wages or hours are subordinated.

On the other hand, the Shipbuilding Federation has handed notices of a lock-out to about 40,000 shipbuilders and boilermakers, who, as the result of a ballot, decided—against the advice of their officials—not to accept the employers' proposals that all labor disputes should be considered and settled by representatives of employers and workmen, without stoppage of work in the meantime. The employers have suffered considerably in the past through workmen in this branch throwing down their tools and leaving work without consultation with, or authorization from, their trade union executives. It is probable that the men will take another ballot, and, as many men did not vote on the first one, the previous decision will very likely be reversed. In any case, considered simply as a matter of expediency, they will be wise in doing so, as the employers are in a strong position, and have chosen a favorable time for settling the matter. Though just now a larger tonnage of shipbuilding has been placed on the Clyde than during any corresponding period, some time will elapse before it is ready to be dealt with in the yards, and on the East Coast one or two of the largest concerns have scarcely an order on the books, the influence of the depression extending to the drawing office staffs, which have been reduced to a quite unusual extent.

The Shipbuilding Industry.

At Devonport, the *Temeraire* was launched on August 24. Her length and width, like the previously launched *Bellerophon*, are 490 feet and 82 feet, respectively, and her displacement 18,600 tons, or 700 more than the *Dreadnought*. Turbine engines will give a speed of 21 knots. She will carry ten 12-inch guns, as compared with eight on the *Dreadnought*. Orders have just been given at Portsmouth for another *Dreadnought* of 19,300 tons, and a similar vessel is to be built at Devonport. The last two vessels will be armed with 13-inch guns, the heaviest carried in any navy.

The trials of the *Mauretania* are just commencing, and indications point to very satisfactory results. Though built on the general lines of the *Lusitania*, there will be a number of alterations in details.

Cotton Machinery.

As mentioned earlier, textile machine builders are extremely busy, more especially in the cotton section. It is rather surprising that American builders do not make a better show in this connection as regards export business, as the conditions are all in favor of repetitive methods, the various details being mostly made in lots of many thousands. Prices have also been advanced considerably during the last year or so. During average times, however, it is wonderful at how low a cost really good and well-finished machinery in this line is produced and sold. One reason for this possibility is, doubtless, the fact that the population in the districts where cotton goods are manufactured, and the requisite machinery built, is very stable and apt, machinery having been built alongside its manipulation since the commencement of the industry. A considerable proportion of the most modern machine tools has recently been installed in the textile machine shops, and the splitting up of processes into individual operations on very simple machine tools has been carried to a high degree of efficiency. A machine which appears to lend itself to this class of work with excellent results is the Potter & Johnston automatic turret lathe, with magazine attachment, especially on wheel blanks, pulleys, etc. For the manufacture of the rings used on frames for ring spinning, the "Ajax," an American forging machine, turns out a very superior article as regards homogeneity at a wonderfully quick rate, and without waste of material, as the ring is upset to outside diameter from a bar of the same size as the hole afterwards punched in, the ring being forced off its core, which is thus available for the next ring forged. These rings are now made from mild steel bar, and after boring and turning, are case-hardened and highly polished. They were formerly made of malleable iron, but drop or press forgings in mild steel are found superior and cheaper. For hardening the rings after carbonizing, the Brayshaw furnace (see MACHINERY, January, 1905), which utilizes a bath of liquid salts, the temperature of which may be ascertained and varied to a high degree of exactitude, is found very well adapted. Many of the smaller castings used in the business are annealed by packing them, in suitable pots, with cast iron turnings and leaving them over night in a heating furnace. The ease of subsequent manipulation of the castings and the longer life of the tools amply justify the cost of annealing.

Automobile Industry.

The building of motor-cars now appears firmly established in Great Britain, the imports from the Continent having greatly decreased relatively to the total output, coincidentally with a decided increase in British exports in this line. However, there are indications that the facilities for the manufacture of cars built for the luxury trade are now more than sufficient, and the needs of the less wealthy are receiving attention. Continental makers are also making a study of the problem. The Royal Automobile Club is now carrying out a valuable series of trials of commercial vehicles. The various classes travel by a route which tests the characteristic features of each class, and at certain towns the whole of the vehicles are on view a day or two, thus giving prospective users an opportunity of comparing the merits of the different designs. From point to point the routes are so arranged that the heavier types travel the shortest distance, and the lighter ones travel a roundabout journey, so that all have practically the same duty to perform. The report of the trials—the methods employed on which are approved by both builders and users—will be of considerable commercial value.

Iron and Steel Industry.

Mention has previously been made of improvements adopted by British iron and steel works during the last few years. At the large works of Sir Bernard Samuelson, near Middlesboro, two steam turbines, each capable of giving a normal output of 1,350 K.W. at a speed of 2,400 R. P. M., are being installed. They will work from the exhaust steam of blowing engines, which have previously worked non-condensing. Portable machine tools increase in size and adaptability in every tool-using country, and in this connection may be mentioned a portable facing machine for gun turrets, swing bridges, turntables, etc., built by John Hetherington & Sons, Ltd., Manchester, which weighs 33 British tons. An old engineer commenting on this and other recent tools of this class, stated that in his younger days portable tools were mostly represented by ratchet braces, screwing tackle, etc. He could understand Mahomet going to the mountain when

the mountain refused to come to him, but when Mahomet started getting bigger than the mountain, our friend thought it was almost time to give such machines a fresh title.

J. Butler & Co., Halifax, have introduced a line of girder drilling machines for handling work up to 30 inches by 24 inches by 60 feet long. The machine has six heads, and roughly resembles a traveling head shaper with six heads. The machine has been very successful drilling holes in straight or zigzag lines, each head having automatic stop and withdrawal.

In the September, 1904, issue of MACHINERY, there was illustrated and details given of a 12, 14 and 18-inch swing lathe as built by Clark's Machine Tool Co., Ltd., Luton. As may be remembered, these lathes come about halfway between the ordinary lathe and the special turret lathes, lending themselves to both repetitive and general work, the bore of the spindles being quite large relatively to the height of centers. A 20-inch swing lathe recently produced by these makers will pass 4½-inch black bars through the spindle, and has ample power for dealing with this diameter. As in previous examples, the spindle bearings are placed diagonally, with the idea of giving a double adjustment, and relieving the strains on the cap bolts. Detail improvements have also been introduced into the screw cutting arrangements, allowing of specially coarse threads being cut without risk of breakdown. As in the other sizes, the spindle of the loose head is arranged, when desired, for automatic boring. The back rest for carrying cutting-off or forming tools is detachable from the front rest, allowing a larger diameter of work to be turned in the ordinary way, the front four-tool turret rest remaining as before. The weight of the lathe has been increased, and, generally, the lathe appears likely to give a good account of itself. JAMES VOSE.

Manchester, England, September 30, 1907.

MISCELLANEOUS FOREIGN NOTES.

THE EXHIBITION IN TOKIO IN 1912.—The Japanese authorities have now begun in earnest to make arrangements for the great international exhibition to be held in 1912, and they are setting about their work with that thoroughness which has characterized all their performances of late years. The exhibition is primarily intended for the promotion of education and industry, but is expected to be an important link in the good feeling between the Japanese and western nations. The exhibition ought to be the means for furthering the trade of our own nation in Japan.

THE TANGYES, LTD., Birmingham, England, has placed on the market a high-speed motor driven radial drill which embodies several improvements. The spindle is 3 inches in diameter and bored to receive a No. 5 Morse taper. The working radius is from 1 foot 9 inches to 5 feet. The spindle has 16 speeds, varying from 10 to 300 revolutions a minute, and automatic feed with four changes. An automatic stop is provided for the vertical motion of the spindle. The vertical adjustment on the column is 2 feet 8 inches. The base plate of the machine is about 6 feet long by 4 feet wide. There is also a small table placed on the base plate and revolving about the column. This table is 2 feet 6 inches long by 2 feet wide, and is provided with T-slots on the top and sides.

PERMANENT MUSEUM FOR SAFETY APPLIANCES IN BERLIN.—The permanent exposition for safety appliances in Charlottenburg, near Berlin, has now been opened for three and one-half years. As the material of the exposition relating to hygiene and safety appliances for machinery has considerably increased during these years, the German government has appropriated $45,000 for the erection of additional buildings. The constantly increasing interest taken in the matter of safeguarding the life and health of industrial workers in Europe, as well as on this side of the Atlantic, is one that merits attention, and it is gratifying to notice the great change that has taken place in public opinion of late years in regard to this matter.

INDUSTRIAL AWAKENING IN SPAIN.—While the American war on the one hand, and the political changes due to it on the other, dealt a crushing blow to the credit of Spain, and many foreign dealers, in view of existing difficulties, refused to trade with the country, conditions of affairs are now settled, and the prospects are very much different. The government as well as leading individuals in the industrial world are making every effort to regain the economical prosperity of the country. The imports and exports have trebled in the last ten years. There, as in Italy, mechanical industries are commencing to flourish, and while at first exporters may not expect very great trade, it would be well for machine dealers to keep an eye on the future possibilities for their trade in that country. The immense natural richness of the peninsula, which have not yet received the attention that similar natural resources have received elsewhere, are about to be exploited, and Spain no doubt will, within a few years, show an industrial awakening the same as has Italy.

ELECTRIC STEEL FURNACES IN GERMANY.—In our foreign notes of our September issue we mentioned that a Kjellin induction furnace, having a capacity of 24 tons, had been installed at the Rœchling Iron & Steel Works, Voelklingen, Germany. We have been informed by the Gesellschaft für Elektrostahlanlagen, Berlin, which firm possesses the patent rights in Europe of the Kjellin and Rœchling-Rodenhauser induction furnaces, that, while it is possible in the course of time these furnaces may be made with a capacity of 24 tons, the statement that such was the case in the installation mentioned was not correct. At the present time the furnaces have capacities of only 3 and 8 tons, respectively.

MESSRS. THOMAS ROBINSON & SON, LTD., of Roachdale, England (as reported by *Engineering* of London), have recently completed a machine which can be described in no better way than by calling it a gigantic pencil sharpener. Most of us are familiar with the five-cent hollow cone with inserted blade, which is sold for a pencil sharpener in most stationery stores. This machine has a similar hollow cone, revolved by powerful gearing, with a series of inserted blades acting in exactly the same manner as the tool of our schoolboy days. It is of such size, however, as to be able to sharpen a "pencil" 28 inches in diameter, if necessary. Of course, it is not used for pencils. The machine is built for the harbor works of Rotterdam, Holland, and is to be used in sharpening piles, which are afterward shod with iron shoes. The whole tapering head is arranged on a slide, which is moved forward by a belt-driven feed motion. Suitable clamping devices are provided for supporting the end of the pile. A timber 20 inches square can be tapered in about 15 minutes, the diameter left at the point being 5 inches.

GERMAN MACHINE TOOL TRADE.—The Association of German Machine Tool Builders has given out the following statement for the second quarter of this year. The business was on a firm basis, and employment of workers in the machine tool branch was steady. There was and is a lack of skilled labor, which is charged to the desire for young men to try to earn at once more money than can be paid to apprentices in the machine tool business. The automobile business has also deprived the machine tool builders of many of their best men. Wages have either increased, or at least been permanent, during the first part of this year. From 1901 to 1905 there was an increase in wages of 40 per cent in many districts. The ordinary length of the working day is 9½ and 10 hours, but it has been necessary to require the men to work overtime in many cases, in order to be able to keep up with the demand for machine tools. Consul-General Richard Guenther, of Frankfort, Germany, reported some time ago that at a meeting of a committee of the Association of German Machine Tool Builders, the present business conditions were said to be excellent. The works have orders for a long period ahead, and the increases in prices of machines, due to the prevailing conditions, have not met with any difficulties, nor caused any decrease in the sales. The foreign competition, particularly that from the United States, however, is very keen, and the prices, particularly for medium size and small foreign machines, low. There is a strong tendency for greater specialization in the manufacture of machine tools, this being necessary for meeting on an equal basis the American competition. By adopting American methods the Germans consider that they will be fully able to keep up with the competition, although they do not expect to be able to eliminate it in any way.

NATIONAL MACHINE TOOL BUILDERS' CONVENTION.

The sixth annual convention of the National Machine Tool Builders' Association was held on October 15 and 16 at the Hotel Imperial, New York City. The meeting was addressed by President E. M. Woodward, of Woodward & Powell Planer Co., Worcester, Mass. In the course of his address he referred to the benefits resulting to machine tool builders from the existence of the association, which has brought them into close contact, promoted friendly feeling, and made cooperation possible. Secretary P. E. Montanus, of the Springfield Machine Tool Co., of Springfield, Ohio, spoke of freight charges on fractional car loads. He pointed out the injustice of the present regulations, which oblige manufacturers to pay excessive freight charges on fractional car loads, even when they form part of a large shipment to the same consignee. For example, if a machine tool builder has four planers to ship and a car will accommodate only three, a second car is required for the extra machine, and the additional freight bill is out of all proportion to that for the others. Mr. Montanus argued that under such conditions the manufacturer should receive the benefit of the car load rate on the entire shipment, and that he should not pay a high rate on a part when it happened that one car has not sufficient capacity for the entire shipment. A standard apprenticeship agreement known as the "National Machine Tool Builders' Apprenticeship Contract" was adopted, subject to the modifications necessary to conform to various State laws. It was further decided that a standard diploma would be used for apprentices upon the completion of their terms of service. The need of special apprentices or operators trained to do one kind of work was discussed and action taken to provide for them.

The association is in a prosperous condition, eighty-one concerns now being members, eleven new ones having been added at this meeting, as follows: Aurora Tool Works, Aurora, Ind.; Champion Tool Works Co., Cincinnati, Ohio; Cincinnati Lathe & Tool Co., Cincinnati, Ohio; Eberhardt Bros. Machine Co., Newark, N. J.; Fellows Gear Shaper Co., Springfield, Vt.; E. J. Flather Mfg. Co., Nashua, N. H.; Hilbert Machine Co., Cincinnati, Ohio; Lucas Machine Tool Co., Cleveland, Ohio; Mueller Machine Tool Co., Cincinnati, Ohio; Seneca Falls Mfg. Co., Seneca Falls, N. Y.; Western Machine Tool Works, Holland, Mich.

The following officers were chosen for the ensuing year: President, Fred L. Eberhardt, Gould & Eberhardt, Newark, N. J.; first vice-president, C. A. Johnson, Gisholt Machine Co., Madison, Wis.; second vice-president, E. P. Bullard, Jr., Bullard Machine Tool Co., Bridgeport, Conn.; secretary, P. E. Montanus, Springfield Machine Tool Co., Springfield, Ohio; treasurer, W. P. Davis, W. P. Davis Machine Co., Rochester, N. Y.

The next meeting of the association will be held at Atlantic City, N. J., in May. The date of meeting will be announced later.

* * *

MACHINERY'S ANNUAL OUTING.

On October 17 MACHINERY gave its fifth annual outing, the invitations to which were accepted by five hundred machine tool builders, manufacturers, mechanical engineers, superintendents, and others interested in the machine tool business, from all parts of the country and some from Europe—nearly all of whom were able to attend. The steamer *Sagamore* of the Long Island Railroad was chartered for the day, and the start was made from the foot of West 22d Street, the route being laid out so as to give the visitors a comprehensive idea of the great coast defenses of New York City, and incidentally to include some other objects of general interest. The *Lusitania* of the Cunard Line was lying at her dock at the foot of 14th Street, and the *Sagamore* was warped in and lay there for a few minutes to give a close view of this enormous ship which had just broken the transatlantic record. The steamer then rapidly made her way south, through the upper bay, past the Statue of Liberty and Ellis Island, and reached Forts Wadsworth and Hamilton, which constitute the inner defenses on opposite sides of the Narrows. Passing between these, the *Sagamore* circled through the lower bay in view of Sandy Hook, Fort Hancock, Romer's Shoal and Coney Island. The outer defenses to the main entrance were thus included, and the course retraced to the upper bay, past Governor's Island, through the East River by Blackwell's Island, and under the uncompleted cantilever bridge of the same type as the one which recently fell at Quebec; thence through the beautiful scenery of the East River to Fort Totten, where all disembarked. This fort is the headquarters of the submarine artillery for the United States and a school of submarine defense. Through the courtesy of the Commanding Officer, Colonel G. N. Whistler, all the officers of the post were waiting to receive the party, which was divided into groups, and taken through the electrician sergeants' school, the officers' school, the 54th company's barracks, the mortar battery, gun batteries, torpedo store house, and shown the cable tank, range towers, and the method of plotting the position of a ship, which excited general interest. By the observations taken in the range towers, the positions of the ships of an enemy's fleet is plotted, and the angles and elevation of guns determined. The men who fire the guns do not see the enemy's ships at all. The guns are trained entirely by telephone and telautograph directions giving the elevation and angle of fire, these having been determined by the observations taken from the range towers located at Forts Totten and Schuyler, the latter of which is just across the Sound from the former. The return trip was made through the East River to East 24th Street, which was reached promptly at 6 o'clock.

These annual outings, which began in a small way in 1903 with some twenty guests, have gradually increased until they have now become an established feature in the machinery trade, and afford those who attend an opportunity to meet in an informal way, and to greet their business friends as well as to extend their acquaintance.

* * *

TRANSATLANTIC WIRELESS TELEGRAPHY.

An event of much importance was the starting of transatlantic wireless telegraph service by the Marconi Company, October 17. On this date the stations at Glace Bay, Nova Scotia, and Clifden, Galway, Ireland, 2,000 miles apart, were opened to commercial business, and 10,000 words were sent the first day, the messages, of course, being largely of a congratulatory nature, as befitted the initiation of so signal an advance in telegraphy. The establishment of commercial wireless telegraphy across the Atlantic is the culmination of years of patient work by Signor Marconi and his able assistants. The first wireless signals were sent across December 16, 1902, consisting simply of the letter S many times repeated. The simplicity of the signal inclined many critics to question whether the wireless signals were actually received, or whether it was not some electrical disturbance which simulated the simple signals and deceived the operator. But later events showed that the wireless signals were actually sent and received. Since then the work has consisted of improvements in the apparatus to meet the demands of commercial work. The Marconi Company accepts commercial messages at the rate of ten cents per word, and press messages at five cents. The cable rates are twenty-five cents and ten cents.

Marconi is not, by any means, the first discoverer of the ether disturbances employed in wireless telegraphy. These disturbances, commonly called Hertzian waves in honor of Dr. Hertz, an early investigator, who performed many interesting experiments which demonstrated that it was possible to send electric signals through space without the use of wires, were also known to still earlier experimenters. But Marconi's indefatigable work, dating from 1895, in developing wireless telegraphy and putting it upon a commercial basis, will doubtless forever establish his claim as the chief promoter of the art.

* * *

Preparations are being made to furnish the soldiers of the German army with paper kettles, says the *Industrial Magazine*. These paper kettles are a Japanese invention, and although they are made out of pliable paper, they hold water securely. When water is poured into them, they can be hung over a fire, without burning, for a length of time sufficient to boil the water. One kettle can be used about eight times.

FIRST ANNUAL INDUSTRIAL SHOW IN HARTFORD.

A New England exhibition of manufactured goods in the machine tool and kindred products line, known as the Annual Hartford Industrial Show, will be held December 16-21, 1907, in Foot Guard Hall, Hartford, Conn. The leading manufacturers of New England will be represented by their machines, tools, etc., and about 25,000 complimentary tickets will be issued to mechanical men in New England, so that all may see the latest improvements in the mechanical field in which they are represented. Mr. R. B. Jacobs, secretary of the Jacobs Mfg. Co., Hartford, Conn., is promoting the show, and communications should be addressed to him.

* * *

A 5-foot band-wheel in the Waclark Wire Co.'s mill at Elizabeth, N. J., burst October 8, without causing loss of life or injury to any one, which is remarkable, considering the nature of the accident and the surroundings. The pulley had twelve arms, six on each side, and ran at a rim speed of nearly 5,300 feet per minute. One piece weighing about 100 pounds went through the roof and dropped on the opposite pitch of the same roof. Three 10-inch steam mains were in direct line with the plane of the burst pulley, but, strange to say, none was touched. After clearing away the wreckage, one spoke was found in the basement nicely balanced on the edge of an oil filter, where it had fallen without causing damage.

* * *

The 16-spindle drill built by the Crane Co., Chicago, Ill., for its manufacturing plant, and which is illustrated in another part of this issue, is provided with variable speed motors built by the Colonial Fan & Motor Co., Warren, Ohio. The drill spindle motors are wound for 220-volt direct current and are of 5 H. P. each. They have a speed variation of 350 per cent or 3½ to 1. The feed motor is 10 H. P., and has a speed variation of 3 to 1. The drill motors operate in groups of four.

OBITUARY.

F. B. Duncan, of Hale & Duncan, Cleveland, Ohio, died after a short illness with typhoid fever at his home in Cleveland, September 17.

* * *

PERSONAL.

E. W. Buechling has been made assistant manager of the sales department of the Pittsburg Automatic Vise & Tool Co.

S. H. Bullard, vice-president and sales manager of the Bullard Machine Tool Co., Bridgeport, Conn., sailed on October 3 for an extended business trip in Europe.

E. R. Fellows, president of the Fellows Gear Shaper Co., Springfield, Vt., sailed October 1 on the steamer *Kaiser Wilhelm II* for a six weeks' trip abroad.

Franklin Jones, for the past four years draftsman and outside man with the Guild & Garrison Pump Co., Brooklyn, N. Y., has joined the editorial force of MACHINERY.

T. J. Shanahan, formerly with the Polo Manufacturing Co., Polo, Ill., has been made factory manager of the General Manufacturing Co., Elkhart, Ind. The company will make a specialty of air-cooled gasoline engines.

Lewis H. Morgan, formerly manager of the Ridgway Machine Tool Co., and later superintendent of the Pond plant of the Niles-Bement-Pond Co., is now connected with the Vandyke-Churchill Co., New York.

David B. Carse, of Carse Bros. Co., New York, has resigned from the advisory board of the United States Steel Corporation to again take up active work with his company in the machinery and railroad supply business.

J. W. Bray, who has heretofore represented the Bullard Machine Co. in New England, is now located at No. 1414 South Penn Street, Philadelphia, where he will represent the company in the Philadelphia territory.

Fred H. White, formerly correspondent of the Pope Mfg. Co., Hartford, Conn., will assist Mr. R. B. Jacobs, secretary of the Jacobs Mfg. Co., Hartford, Conn., in promoting the First Annual Hartford Industrial Show.

Walter B. Snow, formerly mechanical engineer and publicity manager with the B. F. Sturtevant Co., Hyde Park, Mass., where he was employed for nearly twenty-five years, has opened an office at 170 Summer St., Boston, where he will undertake any publicity work for manufacturers of machinery and allied products.

Henry M. Lane and Robert I. Clegg, both well-known editors and contributors to the technical press, have started a new monthly journal for the foundry trade, named *Castings*, which will be under their joint editorship. The first issue of the new journal appeared October 15. The publisher is the Gardner Printing Co., Caxton Building, Cleveland, Ohio.

* * *

NEW BOOKS AND PAMPHLETS.

STRIKES AND LOCKOUTS. Twenty-first annual report of the Commissioner of Labor, 1906. 979 pages, 6 x 9 inches. Published by the Government Printing Office, Washington, D. C., for general distribution.

The character of this report is indicated by the title. It gives the results of investigations of strikes and lockouts in the United States from the years 1901 to 1905, together with summaries covering the 25-year period from 1881 to 1905.

POWER STATIONS AND TRANSMISSION. By George C. Shadd. 157 pages, 6¼ x 9¼ inches. Illustrated. Published by the American School of Correspondence, Chicago, Ill. Price $1.00.

The book is divided into two parts, the first being on power stations and the second on power transmission. It is almost needless to say that the work deals almost entirely with electrical equipment, for in fact the rapid growth of electric power development and electrical transmission of power has put all other power systems completely into the background. The book is prepared in the characteristic style adopted for all its text-books by the American School of Correspondence, and, therefore, is marked by clearness and lucidity of style, numerous illustrations and frequent practical examples.

REGULATIONS AND INSTRUCTIONS CONCERNING DENATURED ALCOHOL, CENTRAL DENATURING BONDED WAREHOUSES, AND INDUSTRIAL DISTILLERIES. 169 pages, 6 x 9 inches. Published by the U. S. Treasury Department, Washington, D. C., for free distribution.

This pamphlet giving revised United States internal revenue regulations under act of Congress June 7, 1906, and amendatory act March 2, 1907, is No. 30, revised July 15, 1907. It is of general interest, as its provisions are supposed to permit the general manufacture of denatured alcohol by small producers. That liberal revenue regulations are required to extend the use of denatured alcohol so as to largely displace gasoline and kerosene is generally conceded, and it is to be hoped that the present regulations will be liberally administered. It is our impression, however, that the unwinding of red tape will tend to discourage many who might be inclined to enter into the manufacture of denatured alcohol from farm products.

SYMPOSIUM OF INDUSTRIAL EDUCATION. Bulletin No. 3, issued by the National Society for the Promotion of Industrial Education. Collated by James P. Haney. 58 pages, 6 x 9 inches. Published by the society. Copies supplied free by the secretary, Charles R. Richards, Teachers' College, West 120th St., New York.

The bulletin is a compilation of letters received in answer to a set of categorical questions on industrial education, and it includes letters from President Theodore Roosevelt, representatives of trade unions, and leading manufacturers throughout the country. The sentiments expressed are almost uniformly in favor of improved methods of industrial education, and the pamphlet contains a number of valuable contributions to the literature on the subject. It is quite evident from reading the pamphlet that the general feeling throughout the country is that our public school system needs to be reformed so as to include more practical education which will better fit the boys for learning trades.

THE BLACKSMITH'S GUIDE. By J. F. Sallows. 157 pages, 4½ x 7 inches. Illustrated. Published by the Technical Press, Brattleboro, Vermont. Price, cloth binding, $1.50; leather binding, round corners, $2.00.

The author of this interesting work is not unknown to the readers of MACHINERY, as he has contributed to its columns a number of unique and valuable articles on tool-dressing, case-hardening, etc. Mr. Sallows has had twenty-seven years of experience at blacksmithing, covering a wide range of work in railroad, printing press, marine, automobile and other shops. The arrangement of the work is, by chapters, as follows: Machine Forging; Tool Forging, Hardening and Tempering; High-Speed Steel; Case-hardening and Coloring; Brazing—General Blacksmithing. The general make-up and typographical appearance is excellent, and the same adjective applies to the contents. The chapter on case-hardening is particularly valuable. The author's experience in this line has specially fitted him to write authoritatively on the art of case-hardening for beauty of product as well as for uniform surface hardness. The chapter on tool forging is of practical interest to all machinists.

ENGINEERING WORK SHOP PRACTICE. By Charles C. Allen. 254 pages, 4¾ x 7¼ inches. Illustrated. Published by Methuen & Co., 36 Essex St., W. C., London. Price, $1.00.

The work treats of properties of materials, transmission of power, measuring, gaging, tool steel and its treatment, joining of metals, laying out, chipping, filing and scraping, cutting tools, lathe work, planing, shaping, slotting, drilling, boring, milling, grinding, lapping, screw cutting, gear cutting, etc. Special attention has been given to highly accurate methods of measurement, gages and other measuring instruments being described in detail. The book is of good appearance and is well prepared. It contains a large amount of valuable instruction and information for the machinist and student in workshop practice. The drawings from which the cuts showing machine details were made, were carefully prepared. They are a very creditable addition to the work, and "shine by contrast" when compared with many other books on shop practice. The bad character of the cuts used to illustrate many examples of otherwise excellent engineering books is notorious. It is a pleasure to examine a book having cuts made from well-executed drawings.

TESTS OF INTERNAL-COMBUSTION ENGINES ON ALCOHOL FUEL. By Charles E. Lucke and S. M. Woodward. 89 pages, 6 x 9 inches, Illustrated. Published by the U. S. Department of Agriculture, Washington, D. C., for free distribution.

This report, designated as Bulletin No. 191, contains an account of the tests made by Dr. Lucke of Columbia University and Prof. Woodward, Irrigation engineer, U. S. Government, to determine whether gasoline and kerosene engines at present in general use can run with alcohol as fuel, and to learn what improvements are desirable to adapt such engines especially for alcohol. The conclusions are that any gasoline engine of the ordinary types can be run with alcohol without any material change in construction; that when run with alcohol the operation is less noisy; that alcohol is specially well

adapted for air cooled motors; that the consumption of fuel in pounds per brake-horse-power-hour depends chiefly on the horse-power of the engine; and that with any good gasoline engine as small a consumption as 0.70 pound of gasoline or 1.16 pound of alcohol per brake-horse-power-hour may reasonably be expected under favorable conditions.

HENDRICKS' COMMERCIAL REGISTER OF THE UNITED STATES. 16th annual edition. 1,224 pages, 7½ x 10 inches. Published by S. E. Hendricks Co., 74 Lafayette St., corner Franklin St., New York City. Price $10.00.

This comprehensive work is a commercial register of the United States for buyers and sellers, and it is undoubtedly properly designated, as it is one of the most complete works of the kind published. The register is now in the 16th annual edition, the first edition having been published in 1891. That issue contained about 500 pages, while the present issue contains over 1,200 pages and upwards of 350,000 names and addresses classified under 31,212 trade headings. Seventy-six pages alone are required to index its contents. The first edition was devoted solely to the building industry of the country, but the present edition covers not only that but also engineering, mechanical, railroad, electrical, mining, iron, steel, export and kindred industries. It is said to be the only publication of the kind ever issued that is so classified that it can be used either for purchasing or mailing purposes. The publishers assure us that each annual edition is corrected and verified item by item so far as lies in their power, a task which is of no mean order, as any one will concede upon examining this great and valuable work.

CATALOGUES AND CIRCULARS.

THE HILBERT MACHINE CO., 2116 Colerain Ave., Cincinnati, O. Pamphlet illustrating and describing its 2½-foot radial drill.

CHAIN BELT CO., Milwaukee, Wis. Catalogue of elevating, conveying, and power transmission machinery.

MELVIN & HAMAKER, Meadville, Pa. Catalogue descriptive of the Melvin boring head, which s a new tool offered to the trade, made in all sizes up to 18 inches diameter.

PATENT FILE & TOOL CO., 8 White St., Moorfields, London, Eng. Catalogue descriptive of the "Dreadnought" milling or circular cut file, described in MACHINERY, March, 1907.

THE RIDGWAY DYNAMO AND ENGINE CO., Ridgway, Pa. Bulletin No. 18 entitled Power Plants, containing half-tone views of the installations made by this company in the power plants of various concerns.

THE DAVID BELL ENGINEERING WORKS, Buffalo, N. Y. Catalogue No. 806 on Bell's steam hammers, illustrating and giving specifications of the single frame guide type and the open frame type.

FITCHBURG MACHINE WORKS, Fitchburg, Mass. Circular on the Lo-swing lathe describing its various parts, and telling of the special work for which it is built.

JENKINS BROS., 71 John St., New York. Pamphlet on extra heavy valves, giving dimensions of brass globe valves, brass angle valves, brass check valves, blow-off vales, iron body globe valves, etc.

PIKE MFG. CO., Pike, N. H. Catalogue giving dimensions and prices of scythestones, axe stones, oilstones, water stones, razor hones, knife sharpeners, grindstones, corundum wheels, emery wheels, and abrasives.

THE CRESCENT MFG. CO., Scottdale, Pa. Catalogue of small tools and machine shop appliances giving tables of specifications for detachable counterboring and facing tool, reamers of various types, milling cutters, die heads, taps, tool-holders, angle plates, etc.

B. F. STURTEVANT CO., Hyde Park, Mass. Bulletins Nos. 144 and 147 describing eight-pole, bipolar and four-pole electric motors, respectively. The bulletins contain general description, construction details, principal dimensions, etc.

BUCKEYE ENGINE CO., Salem, O. Circular containing another talk by Professor A. C. Tinic, in which he tells of some of the advantages obtained by using the Buckeye electric blue-printing machine, and reproduces a letter from a well-known firm commending this machine.

H. W. JOHNS-MANVILLE CO., 100 William St., New York. Leaflet descriptive of "Leak-No," a peculiar metallic compound in powder form that is mixed with water to stop leaks in steam, water, gas, air, ammonia and brine pipes, to fill cracks in fire-pots, wash basins, bathtubs, etc.

THE GRAHAM MFG. CO., Providence, R. I. Leaflet descriptive of the universal jig vise which may be used as an ordinary drill vise or as a jig drilling vise by the use of attachments. It is universal in its character for all work within its capacity, and often saves the making of expensive drilling jigs.

THE BROWN HOISTING MACHINERY CO., Cleveland, O. Pamphlet illustrating "Brownhoist" locomotive cranes with grab-bucket equipment, showing the cranes handling ore from stock piles, gondola cars, etc. A general description of this equipment and a summary of its advantages are included. Attention is called to the partial list of steel companies using these cranes.

EUGENE DIETZGEN CO., New York. Catalogue of drawing instruments, drawing materials, surveying instruments, etc. This attractive catalogue contains 473 pages, 5½ x 8½ inches (dealer's size), and lists a great variety of drawing supplies, surveying instruments and other materials and devices required by draftsmen, mechanical and civil engineers, architects, etc.

THE R. K. LE BLOND MACHINE TOOL CO., 4605 Eastern Ave., Cincinnati, Ohio. Catalogue of engine lathes, including both standard and quick-change, special turret lathes, motor-driven lathes, etc. The catalogue also lists all lathe attachments. The illustrations are specially attractive, and the catalogue as a whole is of much interest to manufacturers and lathe users.

NORTON CO., Worcester, Mass. Circular of Norton alundum stones which are made of specially prepared alundum by the same process used in the manufacture of Norton grinding wheels. These stones are recommended for glass cutting, lens grinding, etc. The circular is printed in three colors and is an attractive piece of advertising literature.

NILES-BEMENT-POND CO., Trinity Building, 111 Broadway, New York. Catalogue of the Pond rigid turret lathe. This machine was designed for work ordinarily done on engine lathes, and is specially adapted to gear blanks, small fly-wheels, engine cylinders, etc. It is built in two sizes, 21 and 28 inches swing. The catalogue is illustrated with views showing attachments, equipment, and samples of work that can be handled advantageously.

THE HISEY-WOLF MACHINE CO., Cincinnati, Ohio. Catalogue No. 6, illustrating and describing the company's complete line of portable electric drills and grinders which are wound for both direct and alternating current. These electric drills and grinders represent an important advance in the growth of the portable tool idea and the catalogue will be found of much general interest. It is mailed to any one upon application.

WALTER B. SNOW, 170 Summer St., Boston, Mass. "Productive Publicity," a booklet outlining the proposed activities of Mr. Snow as a "publicity engineer." His long experience in engineering and publicity work has specially fitted him for intelligently handling this business—a business that is rapidly growing in complexity and which demands technical training and experience of a high order to satisfy present needs in marketing manufactured products.

GENERAL ELECTRIC CO., Schenectady, N. Y. Bulletin No. 4534 on Curtis steam turbines of the horizontal type for driving horizontal shaft generators. Curtis turbine generator sets are built up to 300 K. W. capacity for both direct and alternating current. The bulletin fully describes the construction, and points out the advantages, among which are less floor space required, absence of reciprocating parts and attendant freedom from vibration, etc.

THE RIDGWAY DYNAMO AND ENGINE CO., Ridgway, Pa. Set of templets showing the floor space occupied by the Standard Ridgway generating units in sizes from 10 K. W. to 200 K. W., inclusive. These templets are made to a scale of ¼ inch to the foot, and are seven in number. They should be of great convenience in the laying out of power plants, as the templets may be laid on a drawing scaled ¼ inch to the foot, and shifted to whatever position best suits. The company is sending the templets free to all interested.

A CATALOGUE has been received from the Twenty-third St., New York, Y. M. C. A., giving a synopsis of the courses of study in the night school which began in October and continues until June. The courses include the ordinary common school studies and instruction in industrial chemistry, paper making, leather making, architectural drawing, plan reading and estimating, mechanical drawing, salesmanship, advertising, accountancy, plumbing, railway transportation, electricity, steam engineering, etc.

GENERAL ELECTRIC CO., Schenectady, N. Y. Bulletin No. 4530 on mercury arc rectifiers. It describes the simplicity and reliability of these devices for producing direct current for charging storage batteries and for many other commercial purposes. They are inexpensive, flexible and reliable, require small floor space, have remarkably high efficiency at full and light loads, and in operation are the simplest rectifying devices yet produced. A brief outline of the theory of the apparatus is given in the bulletin and various types of rectifying sets are described and illustrated.

GOLDSCHMIDT THERMIT CO., 90 West St., New York. Circular describing applications of thermit in foundry practice. Thermit has proved to be a most valuable means of producing high temperature (5,400 degrees F.) anywhere with very simple apparatus, and for foundry purposes no apparatus is required. It provides means for maintaining or even increasing the temperature of metal poured into the ladle. It is prepared in special cans for foundry use, and is particularly valuable for reviving "dull" iron and for many other purposes described.

THE HENRY & WRIGHT MFG. CO., Hartford, Conn. Catalogue of ball bearing drill presses, illustrating the line of sensitive drills, including single spindle, multiple spindle and radial drills. The great reduction in power required due to the use of ball bearings and the balanced feather system on the spindle enables a 1¼-inch belt to efficiently drive high-speed drills up to ¾-inch diameter, and even larger, and has made possible a production of from 200 to 400 per cent more work, it is claimed, than is possible with the ordinary drill press construction. The catalogue is copiously illustrated and is an attractive piece of advertising literature.

HERMANN BOKER & CO., 101-103 Duane St., New York. Circular descriptive of "Intra" steel, giving working instructions for heating, hardening and tempering. "Intra" steel is *not* a high-speed steel, but closely approaches it in point of cutting speed, having an average of 50 to 75 greater cutting power and durability than the carbon steels hitherto available. The new steel is readily made up into milling cutters, reamers, twist drills, taps, dies, punches, machine knives, etc., and being hardened at a temperature of 1,500 to 1,550 degrees F. there is not the trouble from blistering and scaling common with high-speed steels. It is notably tough, and being far cheaper than high-speed steel, it naturally promises to be a very valuable brand of steel for general purposes.

MANUFACTURERS' NOTES.

CINCINNATI ELECTRICAL TOOL CO., Cincinnati, O., has opened a Western office and salesroom at Eighteenth and Rockwell Sts. Mr. Oscar P. Wodack has been made manager.

SIBLEY MACHINE TOOL CO., South Bend, Ind., manufacturer of upright drills, has recently made a two-story addition to its shop. The addition is 42 x 75 feet, and it will accommodate a fine new office and increase the size of the present work rooms.

AMERICAN LOCOMOTIVE CO., 111 Broadway, New York, reports an order of 125 locomotives for the Harriman lines made up as follows: 30 Mogul type; 10 Atlantic type; 43 consolidation type; 24 ten-wheel type; 18 six-wheel switching locomotives.

NELSON WHEEL CO., 141 E. Ontario St., Chicago, Ill., has lately been incorporated to manufacture automobile wheels and accessories. The company desires to receive catalogues from the various machine tool builders for its files.

AKRON CLUTCH CO., Akron, Ohio, manufacturer of the "Akron" friction clutches, has moved into a new factory which is a two-story fireproof building 32 x 135 feet. The concern has been forced to build the new and larger shop to accommodate the demand for its clutches.

DIAMOND SAW AND STAMPING WORKS, 357-361 Seventh St., Buffalo, N. Y., announces that Mr. Frederick Peters, Pickhuben Huben 4, Hamburg, Germany, is its representative on the Continent for the "Sterling" hack-saw blades, frames and power hack-saw machines.

EDGEMONT MACHINE WORKS, Dayton, Ohio, manufacturers of friction clutches for counter-shafts and line-shafts, has just completed a two-story brick addition, 50 x 75 feet, which will enable the company to more than double its present output.

THE WARNER & SWASEY CO., Cleveland, Ohio, has opened a Chicago office in the Commercial National Bank Building, Adams and Clark Sts. The new office will be under the management of Mr. E. B. Boye, who will supply any information regarding the machine tools built by the company.

THE TECHNICAL PUBLICITY ASSOCIATION, composed of the publicity managers of leading manufacturing concerns, devoted the first meeting of the year (September 26) to a discussion of the "mailing list," its relation to general advertising, etc. The secretary of the Association is Mr. Rodman Gilder, of the Crocker-Wheeler Co., Ampere, N. J.

THE MCCROSKY REAMER CO., Meadville, Pa., was organized October 1 under the laws of Pennsylvania, and has taken over the business of the F. B. McCrosky Mfg. Co. The new company has a paid-up capital of $40,000, and it will continue the manufacture of the patent reamer formerly made by the F. B. McCrosky Mfg. Co.

VANDYCK-CHURCHILL CO., 91-93 Liberty St., New York, has just concluded an agency arrangement with the Cleveland Crane & Car Co. to represent it exclusively in the New York and Philadelphia territory. The new department will be in charge of Mr. Lewis H. Morgan, recently manager of the Ridgway Machine Co.

THE CUTLER-HAMMER MFG. CO., Milwaukee, Wis., announces that the New York plant of the Wirt Electric Co. of Philadelphia, which business was purchased by the Cutler-Hammer Mfg. Co. some months ago, has been consolidated with the New York plant of the Cutler-Hammer Mfg. Co. at Park Ave. and 130th St.

THE NATIONAL TWIST DRILL AND TOOL CO., Detroit, Mich., is now located in its new factory at the corner of Brush St. and Boulevard. The new building is of concrete 38 x 145 feet, three stories high. It is equipped with up-to-date machinery throughout, and represents the latest type of factory in all details. The company expects to triple its output when in full working order.

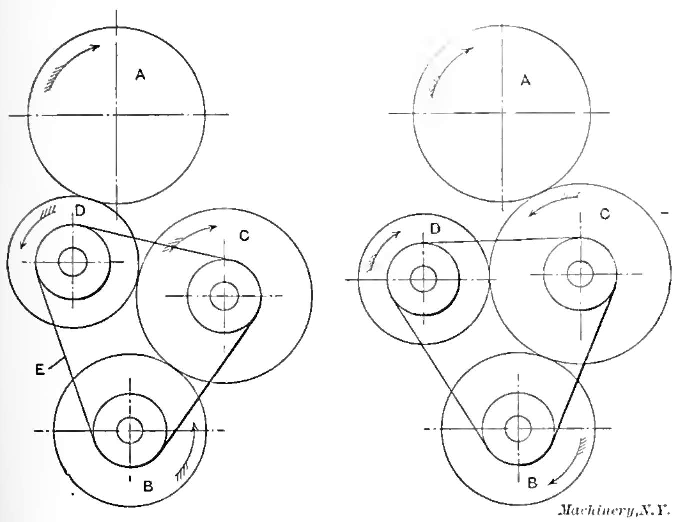
MACHINERY.

December, 1907.

TUMBLER GEAR DESIGN.

JOHN EDGAR.*

OF the different mechanisms that have been used in the machine tools of the past, one—the tumbler gear—could be found in some form or other in almost every machine. Its office, in most cases, was to reverse the direction of the feed. Fig. 1 shows the usual form in which it is found when used for this purpose. The gears *A* and *B* are to be connected so that motion may be transmitted from one, which runs constantly in one direction, to the other, which it is desired to run in either direction. Suppose that *A* is the driver and runs as shown by the arrow. As connected, *A* drives *B* through the intermediate gears *D* and *C*, *B* rotating in an opposite direction to *A*, as shown by the arrows.



Figs. 1 and 2. Examples of Tumbler Gears.

This mechanism is termed the tumbler gear, because the gears *D* and *C* are supported in a frame which swings about the axis of either the driving or the driven gear. In the case in hand, the intermediate gears are carried in the frame *E*, which rotates about the axis of the gear *B*. Some means, not shown, must be provided by which the rocker frame may be changed from one position to the other, and locked. Fig. 2 shows the mechanism shifted so that the motions of *A* and *B* are in the same direction.

The tumbler gear has been used as a reversing gear ever since present forms of machine tools were first invented. While it has always given considerable trouble, it has shown up to disadvantage mostly when applied to the modern machine with positive gear feed, where great power has to be transmitted by it. It is the purpose here to show where this gear may be used to advantage, and also to explain the theory on which the principles of its design are based.

All of us have met with this mechanism in some form or other, and may have formed an unfavorable opinion. The prejudice thus created keeps us from fully appreciating the tumbler gear, even when properly designed, and when used in the right place. It has been placed by many along with the worm drive and the spiral gear as undesirable, and to be avoided unless it is absolutely impossible to get along without it. This opinion has been responsible for the adoption of many combinations used for purposes that rightly belong in the field of the tumbler gear, and many times, in order to avoid using this mechanism, much unnecessary complication has resulted.

What are the faults of the tumbler reversing gear? That one on So-and-So's lathe used to kick furiously when one tried to throw it over. Then, the one used on the milling machine used to go into mesh easily enough, but when any amount of strain was put onto it, the teeth used to crack and growl, showing that the tendency was to drag the gear farther into mesh, causing the teeth to bind on one another and sometimes break. Let us look into the case represented in Fig. 1. Fig. 3 shows the gear *D* just entering into mesh with *A*. An examination of this figure shows that the tendency is for the teeth of gear *A*, when they strike those of gear *D*, to cause the latter to rotate about the axis of the rocker frame, should the gear *B* be locked against turning. This tendency opposes the motion in the opposite direction necessary to bring the gears wholly into mesh. In practice, *B* is not locked, but it is necessary to overcome a certain amount of resistance in order that it may be set in motion, and the presence of this resistance has the same effect as if the gear were locked. The greater this resistance is, the greater is the effort necessary to bring the gears into working position.

Examining the conditions in the case of Fig. 2, we see that the effect would be just the opposite, that is, the gears would come into mesh of their own accord as soon as a contact is produced between the teeth of *A* and *C*. Practically no effort is necessary to bring the gears into mesh, but, in order to withdraw the gear *C* from *A*, considerable effort would be required. When the gears *C* and *A* are in mesh and transmit power, the tendency for gear *C* is to crowd farther into mesh with *A*, which has the effect of binding the teeth. Should the pressure of contact be sufficient, the binding tendency would cause the motion to cease, or would break the teeth.

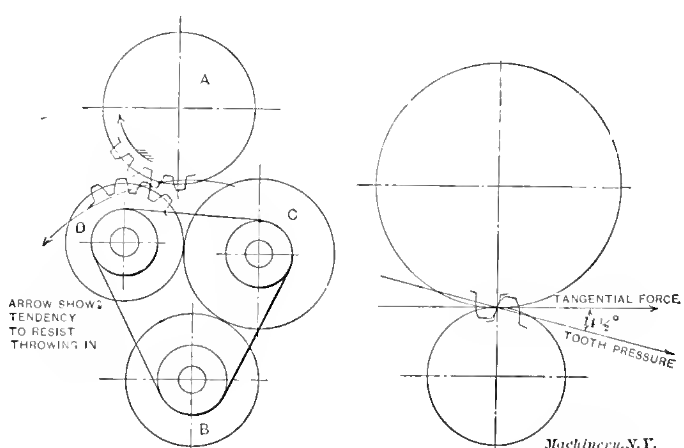


Fig. 3. Illustrating the Tendency to resist Throwing-in of Gear. **Fig. 4. Illustrating the Direction of Line of Pressure.**

This is one of the points on which many have based their verdict against the tumbler gear, and when designed so that such results are obtained, it is not to be wondered at.

Direction of Tooth Pressure in Ordinary Cut Gears.

The first consideration in the design of tumbler gears in any form is that of tooth pressure and its line of application. As all cut gears used in machine tools are made to the $14\frac{1}{2}$-degree involute system, we will confine ourselves to that system. In this, the force tending to revolve the driven gear is not a tangential force, applied as a tangent to the pitch circle, but is a force applied at an angle of $14\frac{1}{2}$ degrees to the tangent of the pitch circle, this $14\frac{1}{2}$-degree line being termed the line of pressure. In case that there may be some confusion as to the above statement regarding the tangential force and the line of pressure on the teeth, the case is graphically shown in Fig. 4. The tangential force is equal to the twisting moment divided by the radius of the pitch circle. This force is equivalent to that which transmits motion between two disks by friction alone, the diameters of the disks being equal to the pitch circles of the gears. This force is,

* Address: 7 Webster St., Hyde Park, Mass.

in the case of a gear, resolved into two component forces. One component acts perpendicular to the tangential force and tends to force the gears apart; the other acts in the direction of the line of tooth pressure shown in Fig. 4. The tooth pressure thus is somewhat less than the total twisting force, and equals the twisting or tangential force multiplied by the cosine of 14½ degrees.

Influence of Direction of Tooth Pressure on Tumbler Gear Design.

To show what effect the line of pressure has upon the layout of the tumbler gear, we will use the simple case shown in Fig. 5. In this figure, A is the driving gear and B is the driven gear. These gears are connected by means of the intermediate gear C, which is carried in the swing frame E, which, in turn, swings about the axis of A. This mechanism is a simple case of tumbler gear, and while it is little used, it is useful as a means for disconnecting a train of gears when it is desired to stop the motion of the driven section. If we consider the gear B locked in the position shown, and exert a turning effort on the gear A in the direction indicated by the arrow, this effort is transmitted by the teeth of A and C, and a pressure is produced between the teeth of B and C, two of which are shown in the cut. The direction in which this force is applied is shown by the line of pressure $H K$, and is exerted in the direction of H. Since every force is opposed by an equal and opposite force when in a state of equilibrium, we have in this instance a force or reaction opposing the force along the line of pressure referred to. It is this reaction that causes our troubles. In the mechanism shown in Fig. 5, the gear C and the link E are free to rotate about the axis of A, and since the line of pressure does not go through the center of gear A, the force acting along this line tends to rotate the arm E about the axis of A, the direction of rotation being dependent on which side of the center of A the line falls. Thus in Fig. 5, the line falls in a position that produces a tendency for the arm to force the gear C further into mesh with B. The twisting moment thus set up is equal to the tooth pressure multiplied by the normal distance from the axis of A, or $G L$.

If now, instead of trying to turn the gear A in the direction of the arrow, we exert a torque in the other direction, the opposite sides of the teeth would come into contact, and the line of pressure would be located as shown by the dotted

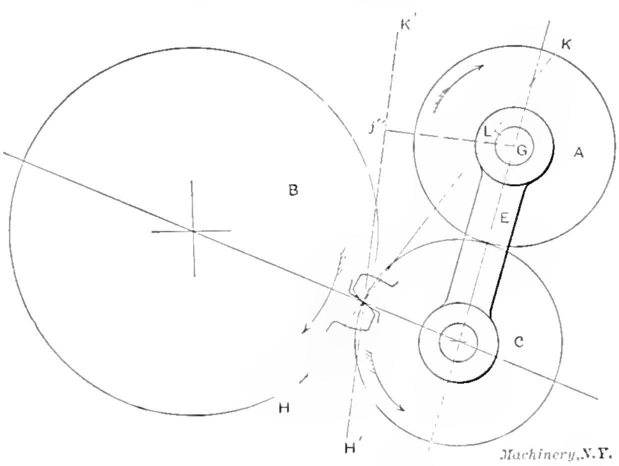

Fig. 5. Objectionable Gear Design.

line $H' K'$. The normal distance of this line from the axis of A is much greater than in the former case; consequently the twisting moment tending to rotate the arm E about the axis is also increased, but the direction in which the torque is applied has changed the direction in which the reacting force along the line of pressure acts, and, since this line falls on the same side of the axis, the tendency of the arm is to rotate in the opposite direction, and to separate the gears C and B. Had the line of pressure gone directly through the axis of the gear A, where E is pivoted, the effect of any force acting along it would have had no rotating influence upon the tumbler gear arm. That this would be the ideal case needs not to be mentioned, and it should be the aim of the designer to approach that condition as nearly as possible.

The tendency for the tumbler to crowd the gears into mesh might be of some advantage were it desirable to throw them into mesh while the gears are in motion; but in cases where any considerable amount of power is being transmitted, a very stiff and rigid design will be necessary for the tumbler frame and the locking device. It is also well in such cases, when setting the locking device, to have the gears mesh with plenty of play or backlash, so that, if there be any give to the frame, the gears will not be likely to bind and cramp. Should B be the driver and run in the direction of the arrow, the line of pressure would be $H' K'$, and the pressure would be in the direction of H'. The arm would then tend to carry the gear C out of mesh with B. Should the direction be reversed, $H K$ would be the line of pressure, and the tendency would be to crowd the gear in.

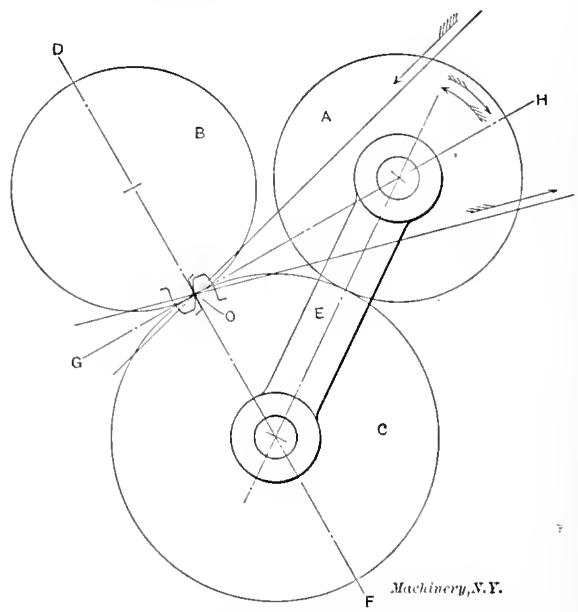

Fig. 6. Correct Tumbler Gear Design to run in Both Directions.

The layout in Fig. 5 has two bad features. In the first place, the gears have a tendency to crowd farther into mesh, which limits the amount of power that can be transmitted, and increases the liability of breakage of the gear teeth and of the tumbler frame should an overload be imposed upon the mechanism. Inaccuracy in the shape and spacing of the teeth aggravates the above conditions. In the second place, the mechanism should be used to transmit motion in but one direction.

In most cases the throwing in or out of the tumbler is a secondary matter as it is done either when the gears are not in motion, or while not under load, if running. In such cases it should be the aim of the designer to overcome the objection of the crowding of the teeth into mesh by having the line of pressure properly located so that the tendency is in the opposite direction. When it is desired to provide a tumbler gear that can be run in either direction, the layout in Fig. 6 is recommended. The object in this case is to have the twisting moment equal in either direction, and such that the gears have no crowding tendency. The arrangement in Fig. 6 is laid out as follows: Draw the pitch circles of the gears B and C and connect their centers by the line $D F$. Through the pitch point O draw a line $G H$ normal to $D F$. Then locate the gear A at some point on $G H$ so that its pitch circle will be tangent with that of C.

The Single Tumbler Gear.

The single tumbler gear is the basis of many of our modern rapid change speed and feed mechanisms, and the principles treated above apply to this as well as to the simple tumbler gear. Take the simple case shown in Fig. 7, which shows the pitch circles of a four-gear cone and the driver A and tumbler gear C. It is evident that only one position of the gear C can be such that the ideal condition prevails, that is, only when in mesh with one gear of the cone can the line of pressure pass through the axis of the tumbler frame. Fig. 7 shows this to be the case when C is in mesh with the gear B'. Each subsequent shifting of the tumbler along the cone brings the line of pressure eccentric to the axis until the position

of extreme eccentricity is reached when C is in mesh with B''''. In mechanisms of this kind, it should always be the aim of the designer to have the line of pressure pass as close to the center of rotation of the tumbler frame as is possible, because the locking devices used with this type of tumbler gear are necessarily of such a design as to be quick in action, and in consequence are not very stiff or rigid. The line of pressure should always be made to fall on that side of the axis where the tendency is to separate the gears rather than to bring them closer together. When the gear C is supported in a swinging frame which does not slide in a lateral direction, but the changes are made by shifting C along an intermediate shaft, the supporting member should be located at the end where the line of pressure has the greatest eccentricity, as the greatest strain comes at that end. Thus, in Fig. 7 the support should be at the same end as B''''. The diameter of the intermediate gear C has an important effect on the location of the line of pressure. It will be found that it should in most cases be as large as B'''', in order that the line of pressure may come right. However, no exact rule can be given by which the diameter of C can be calculated, as it depends greatly on the difference in the diameters of B' and B'''', and also on the diameter of A.

Rules for the Design of Tumbler Gears.

What direct rule can be given that may be used as a guide in laying out the tumbler gear? Referring to Fig. 5, we see that the gear C is revolving in a direction away from the axis of the tumbler at the point of tangency of the pitch circles of C and B, and that the reacting force tends to crowd the gears farther into mesh. Had this line of pressure fallen on the other side of the axis of the tumbler frame, the tendency would have been opposite in effect. When the gear C is revolving so that a point on the pitch circle travels away from the pivot of the tumbler, and the line of pressure falls

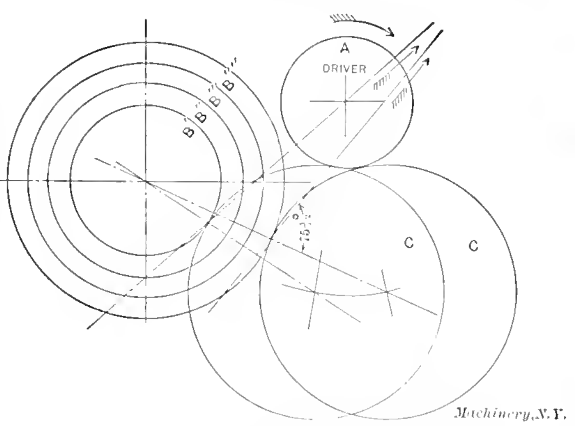

Fig. 7. Single Tumbler Gear in a Feed Box.

somewhere between the pivot point and the axis of the driven gear B, the tendency will be to crowd. From this we therefore may formulate the following rules:

Rule I. When the gear about which the tumbler gear swings is the driver, and the line of pressure falls between the axis of that gear and that of the driven gear, the motion of a point on the pitch circle of the tumbler or intermediate gear, when near the contact point, must be toward the axis of the tumbler frame. Should the direction of a point on the pitch circle be opposite, the line of pressure must fall outside of that area included between the axis of the pivot gear and the driven gear.

Referring again to Fig. 5, it is seen that should the driving gear be B, the above rule does not apply, but may be altered to read thus:

Rule II. When the gear about which the tumbler gear swings is the driven gear, and the line of pressure falls in the space between the axis of this gear and that of the driving gear, the motion of a point on the pitch circle of the intermediate gear at the contact point must be away from the axis of the pivot gear; when the line of pressure falls outside of this space this motion must be reversed.

By following these two rules, more as a precaution than as a compulsory condition, much better success may be expected in the results obtained.

NEW BUILDING FOR THE AMERICAN SCHOOL OF CORRESPONDENCE.

The building recently erected for the American School of Correspondence, Chicago, is of particular interest from both the architectural and the educational point of view. This new home of home study is marked by solidity, dignity and usefulness. In its external, visible lines, it harmonizes with the

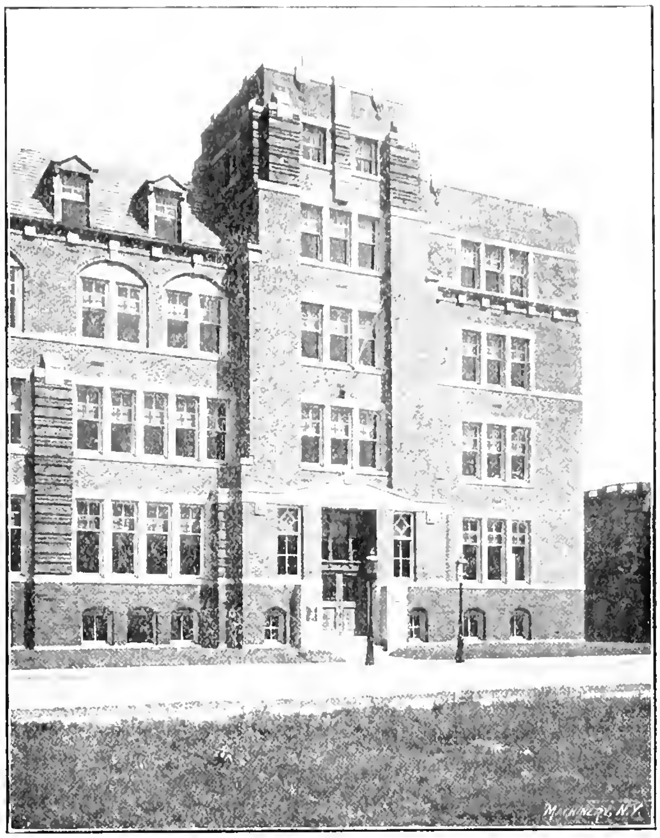

Fig. 1. Detail of Tower, New Building American School of Correspondence.

practical purposes of its design. The structure partakes to some extent of the nature of an office building as well as a school. Its design was, therefore, a complex problem dictated by several different considerations. First, of course, was its intended use as a school and a center of administration; but a factor of almost equal weight was its location. It stands in the immediate vicinity of the magnificent Washington

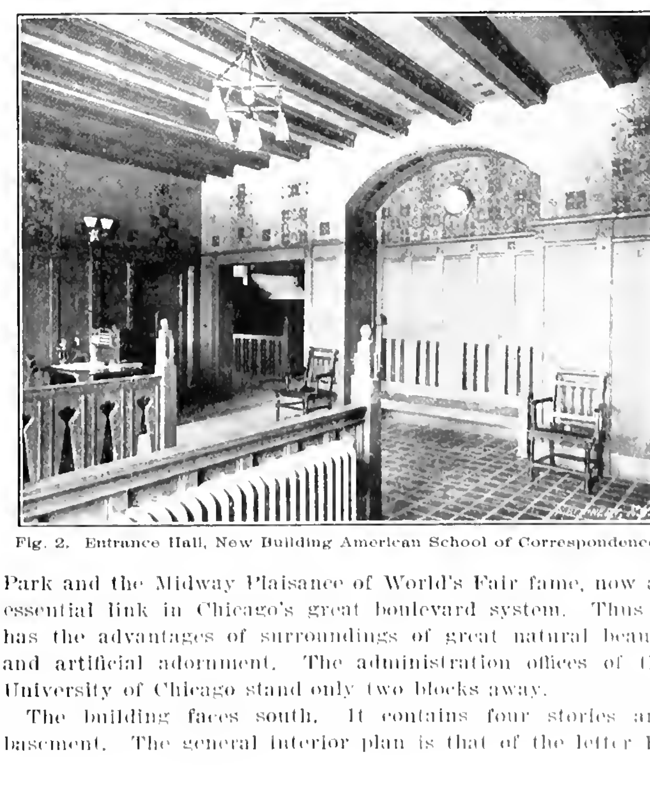

Fig. 2. Entrance Hall, New Building American School of Correspondence.

Park and the Midway Plaisance of World's Fair fame, now an essential link in Chicago's great boulevard system. Thus it has the advantages of surroundings of great natural beauty and artificial adornment. The administration offices of the University of Chicago stand only two blocks away.

The building faces south. It contains four stories and basement. The general interior plan is that of the letter E;

the return of the east and west wings encloses on two sides an open court, 60 feet square, walled in at the rear end and entered through an arched driveway.

The materials of the exterior are paving brick of two shades, with Bedford stone for enrichment, and moss-green tile in the roof. The brick used in the basement and projecting corners of the rustications is of a purplish red, somewhat darker than that used in the body; its depth of tone is strengthened by its being laid with dark joints. The brick in the body of the wall is a medium warm red, variegated enough to have life and pleasing texture; its general contrast to the darker material is emphasized by its being laid with white joints, and by the white finish of the window sash and frames.

The note of green struck in the roof tiling is carried throughout the interior wood finish of the building, which is of quartered oak; the notes of purple and red reappear in the wall decoration, and the red in the polished granite of the entrance steps. Red is also present in the flooring of the vestibule and corridor on the ground floor, which consists of plain red English quarry tile, laid with broad, dark joints, and relieved by occasional mosaics of glazed and varicolored tiling. The general interior color scheme is seen to best advantage in the vestibule. The high oaken wainscoting, the ceiling beams, and the furnishings are tinted a soft green; the walls and ceiling panels a warm buff, relieved with unique, conventional flowered designs in red, green and purple—the whole blending harmoniously and in pleasing contrast with the general darker tinting of the tiled floor.

The administrative offices of the school are on the second floor; the remainder of the building is used for the accommodation of the large staff of instructors, editors, and other employes in charge of the various details of the work of the school. An interior telephone system connects all departments. To facilitate the work of the business office and mailing room, several of the latest electrical appliances have been installed, including adding machines, folding machines, and envelope sealers—all operated by electric power. In the basement are the stock room, the shipping room and the steam-heating plant. The system of heating is known as the "direct-indirect"; the larger radiators are located in juxtaposition to cold-air ducts that lead from the outside through the walls, and that supply an abundance of fresh air at all times. Electricity is used throughout for lighting purposes. The corridors and larger rooms are equipped with Nernst lamps, the other parts of the building with incandescent lamps. Lavatories with hot and cold water are located on each floor.

On the second floor are the lecture room, and the rest room for employes. The lecture room is used as a meeting place for the clubs that have been formed at the works of the Crane Co., the McCormick Harvester Co., and other large manufacturing plants in and near Chicago. At these plants students of the American School of Correspondence have organized, appointed leaders from their own number, and found mutual assistance in studying together. From time to time they meet in the lecture room of the school, where they are provided with instructors, apparatus, and—since most of them come direct from the shop to the school—with a substantial lunch, all for the usual tuition. The school also provides its employes with free coffee and lunch at noontime.

It is the purpose of the American School of Correspondence to take into every home the educational facilities offered by the best resident technical schools; to make it possible for every man, irrespective of age, occupation or condition, to educate himself at home during his spare time; to give the wage earner, the mechanic, the man who has "never had a chance," an opportunity to fit himself for the position in life which he desires to fill.

* * *

It has been estimated that every person in the United States uses, annually, about seven dollars' worth of electricity in some form. Trolley rides lead at $3 per capita; electric light is second with $1.50 per capita. Every man, woman and child buys $1.25 worth of electric apparatus and supplies, uses 75 cents' worth of telephone service, and 50 cents' worth of telegrams and alarms.

BRITISH FILE-TESTING MACHINE.

In the October issue an article on file testing by Mr. Oscar E. Perrigo was published, which gave simple directions for testing files without an apparatus. Presumably this article called forth from Edward G. Herbert, Ltd., Manchester, England, the following description and illustration of that concern's file-testing machine, which was invented in 1905. This machine was designed to give a perfectly reliable mechanical test of hand files and an autographic record of the results produced by each file tested. The machine has revealed an extraordinary difference of quality in files, some files being worn out after filing away less than 1 cubic inch of iron and cutting at the rate of only 1 cubic inch per 10,000 strokes, while the best files (size not given) remove 12½ cubic inches of metal and cut at the rate of 5 cubic inches per 10,000 strokes.

The publication of these results a year or so ago created a sensation in the English file trade, and a public file-testing department was established, and the testing machines were supplied to a number of file makers. The surprising and perhaps, in some cases, painful results obtained by these testing machines at once stimulated file makers to improve their product, and the result has been a general improvement of English files.

The extent of the improvement will be noted from the diagram Fig. 1, being the record of the files tested since the intro-

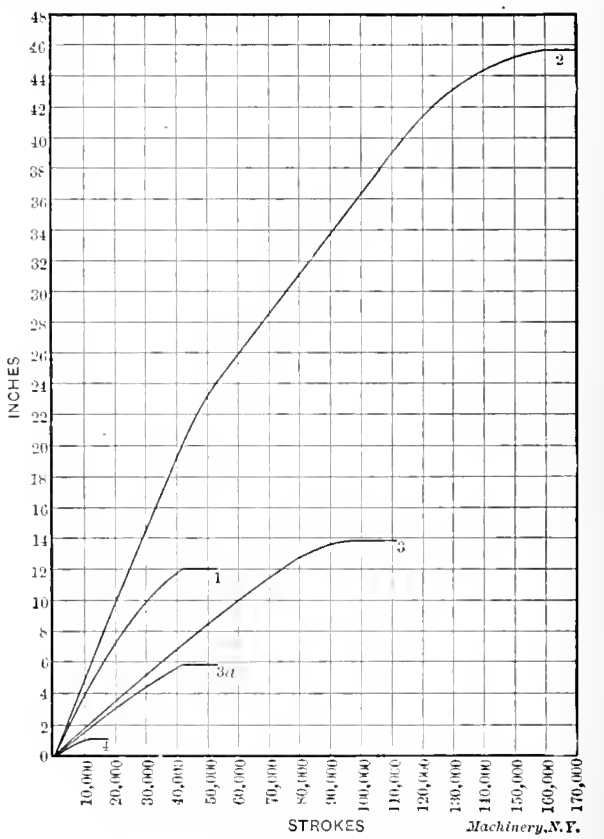

Fig. 1. Records made by File-testing Machine, showing Comparative Life and Cutting Power of Good and Bad Files.

duction of the file-testing machine. Curve 2 indicates that over 45 cubic inches of iron were removed and 160,000 strokes were made before the file ceased to cut. Still better results have been obtained since this sheet was published, files now being made which cut at the rate of 8 cubic inches per 10,000 strokes, and as much as 55 cubic inches have been removed by one side of a single file. Thus, the file-testing machine is directly responsible for an increase of efficiency of very nearly ninefold in the best files, and the end is not yet.

Fig. 2 shows the general construction of the machine. It automatically tests files of any size from 4 to 16 inches and draws a diagram, at the same time indicating the work done in cubic inches. The sharpness of the file is shown by the rate of cutting, and the durability, by the number of strokes taken before the file ceases to cut.

The file A to be tested is held between two head-stocks B B_1, on a reciprocating table C. Head-stock B is provided with a nut and a hollow squared screw D for holding the tang of the

file and exerting end pressure. Head-stock B_1 has a slide and a hand-wheel E, whereby the file may be adjusted with its working face parallel to its direction of motion.

The reciprocating motion of the table is obtained from the pulley and main shaft through a pair of bevel wheels, driving a T-slotted crank disk. A crank-pin, whose position in the T-slot can be varied according to the stroke required, carries a slide block of rectangular form, which slides between two vertical bearing surfaces in an extension of the table C, and serves to drive the latter to-and-fro. The driving mechanism is inside the box frame of the machine and entirely protected from the filings. The machine is started and stopped by a clutch operated by a handle F.

The test bar G is supported in a horizontal position on grooved rollers, and is pressed against the file by a weight H and a chain passing over a pulley and under the bar, to the

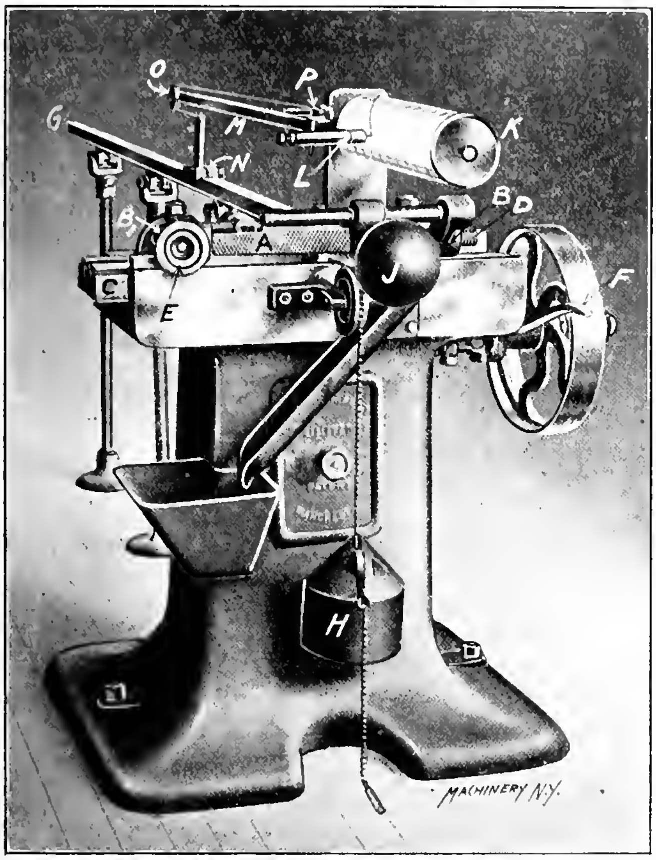

Fig. 2. File-teeting Machine built by Edward G. Herbert, Ltd.

far end of which the chain is attached. The support rollers are grooved to accommodate the chain. The bar is drawn out of contact with the file during the back stroke of the latter, by means of a clutch lever having two hardened jaws embracing the test bar. At the commencement of the back stroke, motion is communicated from a cam on the crank shaft to the outward end of the clutch lever, causing it to tilt and grip the test bar after the manner of a spanner. A slight continuation of the same motion causes it to draw back the test bar, which is again released at the commencement of the forward or cutting stroke. A spherical weight J with a screwed stem, is supported by the head-stock B, and, of course, reciprocates with the file. The end of the stem rests against the back of the file, and the inertia of the weight prevents the chattering and jarring of the file which would otherwise take place. The drum K, round which is wrapped the diagram sheet of squared paper, is driven from a cam on the crank shaft through a pawl and ratchet wheel and a train of reducing gears, so as to make one revolution to 120,000 strokes of the file. A pencil L is pressed against the paper by a light spring, and is carried on a bar M, capable of sliding longitudinally in a fixed bearing. A block N is attached to the test bar, and a fusee chain is attached to this block, and, passing over a pulley O on the pencil bar, is held by a fixed terminal P. It is evident that as the test bar is filed away it is moved forward by the weight H, and a given movement of the test bar causes the pencil to move forward by half that amount. The diagram sheet is graduated in half inches, each of which represents one inch filed off the test bar. The circumference of the drum is 12 inches, and as it revolves under the pencil each inch represents 10,000 strokes of the file. At the commencement of a test, the pencil is set to zero, and, as the drum revolves and the test bar is filed away, a curve is drawn by the compound motion of the drum and pencil. This curve is a complete picture of the life of the file from the commencement of the test until the file is worn out and ceases to cut, the slope of the curve indicating the sharpness or rate of cutting, while the vertical and horizontal ordinates give, respectively, the total amount of work done by the file, and the number of strokes required to do this work and to wear the file out. For example, in Fig. 1, curve 2 shows that the maximum rate of cutting was during the first 15 inches. The efficiency slowly decreased up to 42 cubic inches, when it dropped off rapidly. Cessation of cutting took place at the beginning of the short horizontal line.

On the same diagram, curve 1 was made from a file of good average quality, as usually supplied by the same makers. It cut quickly, but soon wore out, showing that it had sharp teeth, but it was made of poor steel. Curve 3 and 3*a* were made from the two sides of another file. The durability was fair, but the rate of cutting was slow. These diagrams indicate that the file was made of good steel, but had poorly shaped teeth. These diagrams are also interesting in showing the great difference that may exist between two sides of a carelessly made file. Curve 4 was made with a very bad file. It was practically worn out after having removed 1 cubic inch of metal, and 10,000 strokes were required to remove even this small amount.

* * *

DESIGN OF LIGHT STRUCTURAL JIB CRANES.*

W. H. BUTZ.†

In this article, the method of computing the stresses in the various members of the crane in Fig. 1 will be taken up in their proper order. This type of crane is commonly styled

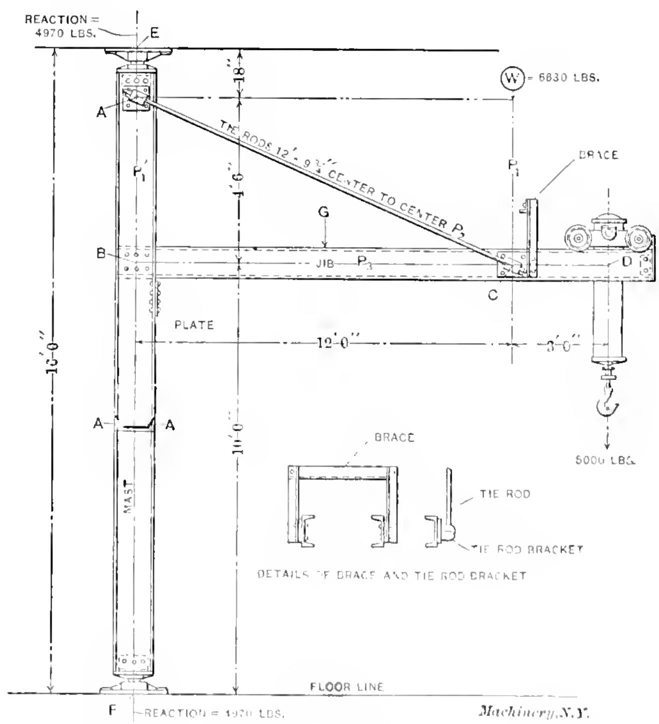

Fig. 1. Outline of the Crane of which Members are to be Calculated.

a jib crane; the radial arm being the jib, and the vertical arm the mast. The tie rods are the adjustable type, the nuts on the end allowing for accurate leveling of the jib when installing crane. A straight lift pneumatic hoist is shown, being the type most familiar to the writer. Assuming the capacity of the hoist as 4,500 pounds, and weight of hoist

* For additional information on cranes and kindred subjects see MACHINERY, November, 1907: Power Required for Cranes and Hoists, and other articles referred to in connection with the article in that issue.

† Address: 27 Clinton Ave., Plainfield, N. J.

and carriage as 500 pounds, the total load on the crane will be 5,000 pounds.

Stresses in Jib and Tie Rods.

To arrive at the stresses or loads in the jib and tie rods, the parallelogram of forces is required, see Fig. 2. Draw P_1 to some scale representing the weight of the load, P_2 parallel to the center line of the tie rods, P_3 parallel to the jib, and complete the parallelogram as determined by length of P_1. Now the forces in P_2 and P_3 will be proportional to P_1, when measured to the same scale.

Let W = load,
S_t = tensile stress in the tie rods,
S_c = compressive stress in the jib.

Then we have:

$$S_t = \frac{W P_2}{P_1} \qquad (1)$$

$$S_c = \frac{W P_3}{P_1} \qquad (2)$$

From this it will be seen that the stresses in jib and tie rods are proportional to their length (figured, of course, on the center lines) and the writer would like to say, before going any further, that he has found it the quicker way to use the actual lengths of same in the formulas, making P_1 in Fig. 2 = to distance $A\,B$ on the mast in Fig. 1. All three dimensions (P_1, P_2 and P_3) have to be figured in working up the crane, and after that the slide rule simplifies matters.

Bending Moments and Stresses in Jib.

The first step is to get at the size and weight of beam to use in the jib, as this will add some to the pull exerted in the tie rods by the actual load. It will be seen that $C\,D$ in Fig. 1 equals one-fourth of $B\,C$. This is the most economical location for the tie rod supports, as a glance at the formulas

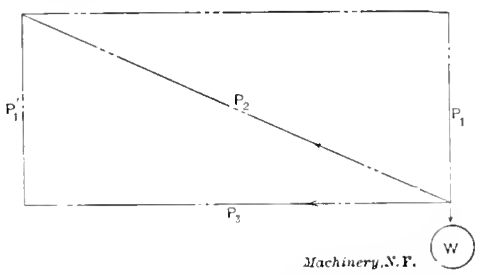

Fig. 2. Force Diagram for the Mast, Jib and Tie Rods.

for bending moments will show. When the load is central between B and C, or at G, we have a beam supported at the ends, and a load in the middle. With the load at D, it is a cantilever, fixed at C, and the load at the end.

Let P = superimposed load (concentrated at one point),
W = total weight of beam,
l = length of beam in inches,
M = bending moment in inch-pounds.

Then for the beam supported at the ends,

$$M = \frac{Pl}{4} + \frac{Wl}{8} \qquad (3)$$

and for the cantilever

$$M = Pl + \frac{Wl}{2} \qquad (4)$$

From this it will be seen that M in a cantilever is four times as great as in a beam of the same length, and the bending moment in either case being proportional to the length of beam, to make the moments equal will require a cantilever one quarter the length of the beam.

When we figure the beam with the load at G, it is also of the proper strength for the load at D. Substituting in formula 3, and assuming that we will use a 10-inch channel, weighing 15 pounds to the foot (remembering that there are two of them), we have:

$$M = \frac{5{,}000 \times 144}{4} + \frac{360 \times 144}{8} = 186{,}480 \text{ inch-pounds.}$$

To get the stress per square inch in the extreme fibers of the beams, we have the formula

$$S = \frac{Mc}{I}. \qquad (5)$$

S = stress in extreme fiber.
M = bending moment in inch-pounds.
c = distance from neutral axis to extreme fiber, in inches.
I = moment of inertia of section, in inches (both beams).

$$S = \frac{186{,}480 \times 5}{66.9 \times 2} = 6{,}958 \text{ pounds per square inch, com-}$$

pression in the upper flange, and tension in the lower.

(NOTE.—The sizes and properties of standard structural shapes can be obtained from any of the steel companies' handbooks.)

In addition to this stress, there is a compressive stress due to the thrust back in the jib. With the load at G, one-half of it, or 2,500 pounds, is supported by the tie rods, together with one-half the weight of the beams between B and C, or 180 pounds, and about 200 pounds additional for the parts outside of C, making a total of 2,880 pounds. Substituting in formula (2), we have:

$$S_c = \frac{2880 \times 144}{54} = 7680 \text{ pounds.}$$

Dividing this by the sectional area of both beams, we have:

$$\frac{7{,}680}{4.46 \times 2} = 861 \text{ pounds per square inch.}$$

Adding this to our stress due to bending moment, we have $6{,}958 + 861 = 7{,}819$ pounds per square inch compressive stress in the upper flange; and deducting $6{,}958 - 861 = 6{,}097$ pounds per square inch tensile stress in the lower flange.

Taking up the allowable stresses in the beam, as compared with stresses obtained above, we find from the handbooks that 12,500 pounds per square inch is the proper working stress (for moving loads) in structural shapes used as beams.

But, we now have to consider an extremely important point. The upper flange is in compression, which makes the same conditions hold as in a column. The longer the column, the lower the allowable working stress, on account of the tendency to buckle in the center, and unless the top flange of our beam can be supported from buckling sideways, the proper reduction must be made to meet this.

Let p = allowable stress in pounds per square inch,
l = length between lateral supports, in inches,
b = width of flange, in inches,

$$p = \frac{18{,}000}{1 + \dfrac{l^2}{3{,}000 b^2}} = \frac{18{,}000}{1 + \dfrac{144^2}{3{,}000 \times 2.6^2}} \qquad (6)$$

$$= 8{,}880 \text{ pounds per square inch.}$$

The allowable stress is 8,880 pounds, and the actual stress is 7,819 pounds, which gives a good margin and insures a stiff crane.

If a 9-inch 13¼-pound channel is looked into, the stress, as calculated from formula 5 (even disregarding the back thrust), will be 8,850 pounds per square inch, while the allowable stress, calculated from formula 6, is only 8,200 pounds, showing that the 10-inch channel is the proper one to use.

The vertical load at C, Fig. 1, with the hoist at D, will be proportional to the lever arms $B\,D$ and $B\,C$.

$$\frac{5{,}000 \times B\,D}{B\,C} = \frac{5{,}000 \times 15}{12} = 6{,}250 \text{ pounds.}$$

Add to this half the weight of beams between B and C, equals 180 pounds, and 200 pounds for structure outside of C, and the total vertical load at $C = 6{,}630$ pounds.

Still another condition to consider is with the load at D. This makes the jib virtually a beam with an upward load at B and downward at C and D, with the added complication of a compressive stress applied at C due to the thrust from the tie rod. Perhaps the best way to calculate the stresses in the part in question, however, will be to consider $C\,B$ as a cantilever fixed at C with the load at D. We may then find the maximum compressive stress due to the flexure at C, and add to it the compressive stresses due to the thrust of the tie rods. Adding together the bending moment due to the 5,000 pounds load, and that due to the weight of the channels and other parts to the right of C, we have

$$M = (5{,}000 \times 36) + (200 \times 18) = 183{,}600 \text{ inch-pounds.}$$

To find the stress per square inch in the extreme fibers of the beams, use formula (5),

$$S = \frac{183{,}600 \times 5}{66.9 \times 2} = 6{,}860 \text{ pounds per square inch.}$$

To this, as before mentioned, we have to add the unit compressive stresses to the thrust on the jib. The total compression is found from formula 2.

$$S_c = \frac{6{,}630 \times 12}{4.5} = 17{,}680 \text{ pounds.}$$

Dividing this thrust by the combined area of the two channels to find the unit compressive stress, we have

$$\frac{17{,}680}{2 \times 4.46} = 1{,}980 \text{ pounds.}$$

The maximum compressive stress immediately to the left of point C is then

$$6{,}860 + 1{,}980 = 8{,}840 \text{ pounds per square inch.}$$

As in the previous case, with the load half-way between B and C, we should examine this condition for safety of the beams as regards failure by buckling. Considering the unstayed length as being that between B and C, as before, we have the same maximum permissible stress of 8,880 pounds per square inch, as given, then, by formula No. 6. It will be seen that our result falls just short of this maximum amount, so we may consider the channels as properly selected.

[In this second case, with the load at D, we would not feel safe in considering the length of the beam as that between B and C when applying formula (6), unless the construction of the brace at C is made differently from that shown, in which case it is possible for the girder to buckle by spreading sidewise at the point where the brace is attached. We would suggest that a cross lattice, or a wide plate, with three or four rivets in each side, be used to connect the two angle uprights shown, rather than to use the single cross angle section with the single riveting, as called for by the sketch.—Editor.]

Size of Tie Rods.

The tie rods must be proportioned to stand the load at D, which is the worst condition. As already figured, the vertical load at $C = 6{,}630$ pounds (with hoist at D).

Substituting in formula (1):

$$S_t = \frac{6{,}630 \times 153.75}{54} = 18{,}875 \text{ pounds.}$$

$$\frac{18{,}875}{2} = 9{,}438 \text{ pounds pull on one rod.}$$

Allowing 10,000 per square inch as a safe working stress,

$$\frac{9{,}438}{10{,}000} = 0.944 \text{ square inches area required at the root of}$$

the thread, giving a 1⅜-inch rod, having an area of 1.053 square inch. A 1¼-inch rod would not be strong enough, having an area at the root of thread of only 0.889 square inch.

Tie Rod Brackets.

These are merely a matter of good design, only making sure that there is sufficient metal to take care of the shearing stress. The rivets for holding the brackets in place must be figured for shear, and for bearing pressure in the channel. We need not discuss the shear, and the safe bearing pressure on rivets in structural work is taken as 20,000 pounds per square inch of projected area in the rivet holes.

One more word with regard to placing the tie-rod brackets at C. The pull of the rods at one side will have a tendency to twist the beams, unless an overhead brace is used as shown. If conditions will not allow this brace, then the rods should be carried very close to the end of the jib.

Stresses in Mast.

This can be arrived at in two ways. Consider the mast as a beam fixed at A, supported at F, and the load at B equal to the greatest back thrust of the jib. A rather complex formula is required for this, and the much simpler method is to figure the reactions on the top and bottom supports, and consider the bottom reaction as a load at the end of a cantilever, fixed at B, and equal to BF in length. The ratio of the reaction on supports to the load at C is proportional to lever arms BC and EF.

$$\frac{6{,}630 \times BC}{EF} = \frac{6{,}630 \times 12}{16} = 4{,}970 \text{ pounds reaction.}$$

M = bending moment in inch-pounds.
P = load = reaction on bearing.
l = length of cantilever in inches = BF.
$M = Pl = 4{,}970 \times 120 = 596{,}400$ inch-pounds.

Substituting in formula 5, and using two 15-inch 33-pound channels, we have:

$$S = \frac{596{,}400 \times 7.5}{312.6 \times 2} = 7{,}155 \text{ pounds per square inch.}$$

The stress for vertical load will add a few hundred pounds to this, but need not be considered in this case, as we have a considerable margin, and the plate shown underneath the jib will prevent side buckling of the compression flange, so that we can figure on the full working stress of 12,500 pounds per square inch. If the stress were very near the limit, then this point would have to be taken up more thoroughly.

A 12-inch channel, 20½ pounds, gives a fiber stress of 14,000, which is too high. A 12-inch channel, 35 pounds, gives only 10,000 per square inch, which would be strong enough, but would not be as economical or as stiff as the 15-inch 33-pound beam, weighing, as it does, 2 pounds more to the foot.

With the hoist at the extreme back of jib, the mast should be considered as a column from B to F. Using formula,

$$P = \frac{50{,}000}{1 + \dfrac{(12L)^2}{24{,}000r^2}},$$

in which

P = ultimate strength, in pounds per square inch.
L = length of column, in feet.
r = least radius of gyration in inches, or about axis AA, in Fig. 1.

We have

$$P = \frac{50{,}000}{1 + \dfrac{(12 \times 10)^2}{24{,}000 \times 0.91^2}} = \frac{50{,}000 \times 19{,}850}{34{,}250} = 29{,}000 \text{ pounds}$$

per square inch, ultimate strength.

Using a safety factor of five for moving loads.

$$\frac{29{,}000}{5} = 5{,}800 \text{ pounds per square inch, safe stress.}$$

Figuring approximately, the load with the hoist at the back is 5,000 pounds, half the weight of jib channels between B and C equals 180 pounds, and the weight of mast parts above B equals 500 pounds, giving a total of 5,680 pounds.

It will be seen from the above that the allowable stress per square inch is greater than the total load on both channels, so that this stress can be ignored entirely in this case, and as a rule, when the mast has been figured for the bending moment, with the load at D, it will be perfectly safe with the load at the back of jib.

Top and Bottom Bearings.

These should be designed with pins amply large to give low bearing pressures, and to take care of shear and bending moments due to the reaction. The bottom plate ought to be large enough to spread the weight over a fairly large area of the foundation. These last points, however, need not be considered here, as this article is intended chiefly to cover the design of the structural portions of the crane.

* * *

Wood Craft calls attention to an important point that is sometimes overlooked by designers who make use of soft rubber as a material for springs. Everyone is familiar with the elasticity of soft rubber. An unconstrained piece of this material, however, acts altogether differently from what it does when it is prevented from changing its shape. Enclosed in a rigid cylinder with an easy fitting cover, it resists pressure solidly and fully, but when free of the cover and allowed to change its form, then it increases in girth exactly as it shortens in length. More than one failure of a rubber spring to do its destined duty has been due to sheer oversight on the part of the machine designer in not giving room for this expansion.

DERIVATION OF THE CROSS-ROLL CURVE.*

ULRICH PETERS.†

The writer offers in the following a practical solution of the mathematical problem known as "the cross-roll curve." This curve is similar to the hyperbola, the curve generating the hyperboloid, but is not the same curve. The cross-roll machine is extensively used for removing the scale on the surface of pipes and round shafts, thereby smoothing, rounding, and to a great extent straightening the work. The angle of the cross-rolls gives rotative and longitudinal motion at the same time to a tube while it is going between the rolls of the machine. The construction of these machines is usually such that on smaller machines there is one cross-roll above and one below, while on larger machines, the cross-rolls are arranged one on each side of the pass. For shaft-

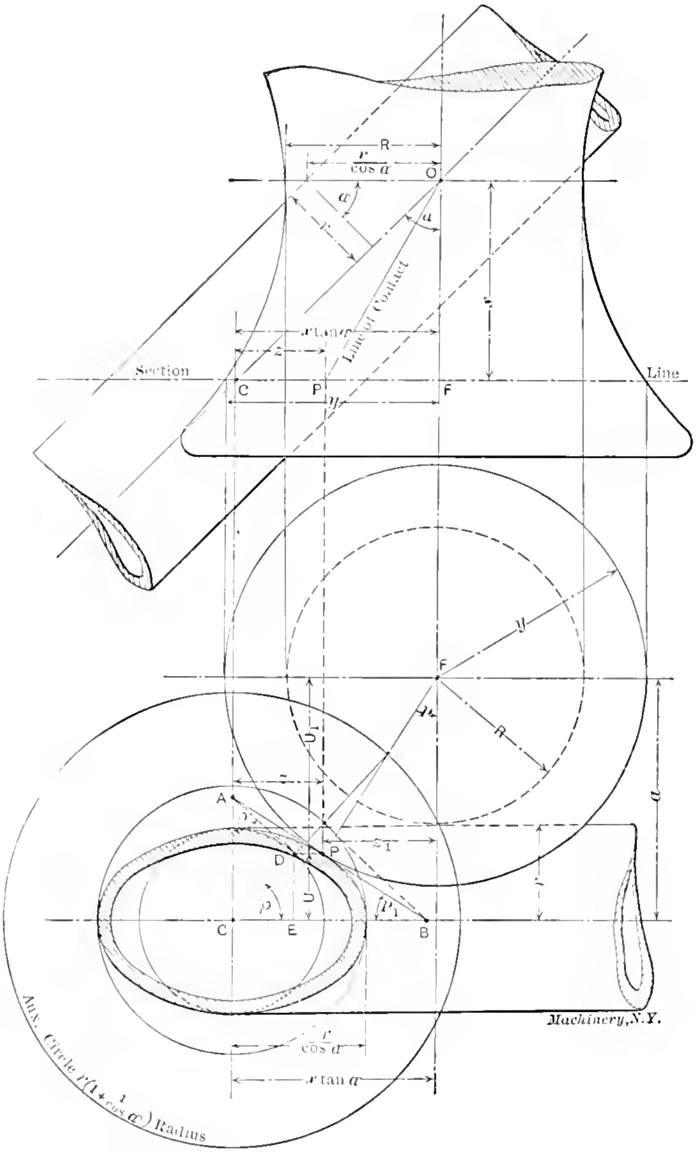

Diagram of Cross-roll Problem.

ing, the best straightening effect is obtained with only one cross-roll working opposite a cylindrical roll, the latter being parallel to the press. The turning of these cross-rolls in the lathe requires considerable skill. The simplest way is to form them to a templet. Of course the work is very much simpler if in connection with this templet an automatic forming lathe attachment is used. The formulas I and II given in the following may be used for determining the true profile of the templet or former.

Let the projected angle of rolls axis on the pipe axis $= \alpha$; the parallel distance of roll axis to billet or pipe axis $= a$ (constant); the middle radius of the cross-roll $= R$; and the outer radius or billet or pipe $= r$.

A section at right angles to the axis of the cross-roll at any distance x from the middle O of the roll (the starting point) will intersect the pipe at an angle. This section when projected, as shown in the lower figure, will show the section of the cross-roll as a true circle of the unknown radius y, and the billet or pipe as an ellipse with half of minor axis $=$ r, and the major axis $= \dfrac{r}{\cos\alpha}$. Both curves touch at a point P where the tangent AB is common to the circle of the cross-roll and at the same time to the ellipse of the pipe, so that $\tan p = \tan p_1$.

By introducing further z, U and z_1, U_1, for abscissæ and ordinates in the ellipse and the circle, respectively, we have according to analysis for the ellipse and circle:

$$z^2\cos^2\alpha + U^2 = r^2 \quad (1) \qquad z_1^2 + U_1^2 = y^2 \quad (2)$$

In the cut it is apparent that $R + r = a$ (3)

$$U + U_1 = a \quad (4) \qquad z + z_1 = x\tan\alpha \quad (5)$$

We also have $\tan p = \tan p_1$, or $\dfrac{z_1}{U_1} = \dfrac{CA}{CB}$, wherein

$$CA = \frac{r}{\sin\beta}, \text{ and } CB = \frac{r}{\cos\alpha\cos\beta}. \text{ Therefore}$$

$$\frac{CA}{CB} = \tan p_1 = \frac{r}{\sin\beta} \times \frac{\cos\alpha\cos\beta}{r} = \cot\beta\cos\alpha.$$

$$\text{Herein } \cot\beta = \frac{CE}{DE} = \frac{\sqrt{r^2 - U^2}}{U}$$

and writing for $\sqrt{r^2 - U^2} = z\cos\alpha$ (taken from formula 1), it follows that for $\tan p = \tan p_1$, can be substituted the following:

$$\frac{z_1}{U_1} = \frac{z}{U}\cos^2\alpha \quad (6)$$

By substituting for $z_1 = \dfrac{U_1 z}{U}\cos^2\alpha$ (from 6) in (2) and (5):

$$y^2 = \left(\frac{U_1 z}{U}\cos^2\alpha\right)^2 + U_1^2 = U_1^2\left(1 + \frac{z^2}{U^2}\cos^4\alpha\right) \quad (2a)$$

$$x\tan\alpha = z + \frac{U_1 z}{U}\cos^2\alpha = z\left(1 + \frac{U_1}{U}\cos^2\alpha\right) \quad (5a)$$

By substituting for $U^2 = r^2 - z^2\cos^2\alpha$, or $U = \sqrt{r^2 - z^2\cos^2\alpha}$ (from equation 1) into (4), (2a) and (5a):

$$a = \sqrt{r^2 - z^2\cos^2\alpha} + U_1 \quad (4a)$$

$$y^2 = U_1^2\left(1 + \frac{z^2\cos^4\alpha}{r^2 - z^2\cos^2\alpha}\right) \quad (2b)$$

$$x\tan\alpha = z\left(1 + \frac{U_1\cos^2\alpha}{\sqrt{r^2 - z^2\cos^2\alpha}}\right) \quad (5b)$$

Finally, substituting from (4a) for $U_1 = a - \sqrt{r^2 - z^2\cos^2\alpha}$ into formulas (2b) and (5b), we obtain:

$$y = \left(a - \sqrt{r^2 - z^2\cos^2\alpha}\right)\sqrt{1 + \frac{z^2\cos^4\alpha}{r^2 - z^2\cos^2\alpha}} \text{ and} \quad (I)$$

$$x = z\cot\alpha\left(\frac{a\cos^2\alpha}{\sqrt{r^2 - z^2\cos^2\alpha}} + \sin^2\alpha\right) \quad (II)$$

Combining formulas (I) and (II) to eliminate the unknown z produces a formula too voluminous for practical application. To solve a given example, it is much better to assume here, by steps, numerical values for z as 0.1, 0.2, etc., inside the limits O and r, and determine the appertaining y and x from above double equations (I) and (II). In this way the cross-roll may be readily plotted and determined.

Mr. Victor Beutner, consulting engineer, Pittsburg, Pa., read a paper before the Engineers' Society of Western Pennsylvania, December 15, 1903, giving a formula:

$$y = \sqrt{x^2\tan^2\alpha + a^2}\left(1 - \frac{r}{\sqrt{x^2\sin^2\alpha + a^2}}\right)$$

which was derived by his assistant, Mr. Edward Hoefer. This formula is not exact and is only approximately correct; in his derivation, the point of contact is incorrectly assumed on the straight line joining C with F, instead of at point P shown in the diagram. Of course the difference would be small for the ordinary cross-roll problem, not exceeding 3/100 inch on the radius y for cross-rolls with small angles of about 5 to 15 degrees.

SHOP PHOTOGRAPHY.*

CARL S. DOW.†

Carl S. Dow.‡

It is customary for a book to have a preface in which the author states his reasons for adding another publication to an already overcrowded supply in that field, or "makes no apology" for bringing it out. A magazine article seldom has a preface, but there is usually just as good a reason for its appearance. What prompted this article was the editorial in the September issue, in which the editors solicited good photographs for illustrations, and deplored the difficulty of obtaining what they want, namely, sharp "contrasty" photographs that make good half-tone plates.

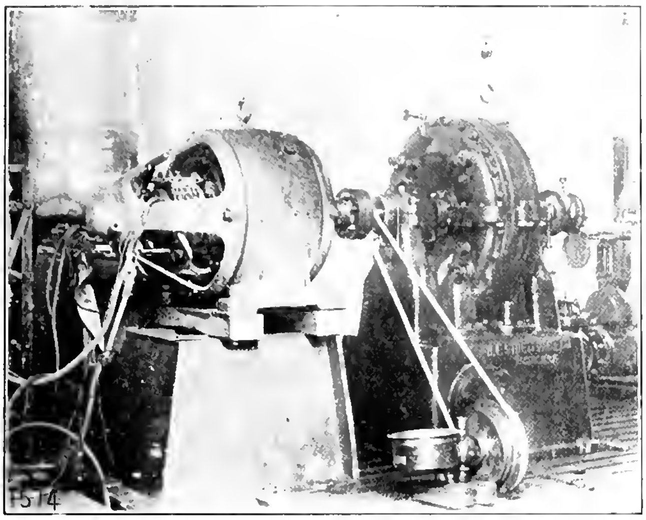

Fig. 1. Photographs taken before Apparatus was Complete. Note the Temporary Base.

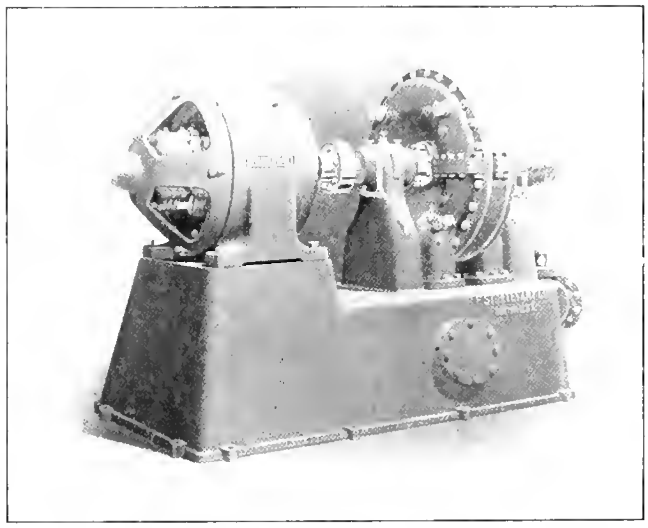

Fig. 1A A Small Generating Set retouched from Fig. 1. An Expensive though Necessary Picture.

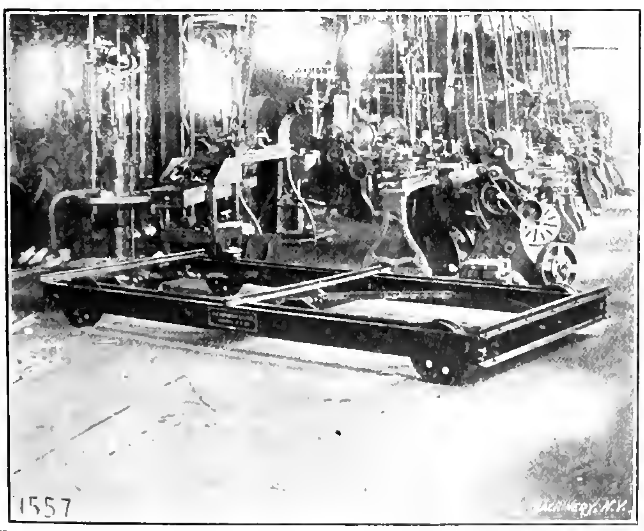

Fig. 2. Lumber Truck photographed without a Background Screen. The Small Stop used brought all Machines into Good Focus.

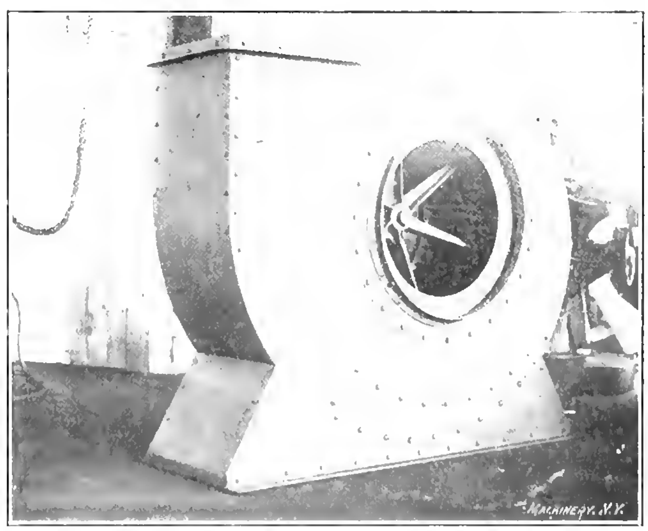

Fig. 3 A Photograph calling for an Opaque Background Screen to prevent Halation from the Windows, and to shut out Surrounding Objects. Otherwise a Good Picture.

It is not for this article to extol the value of photographs as illustrative material, or to tell of the potent influence of good photographs in advertising; but rather to touch upon some of the essential steps in the production of machinery photographs suitable for half toning.

Practically all photographs for technical illustration are made in the shop; this is especially true of large apparatus or machinery in operation, since in the very nature of things, they cannot be taken to a studio. Small parts, gages, valves, and tools, of course, can be moved into good light without difficulty. The three factors which make satisfactory shop photographs of large machines difficult, and necessitate expensive retouching before engraving, are poor light, crowded condition of the shop, and the unpainted or possibly incomplete state of the machine or apparatus.

Poor light cannot be remedied easily, but the manipulation of backgrounds and screens is often an improvement, and flash powders are frequently of service, especially if certain parts are in deep shadow while the major part of the machine is fairly well lighted. Even if a very long exposure is necessary, natural light is usually preferred to a flash-light. A crowded shop makes it necessary to include other machinery and unfinished material, or perhaps renders the best view impossible. When the shop is so crowded that the photograph cannot be taken from a position that will best bring out the desired parts, or if the machine cannot be moved, the

[The photographs used to illustrate this article were reproduced without retouching or change of any kind save in those cases where otherwise stated. This was done to show clearly the points made by the author, but, incidentally, the unretouched views also give the reader a hint of the work ordinarily put on almost all our half tone cuts. Most of the photographs were better than those generally submitted, yet the cuts will not compare well with the average of half tone illustrations used in MACHINERY. We find it necessary to put some retouching on almost all photographs of machinery, shop interiors and similar subjects. If the hints given by Mr. Dow were generally observed the amount of this work would be much reduced and the cuts would gain in snappiness and strength, for a perfect photograph cannot be successfully imitated by the retoucher, although he may be able to greatly improve a poor one. EDITOR.]

* For previous articles on shop photography see "Shop Photography," by H. P. Fairfield, November, 1906, and "Photographs for Illustration," September, 1907.

† Address: B. F. Sturtevant Co., Hyde Park, Mass.

‡ Carl S. Dow was born at Woburn, Mass., in 1874. He graduated from the engineering department, Harvard University, in 1897, with the degree of S. B. From 1898 to 1905 he was in charge of the text book department and instruction of the American School of Correspondence at Armour Institute, Chicago, and since up to July, 1907, was in the publicity department of the B. F. Sturtevant Co. He is now advertising manager of that company. Mr. Dow has specialized on engineering publicity and technical editorial work. He has contributed considerably to the engineering press and was editor-in-chief of two volumes on shop work and of three volumes on practical engineering published by a Philadelphia concern.

making of the negative should be postponed until shipment is made, at which time a better position or light can usually be obtained without much trouble. Obviously a machine should not be photographed until completed and painted, otherwise much expense is necessary for retouching; but of course the negative may be necessary before such state of completion is attained. Speaking of paint—it should always be dull finish, and red, black, or slate color will give good results.

Background Screens.

The probable use for the picture should be known to the artist at the outset. If for a catalogue cut or advertising

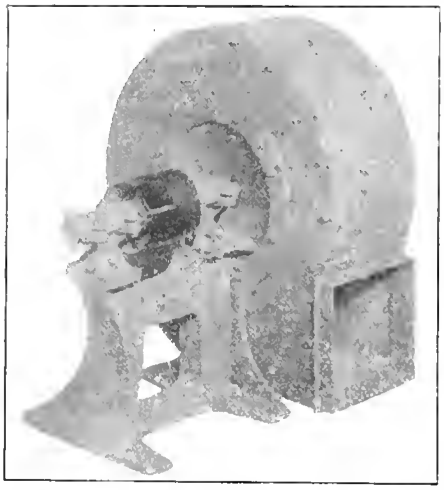

Fig. 4. Made with a Long Focus Lens which was much too High. The Shaft is not Horizontal, the Top and Outlet are Distorted and the Perspective is not Good.

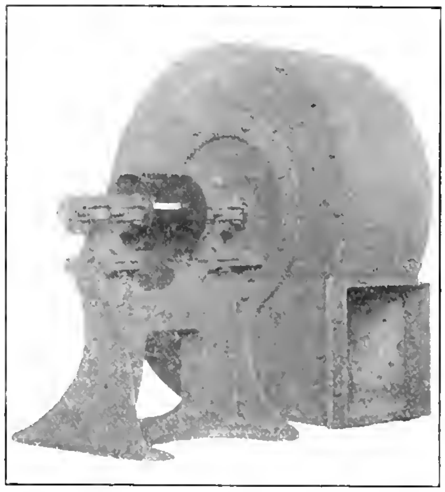

Fig. 4A. Made with Long Focus Lens, with Camera placed at Proper Height. Note the Rectanguler Outlet and General Appearance of Good Proportion without Distortion.

illustration, the irrelevant machines or material surrounding the object must be obliterated after the negative is made; this is usually done by "painting out" with opaque water color. If the machine has many small parts on the profile, it is often difficult to separate them from the surroundings when painting out. For such conditions a white background

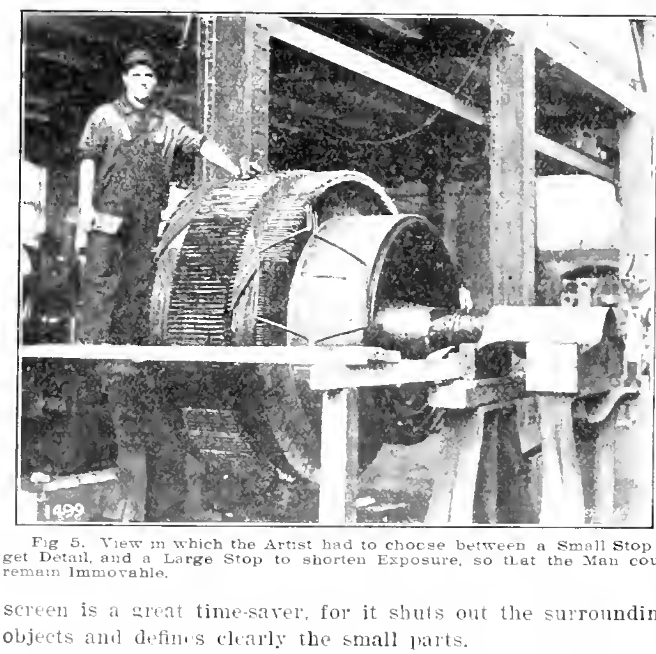

Fig. 5. View in which the Artist had to choose between a Small Stop to get Detail, and a Large Stop to shorten Exposure, so that the Man could remain Immovable.

screen is a great time-saver, for it shuts out the surrounding objects and defines clearly the small parts.

The background screen serves still another purpose. In many shop pictures the desired view necessitates the directing of the camera toward a window, which causes halation around the contour of the machine. An opaque screen will shut off this light which is not only of no assistance in making the photograph but is detrimental. If the background screen is too small to cover the entire machine, it should be placed behind the smallest parts which are the most difficult to paint out. In case no screen is available, the machine should be separated as much as possible from the other apparatus, or placed at some distance in front of it so that the machine only will be in sharp focus. With the light near the floor of less intensity than at a few feet above, white cloth or paper arranged about the bed or frame throws the light upward and brightens up the parts in shadow; it also makes the lower parts more clearly defined.

Position.

In shop photography the features to be brought out are usually those relative to details of construction, or those strongest in selling. The choice of position is one that must sometimes be studied. Shifting the camera a few inches often causes an important detail to become prominent, or, on the other hand, unduly exaggerates a minor or objectionable construction. The writer once had occasion to photograph a blower driven direct-connected by a motor which was large because the air pressure was to be high. Now a good light was easily obtained with the camera in a position that brought the motor into the foreground, but evidently it was not wise to show that the blower required such a large motor because the conditions of pressure might not always be given in connection with the picture. To overcome this, the set was swung around by the electric crane so that the blower came into the foreground, causing the motor to be subordinate to it.

The height of the lens is a point not usually considered with sufficient care, and yet is an important factor in the perspective. One has only to look at two pictures of the same machine to notice the difference. In general, it may

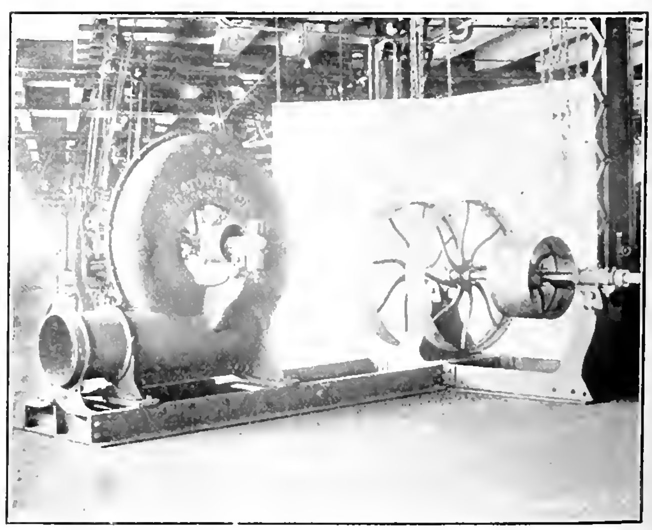

Fig. 6. Showing use of Background Screen too Small to extend over the Entire Apparatus

be said that the lens should be placed at about the middle of the height, and, if the machine has a horizontal shaft, the lens should be placed on that level. With the lens at or below the center, the machine looks large and substantial, which are often desirable features.

As to the lens itself, a long focus lens should be used, if

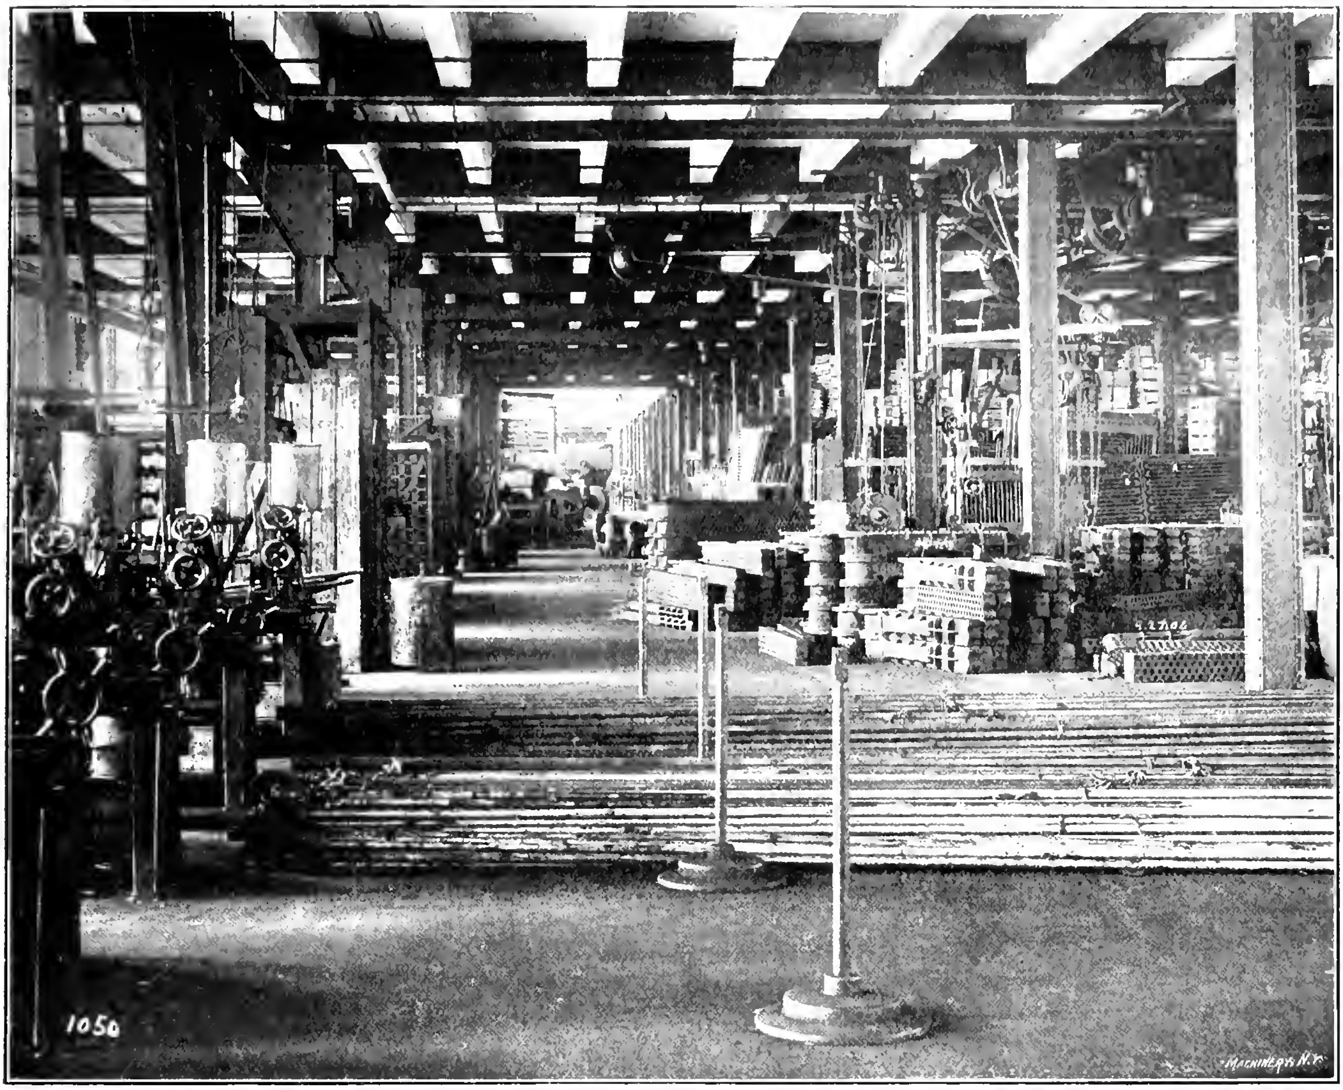

Fig. 7. Well-lighted Shop Interior. The Great Depth required a Small Stop to make all Details Sharp.

possible, when photographing machinery. A wide-angle lens is sure to distort the lines, and make those parts nearest the camera very large; its use should be restricted to cramped places in which it is impossible to get the entire apparatus on the ground glass with a long focus lens.

Focus.

No attempt to focus should be made until the best view has been selected and the camera placed in what is probably the correct position. Focussing is best done with full opening, so that when the opening is reduced the image will be very sharply defined. Curved surfaces are not easily focussed, hence a newspaper, printed sign, or calender, placed against the machine and brought into sharp focus, is a valuable aid. With the black letters in best focus the machine will be sharp.

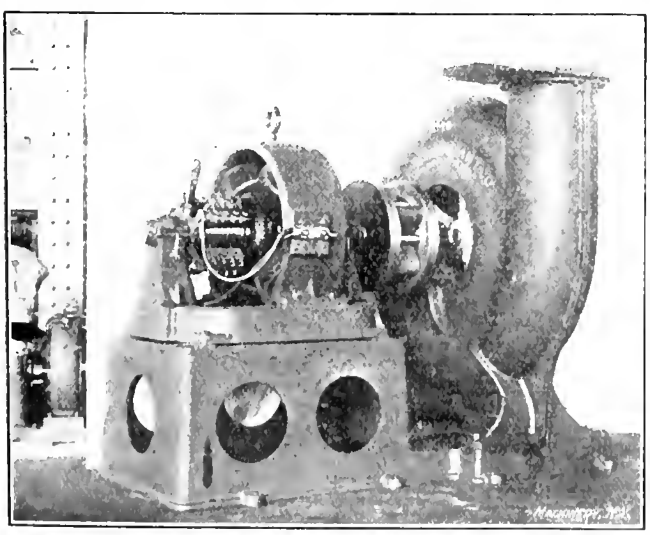

Fig. 8. Illustrating the Use of a Small Stop and Long Exposure. In a Well-lighted Shop about 30 feet from the Windows, at Noon, the Exposure was Seven Minutes, Seed 26 Plate, and F64 Stop

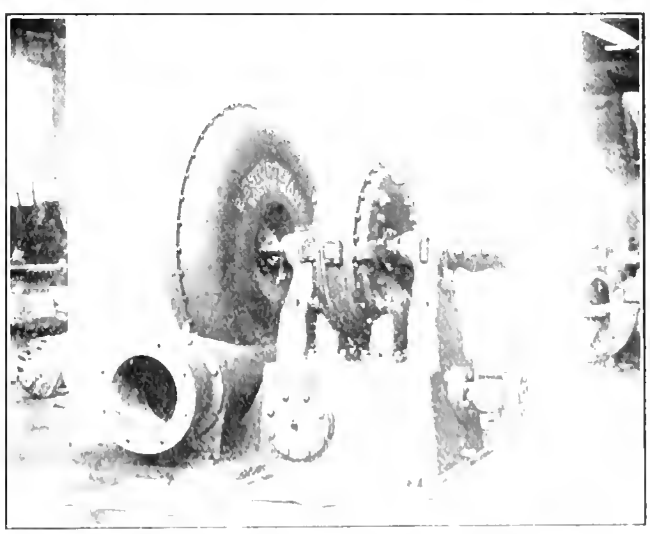

Fig. 9. Under Saw-tooth Roof at Noon, Exposure Seven Minutes, Cramer Banner X Plate, F.32 Stop

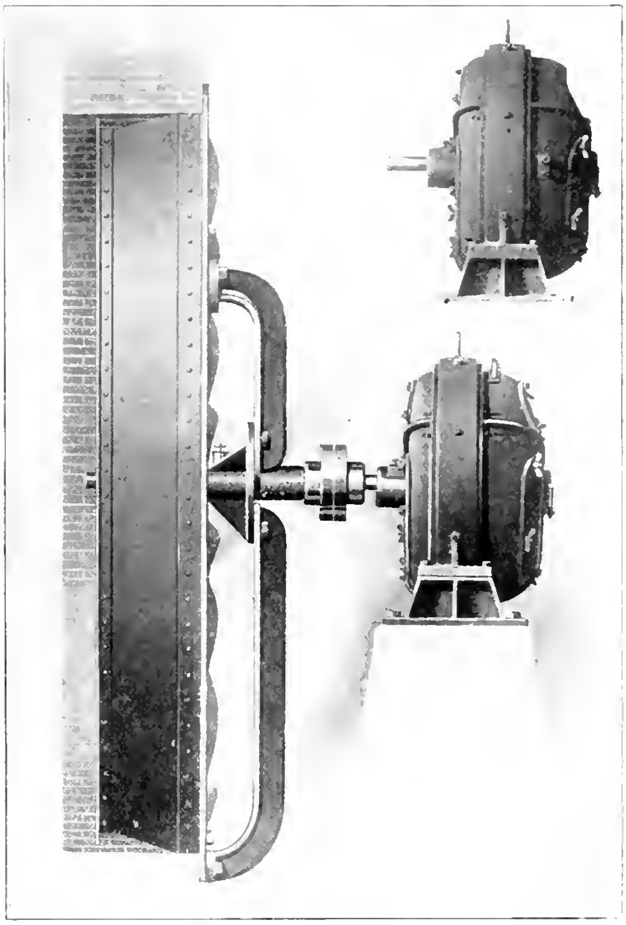
Stop.

The choice of stop, or opening, must be governed by several conditions, and here is a chance for one to use his judgment. A small stop requires a long exposure, gives a sharp picture, and brings all parts of the apparatus into focus. This last point should not be overlooked, if the distance from the camera to some points of the machine is far greater than to others. When all of the machine lies in the same plane a large stop will probably give as good a picture, and the exposure will be of much shorter duration. To get the detail

of small parts, such as the armature of a motor, a small stop is desirable. It sometimes happens that a small stop is out of the question, for a very long exposure (15 minutes to one-half hour) would prevent the men in the shop doing their work, or might delay passing to and from machines. In general, it may be said that the stop should be as small as conditions will allow.

Exposure.

The length of time the plate should be exposed is determined solely from experience and a knowledge of conditions.



Figs 10 and 10A. Photograph of Motor to be combined with Wash Drawing, and the Result. The Photograph of Motor was Retouched to make it blend with Drawing.

It is almost useless to give any figures, for the light varies, not only in different shops, but in the same shop, according to the season and time of day. The size of the stop and the speed of the plate are also controlling factors. Under-exposure is far more common than over-exposure. In a well-lighted shop at a distance of 10 to 20 feet from the windows, with a "Seed 26" or "Cramer Crown" plate, and a small stop, 3 to 8 minutes is usually required. The writer finds a moderate speed plate, such as a "Cramer Banner," very satisfactory, for it has considerable latitude, yet is not so slow as to consume an excessive amount of valuable time.

Exposure is a most important part of photography. The length of time may perhaps be easiest determined by comparing the existing conditions with those under which a satisfactory negative has been made. This determination of exposure is unconsciously followed by everyone. To make the comparison easy, the same size of opening and the same kind of plate should be used as much as possible.

A machine with few polished parts, and painted black, or the armature of a motor, requires a long exposure. When in a bright light, polished parts may show undesirable reflections, but the parts may be given a frosty appearance by dabbing them with putty, which can easily be wiped off with benzine or gasoline. Lettering, such as the maker's name, and the size of the machine, can be well brought out in a photograph by chalking just before exposure.

Developing.

The procedure of development, and the kind of developer to use for negatives made in the shop, are not different for negatives made elsewhere. Almost the only consideration is the printing quality. In any large manufacturing plant, the advertising or sales departments may make a rush call for a large number of prints from a certain negative. Unfavorable weather may render it impossible to get the prints off for several days. In plants of this kind, the developer should be so selected, and the depth to which the development is carried should be such, as to yield clear, quick-printing negatives. Over-exposure should be avoided.

Pyro is deservedly a favorite with many, because of the ease with which slight errors in exposure may be counteracted. But its liability to spoil, and cause stained or slow-printing negatives, has led some to discard it. Pyro developer will be preserved indefinitely by dissolving a small quantity of oxalic acid (10 grains to 16 ounces) in the water in which the pyro is to be dissolved. The oxalic acid should be dissolved before the pyro is added. All stains may be eliminated by using a little acetic acid in the hypo bath (1 ounce to 1 quart of water).

An intelligent manipulation of the developer requires experience and some knowledge of chemistry. Probably the most common difficulty is that of getting negatives with contrast, for the shadows often show too much detail where there should be practically clear glass. To print such negatives to sufficient depth to make these shadows strong, causes the high lights to become dimmed. If the exposure has been properly timed, the cause of excessive detail in the shadows is probably too much sulphite of soda (in pyro developer) or too much alkali. A reduction in the amount of alkali will almost invariably effect an improvement.

Printing and Paper.

The photographer may receive orders for prints of any one of three kinds—blue prints, silver prints, or developed prints. For general sales use, the blue print is widely used, for it is

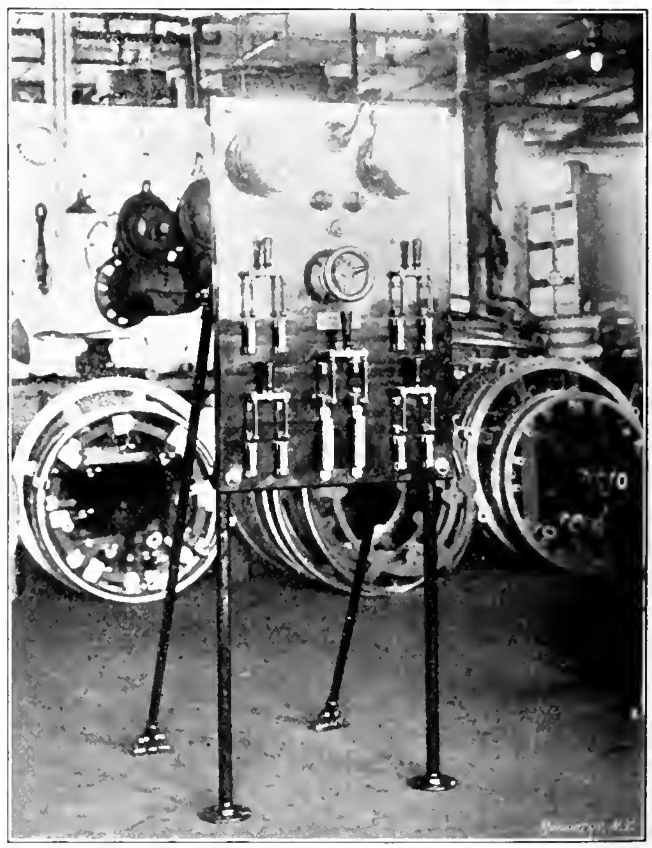


Fig 11. Carelessly-made Photograph. Intense Direct Light from Windows caused Over-exposure and Reflection at top of Switchboard. The Lower Part is Good. Windows should have been Curtained.

quickly made, inexpensive, can be folded without cracking, and is of a businesslike appearance. It is well to purchase the prepared stock in metal tubes; being of higher grade it will yield far better prints than the cheaper blue print paper used for making shop prints from tracings.

The silver print is by far the best for retouching and half-toning; it gives the detail and smooth surface necessary for these processes. When making a print for half-toning, it

should not be too dark in the shadows, and the tone should be of a good chocolate. A deep brown tone is superior to a blue or purple, which photograph lighter. Yellows and reds should be avoided. In mounting a print for retouching, the cardboard should be thick to prevent warping, and very smooth. The smoothest card possible is the only suitable board for mounting.

Machinery salesmen frequently want their prints mounted on cloth so that they will stand the wear and tear of constant use; the cloth also provides a means of binding. Cloth-mounted prints are often ferrotyped, that is given a glossy surface which adds to both appearance and durability. This finish is obtained as follows: The wet print is placed face down on the ferrotype plate, which has been made scrupulously clean and lubricated slightly with soap or glycerine. After removing all bubbles, the back of the print is covered with paste and the cloth pressed in contact with the print. When the print dries the corners will start from the ferrotype plate, from which it may easily be stripped when perfectly dry. It is then trimmed, the strip of cloth or binding being left on the proper edge. Velox or other gas-light prints, except with certain grades of paper, have too rough a surface for retouching. They are more "contrasty" than silver prints, and show less detail. For framing and for rush orders, they are very satisfactory for they can be turned out rapidly, even if the weather is cloudy, or if the short days of winter are at hand. A negative that is too thin, in other words, a "flat" negative, will yield a better print on a gas light paper.

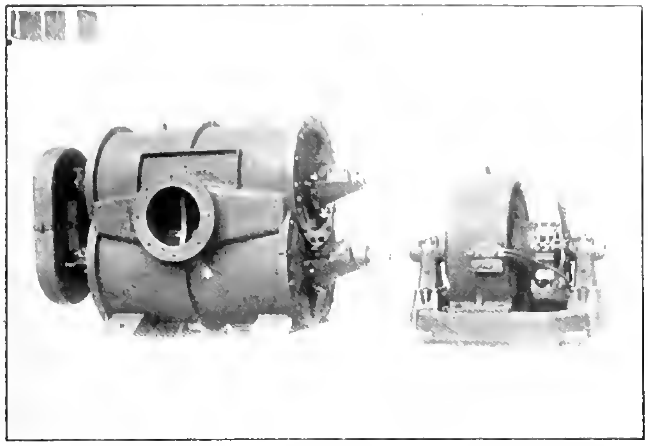

Fig. 12. Blower and Motor posed for Photograph

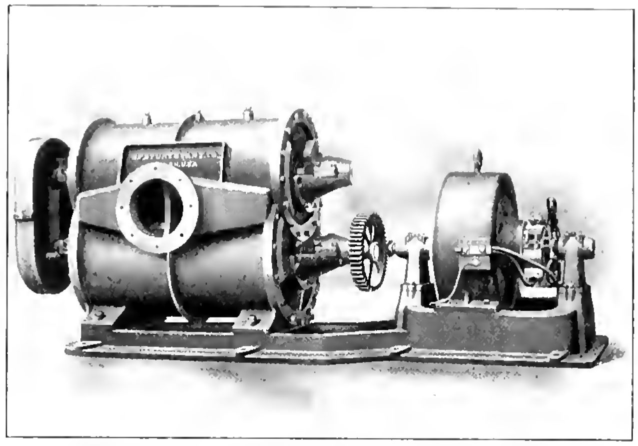

Fig. 12A. The Result after the Artist has done his Work.

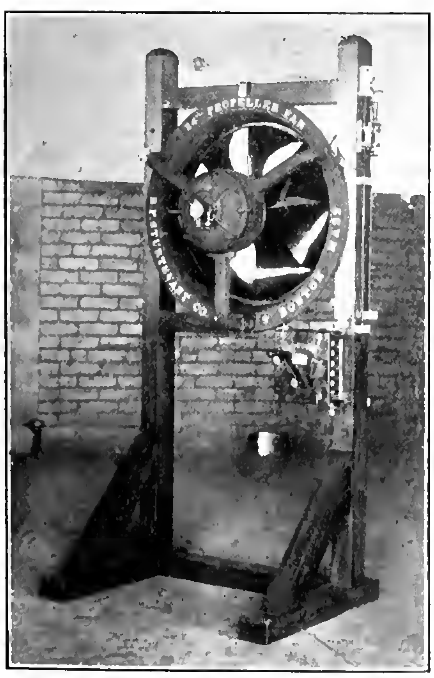

Fig. 13. The Motor-driven Fan and its Controller.

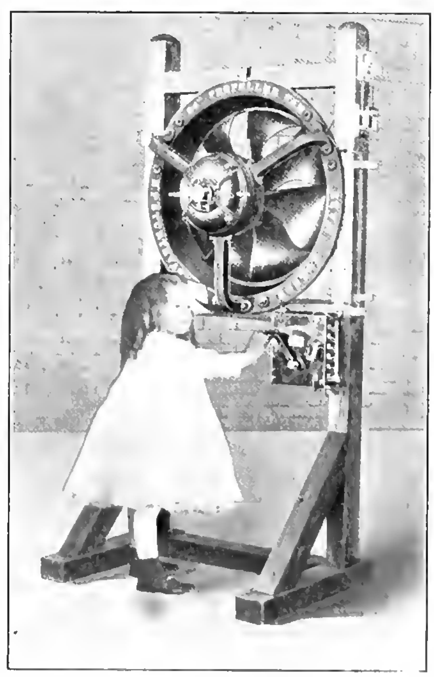

Fig. 13B. The Result of the Combination.

"Faking" or Altering Photographs.

In certain lines of work existing conditions render it impossible at times to get the machine photographed just as it is wanted, or perhaps an effect is desired, which, although reasonable or probable, is out of the question. Innumerable cases of extensive alteration, even to the extent of "faking," might be described, but three will serve as examples.

In preparing a publication on electric propeller fans, the writer was unable to photograph a large fan of certain constructive features, for at the time none was in stock and no order was going through the shop. To get the complete photograph of the motor-driven fan, as shown in Fig. 10, a photograph of a motor of the proper type and size was first made. This was painted out and printed on a 10 x 12 sheet of silver paper. An outline drawing of the propeller fan of the correct size for the motor was then made in pencil on the mounted silver print. The artist had no difficulty in placing the concrete base beneath the motor and making a "wash" drawing of the pencil outline. The illustration is worthy of note in that the motor is an actual photograph, while the fan, brickwork, and motor base are not.

A case illustrating the necessity of photographing machinery before it is complete is shown in Fig. 12. The writer needed a picture of a motor-driven rotary blower before the set had been built. A motor of the proper size to drive the blower at hand was placed in position. The relative speeds being known, the pitch and diameter of the gears were easily determined, and the pitch diameters gave the distance between the shafts. Of course no bed or foundation was at hand so that it was necessary to build up the blocking to the desired height. By the means of the electric crane, the motor was placed with the shaft parallel to that of the blower and at the proper distance from it. To make the painting out easier, the blocking for both blower and motor was covered with white cloth, and two background screens were used. The

artist painted in the bed from the working drawings (the patterns not yet being made) and also the gears.

It may strike some readers that the child photographed in the act of starting the electric propeller fan is out of place in a shop photograph. The picture is, of course, designed to show the simplicity of operation. This effect was produced from two negatives. The fan itself in the supporting frame was photographed in the shop, with an exposure of about seven minutes, and the child was photographed in her home against a dark background, with her hand resting on the corner of a table, the height of which approximated the height of the rheostat handle. A double printing and a little artistic work completed the picture. A point to be remembered in this connection is the height of the lens. If the lens had not been at practically the same height in both cases, the child's feet would have had an incorrect perspective.

* * *

BILL'S GARAGE.

ETHAN VIALL.*

My friend Bill and I often get together after the day's work is over and swap stories and experiences. Bill is the superintendent of the general hardware factory just across the street from our shop. His experience has been wide; he is a hustler, and knows how to handle his men to the very best advantage.

One evening our talk ran into a discussion as to whether a man was better off working for himself, or in getting and keeping a good job with some reliable firm. The talk waxed rather warm, and Bill was so positive in his stand that a man was better off working for someone else, that I finally said, "I'll bet a five-dollar note that you've been burnt, yourself." Bill rubbed his head, and, with a rueful smile, replied, "Yes, I have been burnt, and not only that but burned out, and only three or four years ago at that.

He paused to throw away the stub he had been smoking, and, lighting a fresh cigar, he said, "After several years of successful running of shops for other people, I became imbued with the idea that I could do better in business for myself. At that time the boom of the bicycle business, which had furnished work for so many 'mushroom' repair shops and 'toadstool' mechanics, had died out, and the automobile was just passing the experimental stage, and coming near enough to perfection to enable one to take a ride of at least a mile without breaking down. What was left of the bicycle trade had settled into a steady business with all the flourishes gone. Now my work with the largest manufacturer of bicycles in the United States had given me knowledge of 'kinks' in the business unknown to the average repair man, and I also had an intimate knowledge of the automobile shop work as it then existed, owing to this firm being one of the first to get into the new line. Naturally, with this experience still fresh in my mind, my thoughts ran to the establishment of a general repair shop for bicycles and automobiles, and then perhaps later on an automobile factory and a position in the 'trust' that I felt would come as inevitably as Col. Pope's corner of the bicycle factories. (Teddy the 'trust buster,' hadn't begun to 'bust' at that time.)

"Having decided to place my worldly and mechanical knowledge, and what other capital I possessed, in an automobile, so to speak, my next move was to find a suitable town to settle in, as I had decided that I wanted to get out of Chicago for a change. About half way down the state was an enterprising little town of thirty thousand inhabitants, which seemed to be an ideal place for a shop.

"Having decided on the line, the town, and finally the building, I started to work. My plan was to begin modestly and build up my trade gradually. Dropping the auto repair idea for a time, I devoted my energy to the bicycle business. There were five other shops in town but I could vulcanize tires and do brazing, which they could not, and, using these two accomplishments as drawing cards and headings for my advertisements, I soon had enough business to keep myself and two men hustling. The growth of my trade was really phenomenal, which I attribute to thoroughly knowing my business and to advertising. I advertised in 'catchy' ways in every city and county paper, and on the fences at every cross road.

* Address: 805 N. Mercer St., Decatur, Ill.

"In addition to my repair work, my sale of supplies began to assume really respectable proportions. I had started early in the spring and by fall my business was far beyond my widest hopes, but, fearing a dropping off of business due to the stopping of bicycle riding at the approach of winter, I added another line—barber supplies.

"There were thirty-four barber shops in town, so I left my repair work in the hands of my men, and personally went after the job of supplying these shops with everything they used, from face powder and soap, through the different shapes of combs and shears, to chairs and fixtures. I had three big Chicago supply houses to 'buck against,' and also one from a neighboring town, but before the winter was half over I was selling nine-tenths of the stuff used by the barbers in town, and was reaching after the trade in the little towns nearby. As spring approached, I moved to larger quarters, and, still keeping my grip on all I had gained, I began to pull for the

"One night the whole business went up in smoke."

automobile trade for all I was worth. I had but one rival in this, but it was a formidable one, as this firm had sold practically all the automobiles used in the county, which, at this time, numbered about sixty. Nevertheless, with the prestige I had gained in my other work it was but a few months when the bulk of both the repair work and the selling of automobile supplies was mine. All that year my business grew until I was unable to handle all of it, and I sold my bicycle business to one of the other shops, and devoted my energies to the barber supply and automobile business. By the following spring, having added the agency for two popular automobiles, I had one of the best equipped garages in the country for a town of the size I was in. I carried about two thousand dollars' worth of supplies on hand, and, in addition, tools, machines and other things that brought the total up to about five thousand dollars, which, owing to the nature of the business, was all risk and no insurance, and one night the whole business 'went up in smoke,' or at least most of it, for the stuff that was left was hardly worth sorting over. A big twelve-horse-power gasoline engine which I had just installed to furnish power for my machine shop, brought five dollars for junk!

"Tired and discouraged by a misfortune that had cost me the product of two and one-half years' work and about six thousand dollars, I turned over my trade to the man who had bought my bicycle business, and securing a position as superintendent of the hardware factory, I went out of business for myself, but though my financial loss was considerable, yet I count the experience a valuable asset.

"I have no desire to go back to working for myself where I have to get up at half past four in the morning and work till midnight, with no Sundays or holidays. I much prefer to run some other man's shop, where, while I do my best, it is someone else who has the worry over the bills, the payroll and the business, and if anyone thinks that running one's own shop is a snap, let 'em *try* it."

Then Bill got up and we both started for home.

SAFEGUARD IN MACHINERY.

W. H. BOOTH.*

In Great Britain, and probably still more in Germany, the care of the workman is apt to be more rigid on the part of the government than it is in perhaps any other countries. In the opinion of many people who have watched the statistics of accidents, the effect of this care has been largely nullified in Great Britain by the countervailing influence of the Employers' Liability Act, which provides compensation for a workman, irrespective of whether the accident was due to his own wilful disobedience of safety rules or not. It may seem curious that personal injuries should increase as a result of certain compensation. It can scarcely be believed that any man would wilfully injure himself, and one can only attribute such increase of injuries to the unconscious effects of the acts for compensation.

But it is certain that workmen do take extraordinary risks without being called on to do so. Often one may hear an employer blamed because some poor fellow has gone home crippled, in order to put gold into his employer's pocket, but, careless as some employers may be, it is true that the workers are more often to blame than their employer. Men will dip under a suspended weight to save an extra yard in going round it. They will risk their own lives and their employer's solvency for the sake of a trivial economy of time.

The writer was once forced to lower a weight with tackle not safe for half the load put upon it. All hands were called clear, and the extreme danger pointed out, and yet men would pass beneath the load in this dangerous condition, and it was useless to attempt to stop them. If every one were to detail his experiences of carelessness, it would seem that some men cannot be trusted to care for their own lives or for those of others. They do not mean to be hurt; they simply think it will be all right this time, and probably say to themselves "for the last time," resolving not to do it again, and they do this once too often.

Among the inspectors of the Home Office, which is the department of the English government that cares for these things, nothing is left to chance. Often more is enforced than ought to be, for one is sometimes compelled to place fences so that they add to the danger, as when placed too near to a small gas engine fly-wheel, so that it is difficult to start the engine by the usual method for small engines, namely, by turning of the fly-wheel. Probably, in time, no gas engine will be allowed to be started except by an accumulated air pressure. Wheels are guarded very completely. A pair guarded only on their top or in-running sides were ordered to be fully cased in because "some time it might happen" that in some extraordinary way they would turn the other way round.

Machinery fencing is of two sorts. There is the guard over the pair of wheels or other detail, and there is the general guard or fence or cage which contains the whole machine and prevents all access to it except by key. Some things cannot be guarded, such as the cutters of certain woodworking machinery, and these are perhaps the worst things for accident producing, for they are almost invisible when most dangerous. A circular saw might often be better caged than guarded, but a saw may be very considerably protected by a distance guard, when it is impossible to guard by a close cover. The Home Office takes account also of child labor, of overtime for women and young persons generally, of heating, lighting, ventilation, and sanitation, and especially of the precautions to be adopted when persons are employed, as in the glazing of pottery. All pottery people are on the *qui vive* to find a leadless glaze. One hears of leadless glaze, but investigation generally reveals a hidden source of lead. The trouble comes in the putting on of the glaze in solution, and all the evils of lead poisoning accrue, so that a strict watch is kept on all who are employed in respect of medical examination for detecting the first symptoms. Yet people who know they have symptoms will endeavor to hide them, and pass the doctor. Fans, for removal of dust, and all manner of respirators and other safeguards are more or less attended to by Home Office inspectors.

In the pottery trade, the scheme was tried of putting hoods over the heads of the workers, into which fresh air from an absolutely pure source was brought, so that there should always be a draft away from the workers and lead fumes could not get toward them, but somehow this did not answer. The lead taken into the system is not all taken through the lungs. The file cutter who cuts his files upon a block of lead is often careless how he eats food with leaded fingers, and lead will get into the body through the skin.

Copper poisoning does not appear to attract the same attention as lead, but undoubtedly brass workers suffer in health as a result of the copper. A brass founder never has any infectious complaint, it is said, for copper fumes are fatal to germ life, and, finally, are fatal to the man, but the effects are not so painful as those of lead, possibly because the copper salts are soluble and are eliminated, whereas lead accumulates. Brass workers appear to develop a dislike to fresh air. They will not put up with open windows that other men can enjoy, so that a brass shop ought to be fitted with a ventilation system out of the control of the occupants, and should be suitably warmed to fit the enfeebled workers, who might then be much improved.

One of the reasons why Kaffir labor becomes so scarce in the Transvaal mines was alleged to be the extraordinary high pay given to the "boys" during the war. But probably a much more potent cause has been the discovery by the Kaffirs that working rock drills produces miner's phthisis, so that the men died like flies, and now fight shy of mining work. The drills ought to work through an exhausted hood piece, the dusty air being delivered through a water box to settle out the grit. The provision of good water has been shown to be a great help in keeping machinery going. Good air is equally valuable.

Every industry has its own peculiar crop of accidents, from unexpected directions and least suspected causes. It almost seems necessary for accidents to happen in order that weak points in design may be shown up, just as the true stresses in machinery and structural work only show up in actual work, though this is less the case now than formerly when the failure of bridge details began to teach men that they could not allow the same nominal unit stresses in all details, but must take account of the manner of approach of the stress-producing agent or load.

Familiarity may lead to accident. It may also serve to prevent accident. Thus, if the people of England began to-morrow to walk upon the tracks of a railroad in the way usual in America, many thousands would be killed. In a week's time very few would be even hurt. So it is with ordinary machinery. The worker does not get hurt so often as might be thought likely, but, nevertheless, he does sometimes suffer from lack of guards to the more dangerous parts. The knowledge of what to guard, and how to guard it, is quite a special knowledge, demanding acquaintance with the machine and the method of its operation, and a general acquaintance with machinery and with accidents of all kinds.

*Address: 25 Queen Anne's Gate, Westminster, S. W., London, England.

* * *

The Stockbridge Machine Co., of Worcester, Mass., has its shop in a building that is not as well suited to the needs of a modern machine tool manufactory as it should be, but by adaptation it has been made to serve the purpose fairly well. Not long ago a Gisholt boring mill was purchased, and its logical location to suit previous steps of manufacture was on the second floor, but the floor would not safely permit the installation of this 11,000-pound machine without considerable strengthening. Instead of doing this, and perhaps getting an unsatisfactory foundation after all, it was decided to build a foundation up from the ground through the first story. This might naturally be thought expensive, but it proved otherwise. The column erected was 3 feet 4 inches by 5 feet 4 inches by 16 feet high. It was constructed of concrete, mixed as follows: Cement, one barrel; sand, two barrels; gravel, ½ cubic foot; and broken stone, 9/10 cubic foot. The center was cored, leaving walls 8 inches thick, and a door was set in one side, thus making the inside of the column available as a fireproof storage vault. The cost of the material was but little over $30.

NOTES FROM THE OLYMPIA EXHIBITION.

JAMES VOSE.*

The engineering and machinery exhibition at Olympia, London, is chiefly representative of machine and hand tools, though many general engineering exhibits are on view. An advisory council, representative of leading engineering associations, manufacturing establishments and commercial institutions affords valuable aid to the organizers, while the educational aspect of the show is kept well in view, special facilities being afforded engineering students to visit the exhibition on organized lines under specially appointed guides. Arrangements also have been made, of which considerable advantage is being taken, for workmen to visit London and the show at a very low cost, while a number of interesting lectures are being given by experts in various branches of engineering.

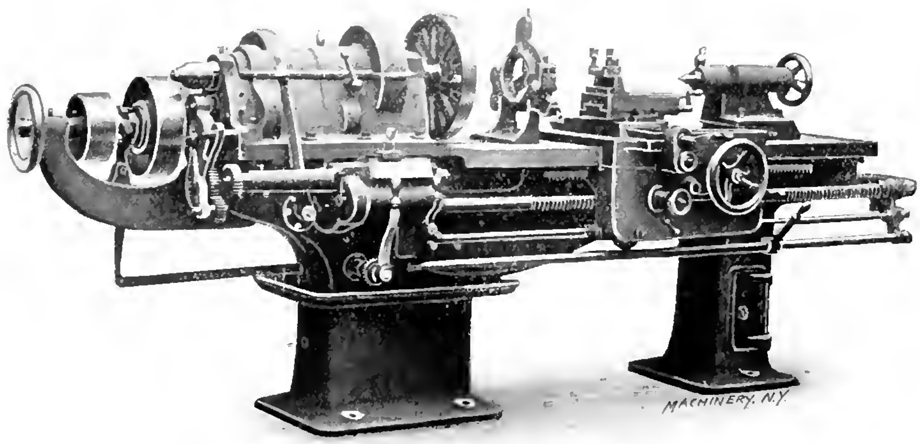

Fig. 1. George Richard's High-speed All-gear-drive Engine Lathe.

Touching on tools particularly, a striking feature is the cosmopolitan character of the exhibits, and the wide distribution of manufacture of types of tools which until recently appeared to be entirely confined to a few pioneers of well-founded reputation. Another noticeable development, emphasized by the exhibits, is the extent to which merchants formerly, by force of circumstances, almost exclusively identified with American tools, now—without in any degree relinquishing their handling of American lines—have taken up British and Continental productions. At the same time, in some cases, the special insight they have gained into the requirements of customers has enabled them to evolve lines of their own which they have commissioned various makers to manufacture for them.

The cutting of spur gears by the process of hobbing appears to have made rapid advances in Europe, quite a number of such machines being shown in operation. We noticed examples built or handled by Reinecker, Biernatzki, Holroyd, Burton-Griffiths, Selig-Sonnenthal, Humpage, Thompson & Hardy, and Henry Wallwork. So far, we have not actually seen an American contribution, though rumors are afloat as to such being under way. (See MACHINERY, October and November, for examples.) New builds of plain or universal precision grinding machines, presenting novel features, are identified with the Newall Engineering Co., Macdonald, Adamson & Co., Ltd., and the Morse Co. The requirements of automobile builders are extensively catered to, crank-shaft lathes, cam grinders, grinders for finishing square holes after the hardening process, cylinder, piston ring, and valve grinders, etc., being prominently in evidence. No lack of choice is experienced in electrically and pneumatically worked portable drills, grinders, etc. Constant-speed belt-and gear-driven lathes, drills, etc., are met with at every turn, though here and there the opinion is expressed that the application of this principle is in some danger of being overdone, and that well-designed cone-driven tools are by no means played out.

In passing, mention may be made of the additional weight provided in American tools, and the increased handiness in manipulative details of current British tools. Judging by the widely-differing types of metal-sawing machines on view, the subject of rapid and economical cutting up of stock is attracting increased attention the world over. A feature of the last year or two is the number of pipe-bending appliances brought to the notice of users, and this tendency is reflected in the variety of machines exhibited, capable of dealing with tubing of the most varied strength and diameters. Some are worked by lever or worm and wheel, while others are hydraulically worked. In some instances, the tubes are filled during bending, and in others this is unnecessary. Although the idea and use of high-speed steels of modern types was introduced from the United States, the large number of British exhibits of such steels, and the articles manufactured from them, contrast rather remarkably with the paucity of American products in this line on view. The high duty imposed on tool steel entering the United States is perhaps not unconnected with this feature of the situation. The show of turret lathes and automatic screw machines is quite comprehensive, the novelties of a few years back being non-accepted standards, and exploited by quite a number of new makers. The systematic grinding of cutting tools has made considerable headway in Europe during the last few years, and a good show of machines for accomplishing this object is to be seen. Many of them have been distinctly influenced by American designs. Several relieving lathes of continental origin, for the production of formed cutters, etc., are shown. It is rather curious that no American or British firm makes this a "leading line." Boring and turning mills are pretty well in evidence in the smaller sizes and also upright drills of the light and medium varieties. A few radial drills are shown, perhaps the most prominent being a Bickford constant-speed belt machine, and a Kendall & Gent double spindle machine also driven by a constant-speed belt. The specialty of the latter machine lies in the fact that one spindle is used for drilling, the other for tapping, and that the saddle carrying them may be instantly moved the required distance for interchanging their positions. Rapid and accurate tapping

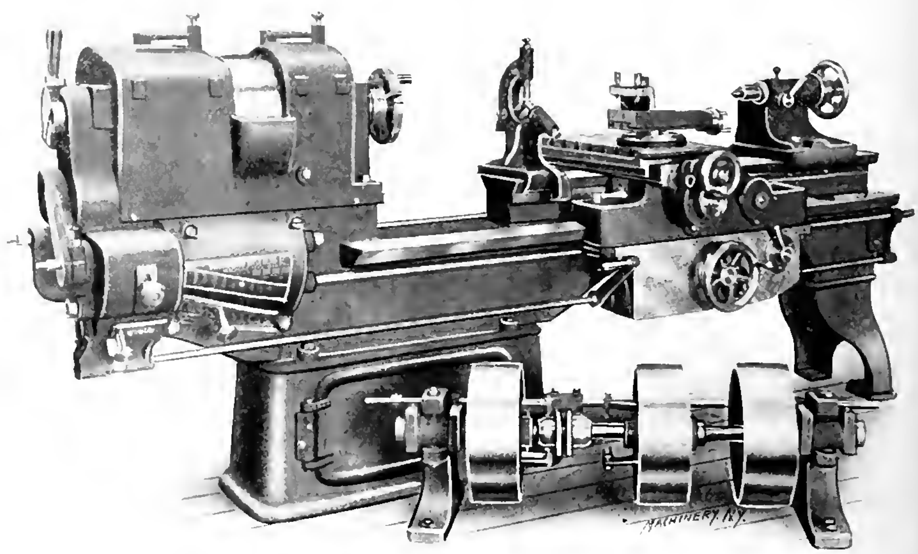

Fig. 2. Drummond Bros. 18-inch Swing Patent Gap Bed Engine Lathe, All-gear-drive.

* Address: 100 Ayres Road, Brook's Bar, Manchester, England.

is thereby assured, the tapping spindle speed being always correctly related to the drilling speed, though the tap is backed out quickly. Bolt and pipe threading machinery is well represented, the American Landis machine attracting attention by its special form of die, while the "Helios" is a continental type possessing a number of good features. Substantial typical British machines are shown by Joshua Heap & Co., and Kendall & Gent.

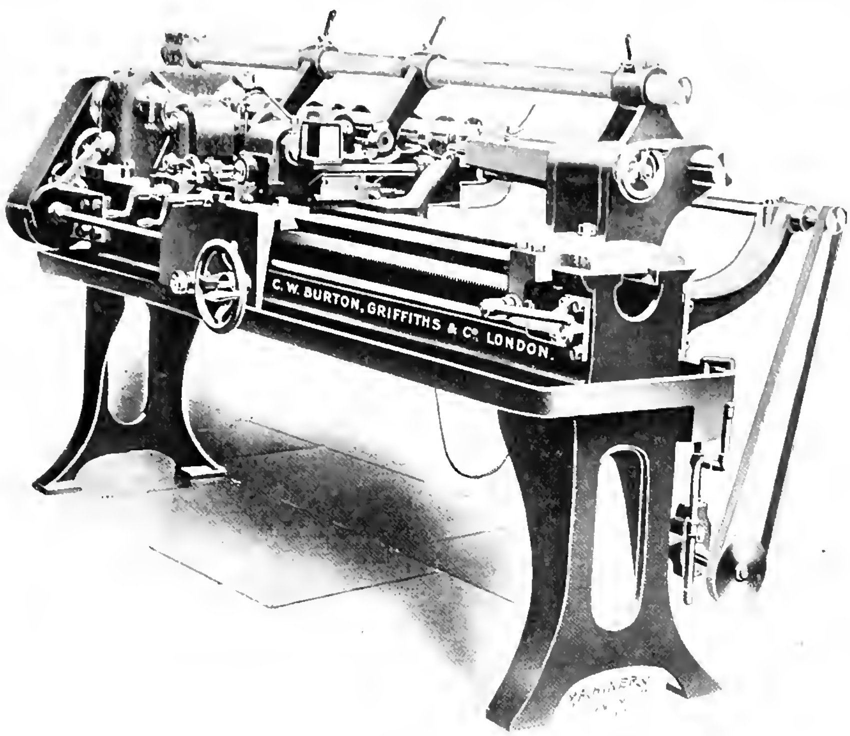

Fig. 3. C. W. Burton-Griffiths & Co.'s Milling and Grinding Machine for Gas Engine Cam Shafts. Cutters and Emery Grinder controlled by Cam Shaft at Rear.

Lathes specially adapted for repair work, in sizes from 7 inches swing to 18 inches swing, are presented by Drummond Brothers, who obtain the advantage of a gap bed while retaining efficient guidance of the saddle by making the sliding ways of the bed in line with the bottom of the gap, the tailstock only being guided by the upper portion of the bed.

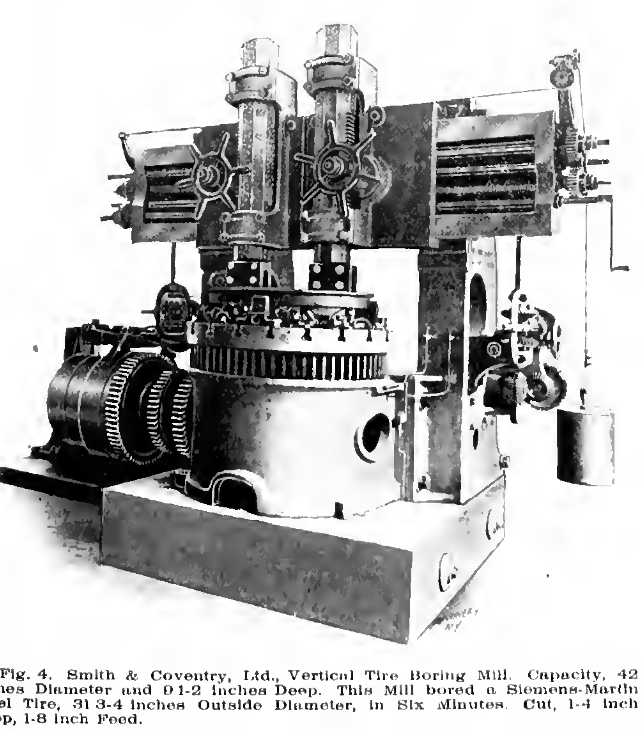

Fig. 4. Smith & Coventry, Ltd., Vertical Tire Boring Mill. Capacity, 42 inches Diameter and 9 1-2 inches Deep. This Mill bored a Siemens-Martin Steel Tire, 31 3-4 inches Outside Diameter, in Six Minutes. Cut, 1-4 inch Deep, 1-8 inch Feed.

The 7-inch swing lathe is powerful enough to reduce a 1⅛-inch steel spindle to ⅞ inch diameter at one cut, or to take a cut ¼-inch deep off a cast iron disk 9 inches in diameter. The saddles of these lathes are arranged to form a tee-slotted boring table—the top slide being quickly removed—well adapted for such repair or new work as motor car cylinders, gear case boring, etc.

In the miscellaneous section, a novelty is the "Dreadnought" file, which has deep semicircular teeth, (see MACHINERY, March, 1907), and is called a milling file, as the cuttings come off in distinct shavings. It is claimed to cut two or three times faster than an ordinary file. A supporting back is used in conjunction with the file. A special feature is its self-cleaning action, which is very marked, and though the teeth are coarse, the surface produced is unusually smooth. It can be resharpened about four times at about half the cost of recutting an ordinary file. The statements of the makers appear confirmed by actual tests at the company's stand, though, of course, fairly prolonged trials will be necessary to obtain data applicable to regular workshop conditions. The show of bevel gear planers is very representative, and includes Bilgram, Reinecker and Zimmerman types, the latter employing two tools simultaneously. The shape of tooth is governed by a former, and a single form controls both tools, thus securing similarity of both sides of the tooth. Taken altogether, the show of machine tools and accessories is probably the most representative ever held in Great Britain, and has attracted visitors from many countries.

The preceding notes only purport to give a general idea of the scope of the exhibition, anything approximating to an adequate description of all the interesting tools would take up the major portion of this issue, but sufficient data have perhaps been brought forward to indicate its value from educational, engineering and commercial standpoints.

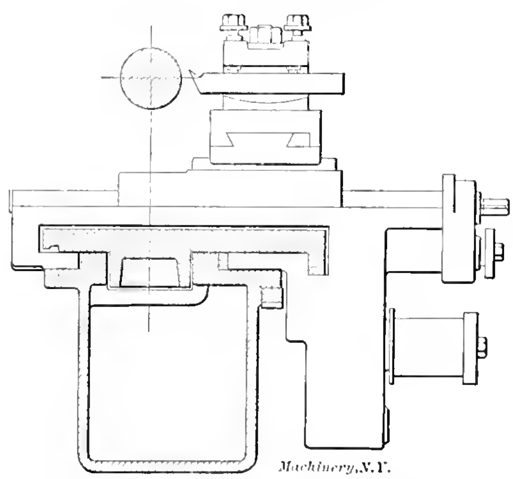

Fig. 5. Cross-section of George Richards High-speed Lathe, shown in Fig. 1, showing Construction which protects Bearings of Bed and Carriage from Chips.

* * *

The development of the shop operation sheet idea, which, by the way, we believe is an entirely new feature in trade journal literature, should bring out methods in machine shop practice that heretofore have been generally overlooked or regarded merely as a matter of course, and we hope to receive the hearty coöperation of our readers in the presentation of what are regarded as standard methods, even though they may be regarded as in the A B C's of the machinist's art. It may be a matter of surprise to some to learn that the preparation and editing of this matter, simple as it looks, is the most difficult of any that we have ever handled. But if any reader has any operation sheet to suggest, he should not let this fact deter him from sending it in and letting the editors wrestle with it, for that is *our* business.

ON DETERMINING SIZE OF FLY-WHEELS FOR MOTOR-DRIVEN PLANERS.*

W. OWEN.†

W. Owen ‡

The question of motor driving for high-speed planing machines brings forward many interesting problems, among which the ascertaining of the correct dimensions for the fly-wheel is not the least.

I read, some time since, in MACHINERY (June, 1905), an article on motor-driven planing machines by Mr. A. L. De Leeuw, in which the writer mentions that he discerns something of a joke in the contemplation of a fly-wheel in combination with a compound-wound motor. Now I, for one, quite fail to appreciate this joke, and always advocate the use of this arrangement for planer driving for the following reason:

The primary function of a fly-wheel is not so much the preservation of a constant speed, as Mr. De Leeuw suggests, as the relieving of the motor from excessive shock at the instant of reversal.

A shunt-wound motor tends to keep the same speed at all loads, but must necessarily slow down for a moment, however large the fly-wheel, at the instant of reversal, thus tending to spark. Of course, the larger the motor, the greater the store of energy in the armature, consequently the smaller the drop in speed and less tendency to sparking, hence Mr. De Leeuw's preference for a *large* shunt-wound motor.

A compound-wound motor, on the other hand, will drop slightly in speed under heavy loads, the percentage of drop, of course, depending upon the amount of compounding. It is this property of the compound motor which enables the fly-wheel to perform its work satisfactorily. A correctly designed fly-wheel will, at the moment of reversal, keep up the speed of the motor slightly higher than that corresponding to the load on the motor at that instant, thus eliminating all possibility of sparking.

Now the determining of the dimensions of the fly-wheel before the machine is made, to fulfill these conditions, necessitates close scrutiny of the engineering press, so as to be continually cognizant of tests taken at different times on high-speed planing machines. A better method, where practicable, is to test the machine before deciding upon either the motor or the fly-wheel.

A machine recently tested under the latter condition gave the following: Average horse-power cutting, 19; average horse-power backing, 11. At the instant of reversal to backing stroke the ammeter needle jumped to 190 on a 220-volt circuit, showing maximum horse-power to be about 55, and the time taken up from the table striking the dog to the attainment of maximum backing speed was 3 seconds.

It was decided to drive this machine by a 30 B. H. P. motor at 500 revolutions per minute, compounded so as to give a maximum variation of about 12 or 14 per cent. Allowing a 40 per cent momentary overload on the motor would bring the maximum horse-power allowable on reversal to 42, and the additional 13 horse-power would have to be supplied by the fly-wheel. The dimensions of the wheel were obtained in the following manner:

As energy in a moving body varies directly as V^2, where V = velocity in feet per second, it is clear that the best place for the fly-wheel is upon the shaft having the greatest number of revolutions per minnte, which, of course, is the motor shaft.

From the figures given, it will be seen that the wheel must be capable of parting with sufficient energy to develop 13 horse-power during the time of reversal, *viz.*, 3 seconds, and its drop in speed must not exceed 10 per cent, so as to keep the actual variation slightly below that allowed by the motor.

Energy to be given out by the fly-wheel $= \dfrac{13 \times 33{,}000 \times 3}{60}$.

Now assnme M to be the store of energy in foot-pounds in this fly-wheel when it makes one revolution per minute, then, as the energy varies as V^2, and V varies as the revolutions per minute, the store of energy in the wheel when making 500 revolutions per minute $= M \times 500^2$.

As the drop of speed of the wheel = 10 per cent speed of wheel at end of 3 seconds then the speed of the wheel = 500 — 10 per cent of 500 = 450 revolutions per minute, and the store of energy then in the wheel $= M \times 450^2$.

Thus the energy given up by the wheel in being reduced from 500 to 450 revolutions per minute $= M\ (500^2 - 450^2)$.

But the energy given up must $= \dfrac{13 \times 33{,}000 \times 3}{60}$, as already shown; therefore $M\ (500^2 - 450^2) = \dfrac{13 \times 33{,}000 \times 3}{60}$.

$$M = \frac{13 \times 33{,}000 \times 3}{60\ (500^2 - 450^2)}.$$

$$= \frac{13 \times 33{,}000 \times 3}{60 \times 47{,}500}$$

$M = 0.45$ foot-pounds.

Therefore, the store of energy in the fly-wheel when making 1 revolution per minute = 0.45 foot-pounds.

The limit of peripheral speed of plate fly-wheels generally allowed in machine tool practice is about 7,000 feet per minute, which quantity will enable us to find the outside diameter of the wheel thus: $\dfrac{7{,}000}{3.1416 \times 500} = 4.4$ feet.

As energy in a revolving wheel $= \dfrac{W\,V^2}{2\,g}$, where V = velocity in feet per second at center of area of rim, $\dfrac{W\,V^2}{2\,g}$ must equal 0.45 when the wheel makes 1 revolution per minute. Therefore $\dfrac{W\,V^2}{2 \times 32.2} = 0.45$.

Velocity of wheel in feet per second when wheel makes 1 revolution per minute $= \dfrac{4 \times 3.1416}{60}$; the diameter of the wheel to center of area, it will be seen, is taken as 4 feet, 4.4 feet being the outside diameter, thus

$$\frac{W \times 4 \times 4 \times 3.1416 \times 3.1416}{2 \times 32.2 \times 60 \times 60} = 0.45.$$

$$W = \frac{0.44 \times 32.2 \times 2 \times 60 \times 60}{4 \times 4 \times 3.1416 \times 3.1416},\quad W = 660 \text{ pounds.}$$

Thus, knowing the outside diameter and the weight of the wheel, the other dimensions are very easily ascertained.

* * *

The muuicipal authorities of Paris, France, on account of the manner in which some lately erected high buildings, imitation skyscrapers, are marring the beauty of that city, are considering to re-enact the lately annulled laws restricting the height of buildings. Such restrictions are very important, not only on account of the appearance of the city, but because of many other problems created by the high buildings. Had it not been for the skyscrapers on the lower part of Manhattan Island in New York, the present traffic problems in that city would not have presented such enormous difficulties. The necessity for hundreds of thousands of people to be transported every morning and night to and from a little plot of land but a few acres in extent is caused by nothing else than the existence of the high buildings, which permit so great a number of people to work on so small an area.

*For previous articles on this and kindred subjects see MACHINERY, June, 1895, Designing and Constructing Modern Steam Engines; May, 1900, Gas Engine Design; July, 1904, Planer with Quick Return of 200 Feet per Minute; June, 1905, High-Speed Planers; July, 1905, An English High-Speed Planer; July, 1907, Size, Weight and Capacity of Fly-Wheels for Punches.

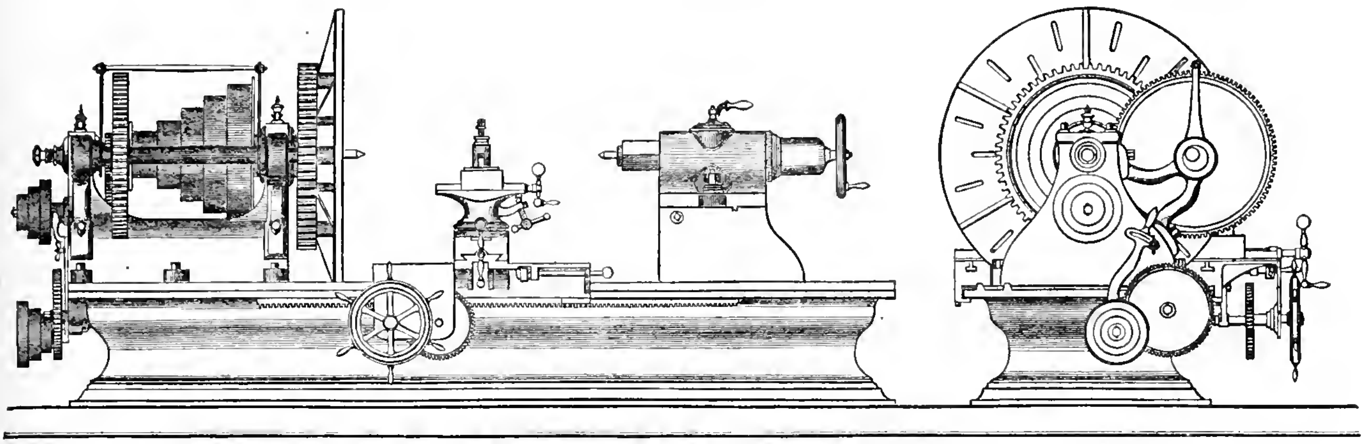
†Address: 28 Church Ave., Weaste, Manchester, Eng.

‡W. Owen was born in Blackburn, Eng., in 1881. He served an apprenticeship with Hulse & Co., Manchester, machine tool builders, and in conjunction with his apprenticeship attended engineering courses at the Royal Technical Institute, Salford. Upon leaving Hulse & Co. he went with Craven Bros., also of Manchester, where he is now employed. Mr. Owen is also on the engineering staff of the Royal Technical Institute, Salford. His specialty is machine tool design.

SOME OLD MACHINERY CATALOGUES.

A few weeks ago the editor had the opportunity of examining a number of old machine tool catalogues collected by Mr. Henry E. Eberhardt, president of the Eberhardt Bros. Machine Co., Newark, N. J. The catalogues are interesting from both a mechanical and commercial standpoint. Some day, if not at present, the catalogues of machinery builders issued in the '60's and '70's will be highly regarded by the historian of manufacturing.

The oldest catalogue in the collection is that of the Lowell Machine Shop, Lowell, Mass. It is dated January, 1863, and is of the fourth edition. J. Thomas Stevenson was treasurer, and Andrew M. Moody superintendent. The first edition of the list of tools made by the Lowell Machine Shop was printed in 1851. The company manufactured all kinds of cotton machinery, locomotives, turbine water mills, mill gearing and shafting, but the catalogue before us is devoted to machine tools, including engine lathes, hand lathes, vertical drilling machines, horizontal drilling lathes, boring and reaming lathes, planing machines, shapers, crank-pin boring lathes, bolt cutting machines, gear cutting and dividing machines, slotters, tilt and trip hammers and punch presses. The illustrations are lithographic reproductions of line drawings, each illustration being an insert, blank on the back side. The prices throughout are filled in with ink. The character of the illustrations is indicated by the accompanying reproduction of a "No. 6 engine lathe." This machine had a bed 16 feet long, and would turn a piece $9\frac{1}{2}$ feet long. It weighed 11,000 pounds, and sold for $2,310. It was also made in 18-, 24-, and 32-foot beds. The spindle was made of cast iron, and the lathe would turn 50 inches diameter over the slide and 32 inches over the tool rest. It will be noted that the lathe was back-geared into a gear on the face-plate. This was the largest and heaviest machine built by the company.



Sample Illustration in Catalogue of the Lowell Machine Shop, showing No. 6 Engine Lathe.

Other firms whose catalogues are included in the collection are: William Sellers & Co., Philadelphia, Pa., 1870; Lucius W. Pond, Worcester, Mass., 1874; Brown & Sharpe Mfg. Co., Providence, R. I., 1875; F. E. Reed, Worcester, Mass., no date; Niles Tool Works, Hamilton, Ohio, 1880; Brainard Milling Machine Co., Hyde Park, Mass., 1880; E. E. Garvin & Co., New York, 1883; Putnam Machine Co., Fitchburg, Mass., 1884. Of course the catalogues issued in the early '80's belong to comparatively recent history, but, nevertheless, one notes a great change in the power, massiveness, and general design of machine tools within the last twenty-five years. If space had permitted, several additional views could have been reproduced, showing some of the marked changes in the product of these machine tool builders.

A comparison made between these catalogues and the present issues of the same concerns is instructive, especially in the case of so widely distributed an example as the catalogue of the Brown & Sharpe Mfg. Co. This company's issue of January 1, 1875, is a $3 \times 5\frac{1}{4}$-inch booklet of 74 pages, including the cover, printed on thin paper; the catalogue for 1907 contains 500 pages, $3\frac{1}{2} \times 5\frac{3}{4}$ inches, and it would be much larger if the matter was not condensed so as to include only the essentials.

THE MACHINE SHOP DON'TS AS A SPIRITUAL FORCE.

Nothing ever published in MACHINERY has attracted more attention from practical machinists and others connected with machine shops than the "don'ts" for machinists and draftsmen, which appeared by installments in June and October, 1905, and February and October, 1906, issues. They were contributed by Mr. H. E. Wood, formerly of Pearl River, N. Y., now of Hartford, Conn., and represented, in concentrated form, some of the wisdom acquired by years of varied experience as a machinist and foreman. So popular were these tabloids of shop common sense that they were reprinted in pamphlet form for general distribution, and over 200,000 copies have been put in the hands of mechanics in the United States, Canada, Great Britain, and other English-speaking countries. Now, what we started to say was that while, in common with mechanics generally, we had a keen appreciation of the epigrammatic vigor and general hard sense of these shop don'ts, we had not looked upon them as a particular force for good in the spiritual world, but it appears that they have been so regarded. The following letter from the editor of *The Sunday School Times*, Philadelphia, refers to them in a very appreciative manner:

Recently *The Sunday School Times* published a couple of editorial notes on its first page based on the strikingly suggestive and helpful points in the little booklet that you published, entitled "Don'ts for Machinists and Draftsmen." Rarely have we had anything attract quite so much attention among these front-page editorial paragraphs. I thought you would be interested to know this, and I enclose clippings of the two paragraphs referred to. So you see you are reaching folks in the realm of spiritual character as well as in the realm of mechanical efficiency.

October 30, 1907. C. G. TURNBULL, Editor.

Following is one of the notes referred to:

There are not two different sets of principles for material and spiritual success. Whatever really helps in one field will help in the other,—only the sons of this world are often wiser than the sons of light. A series of "Practical Don'ts for Machinists," issued by a prominent trade publication, contains a good many hints that all of us in life's big machine shop would do well to heed,—though the series is labeled "For the other fellow—not you." Here are some of them: "Don't say 'that's good enough.' Don't borrow tools; buy your own. Don't let your lathe run and cut air. Don't be always looking for pay-day. Don't be too important to do insignificant jobs. Don't take off your overalls before quitting time. Don't try to fool your foreman, for you may get left. Don't wait until Monday morning to fill your oil-can. Don't deny spoiling a piece of work if you have done it. Don't work to a caliper that has been set by another man; set it yourself." The man or woman whose life is controlled by such principles as these is bound to have the respect of fellow-workmen, and the quality of the work done is likely to mean promotion by the Foreman.

* * *

A recent inquiry into some of New York City's municipal accounts discovered that in one instance 165 coat hooks had been sold to the city at 60 cents apiece, which could be bought at retail for about 5 cents apiece; but the worst is not yet. These hooks were put up by a plumber and a helper, who charged at the rate of $8.00 per day for their time. They consumed 31 days doing the job!

REAMERS.—5.

ERIK OBERG.*

Pipe Reamers.

Pipe reamers, Fig. 21, are used to precede pipe taps. They are made of the same sizes as pipe taps, excepting that the dimensions of the pipe reamer correspond to the root diameters of the thread of pipe taps. The taper of pipe reamers is 3/4-inch per foot. They are fluted with the same kind of cutters as hand reamers of sizes corresponding to the diameters at the small end of the pipe reamers. Finishing reamers only are used. The number of flutes for different pipe sizes is as follows:

Pipe Size.	Number of Flutes in Reamer.
From 1/8 to 3/8	6
From 1/2 to 3/4	8
From 1 to 1 1/4	10
From 1 1/2 to 2	12
From 2 1/2 to 3	14
3 1/2	16
4	18

The small end of pipe reamers is slightly chamfered, as shown in Fig. 21, in order to facilitate the entering of the reamer in holes which are of about the same size as the small diameter of the reamer. Dimensions for pipe reamers are given in Table XIX.

Pipe reamers are tested or measured by means of taper ring gages to insure that they are within the permitted limits of variation. The diameter at the small end of the hole in these ring gages equals the diameter at the small end of the reamer. Thus, when the reamer is tested with the ring gage, if the end of the reamer comes exactly flush with the end of the gage, the size of the reamer is exactly

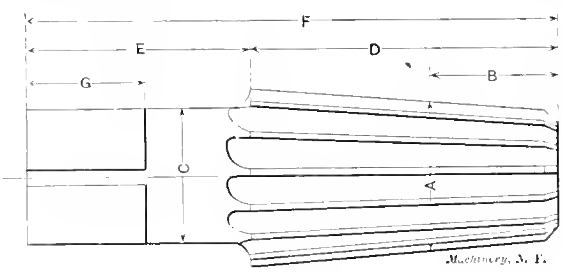


Fig. 21. Pipe Reamer.

TABLE XIX. DIMENSIONS OF PIPE REAMERS.

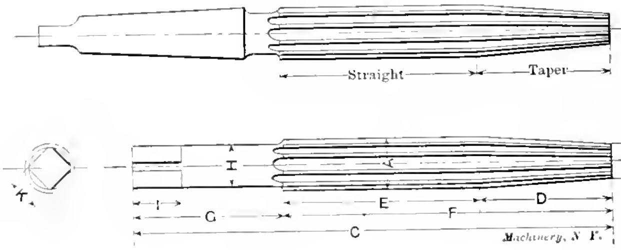
correct. If the end of the reamer projects through the gage, it indicates that the reamer is too small, and if it comes short of the face at the end of the gage, the reamer is too large. It is considered a permissible error if the end of the reamer projects through, or falls short of, the ring gage 1/32 inch for sizes up to and including 1 inch pipe size, 1/16 inch for 1 1/4 to 3 inch pipe size, and 1/8 inch for larger sizes.

Taper Reamers for Bridge Builders.

Taper reamers for bridge builders, commonly called bridge reamers, are made with Morse taper shank or straight squared shank, as shown in Figs. 22 and 23. The fluted portion is tapered for distance *D*, and is straight for the remaining part *E*, of the flutes. These reamers are used for rough structural construction work, and are not required to be finished with the same degree of care as reamers for machine construction. After hardening, the flutes are usually left unpolished. These reamers are made in sizes from 1/2 to 1 1/4 inch. The taper per foot of the tapered portion at the end of the reamer, as usually made, is given in Table XX together with the essential dimensions of the straight shank



Figs. 22 and 23. Taper Reamers for Bridge Builders.

TABLE XX. DIMENSIONS OF REAMERS FOR BRIDGE BUILDERS.

Diameter of Straight Part of Reamer.	Diameter at Point of Reamer.	Taper per foot of Tapered Portion.	Total Length of Reamer	Length of Tapered Part.	Total Length of Flute.	Length of Shank.	Diameter of Shank.	Length of Square.	Size of Square.

1 1/4	7/8	1 1/2	10 5/8	3	7 5/8	3	1 1/8	1 1/4	7/8

type reamer. The dimensions for the fluted portion of those with Morse taper shank are exactly the same, the only difference being the total length, which, of course, is dependent upon the size of Morse taper shank used. The common practice is to provide the 1/2 up to 5/8 inch sizes with No. 2, and all sizes 11/16 inch and larger in diameter with No. 3 Morse taper shank. The size of the reamer is measured on the straight part of the flutes. In the case when an odd number of flutes is employed, the size must be determined by a ring gage. The number of flutes is made 5 in all sizes below and including 7/8 inch diameter, and 6 for larger sizes.

Grooved Chucking Reamers.

The tool shown in Fig. 24 is partly a reamer and partly a twist drill. The cutting is performed by the beveled edges *A*, which form an angle of 60 degrees with the axis of the tool. The reamer is provided with three larger semicircular flutes, which are cut on a right-hand spiral, and with

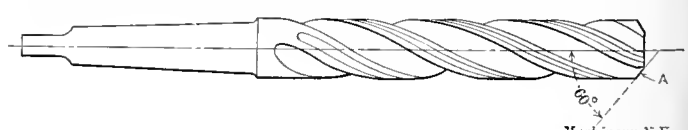

Fig. 24. Grooved Chucking Reamer.

three smaller grooves between these. The larger grooves form passages through which the chips pass away; the smaller grooves convey the lubricant to the cutting edges. This form of reamer is extensively used in screw machines for enlarging cored holes, and also in drill presses for enlarging drilled holes, it being easier to enlarge a drilled hole to size by a grooved chucking reamer than to try to drill the hole to size by an ordinary twist drill.

This reamer is commonly provided both with straight and Morse taper shank. When provided with Morse taper shank,

* Associate Editor of MACHINERY.

the following numbers of taper shanks should be used for the various sizes of grooved reamers:

Diameter of Reamer.	No. of Morse Taper Shank.
From 1/4 to 1/2 inch	1
From 9/16 to 7/8 inch	2
From 15/16 to 1 1/4 inch	3
From 1 5/16 to 1 3/4 inch	4
From 1 13/16 to 3 inches	5

The length of the fluted part being given in Table XXI, the total length of the reamer is dependent upon the length of the Morse taper shank used. When made with straight

TABLE XXI. LENGTH OF FLUTED PORTION OF GROOVED CHUCKING REAMERS.

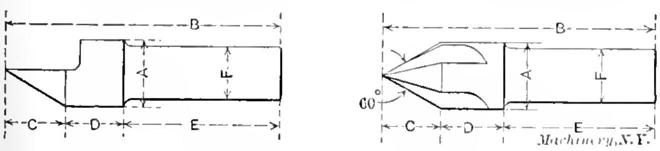
Diameter of Reamer.	Length of Fluted Portion.	Diameter of Reamer.	Length of Fluted Portion.	Diameter of Reamer.	Length of Fluted Portion.
1/4	4	7/8	8 1/4	2	9 3/4
5/16	4 1/2	15/16	8 3/8	2 1/8	9 7/8
3/8	5	1	8 1/2	2 1/4	10
7/16	5 1/2	1 1/8	8 3/4	2 3/8	10 1/8
1/2	6	1 1/4	9	2 1/2	10 1/4
9/16	6 1/2	1 3/8	9 1/8	2 5/8	10 3/8
5/8	7	1 1/2	9 1/4	2 3/4	10 1/2
11/16	7 1/2	1 5/8	9 3/8	2 7/8	10 5/8
3/4	8	1 3/4	9 1/2	3	10 3/4
13/16	8 1/2	1 7/8	9 5/8	..	..

shank, this latter may be selected of such length that the total length of the tool is the same as when a Morse taper shank is used.

The diameter at the point of this reamer is larger than at the shank end of the flutes, the amount of back taper being 0.003 inch per foot. This prevents the tool from binding in the holes chucked. The spiral of the flutes should be so selected that the edges of the flutes make an angle of between 25 and 20 degrees with a plane through the axis of the reamer. This corresponds to a lead of the spiral equal to from about 7 to 8.5 times the diameter of the reamer, respectively. This is practically the same amount of spiral as is used on twist drills.

Center Reamers.

Center reamers are used for forming the centers on which work is to revolve in lathes or grinding machines. They are made in two different styles. The older one, Fig. 25, has



Figs. 25 and 26. Center Reamers.

TABLE XXII. DIMENSIONS OF CENTER REAMERS.

Full Diameter of Reamer.	Total Length.	Length of Beveled Portion, Approx.	Length of Straight Portion.	Length of Shank.	Diameter of Shank.
A	B	C	D	E	F
1/4	1 3/8	7/32	5/32	1	3/16
3/8	1 1/2	5/16	5/16	1	1/4
1/2	2	7/16	7/16	1 1/8	3/8
5/8	2 3/8	17/32	15/32	1 1/4	7/16

7/8	2 7/8	3/4	3/4	1 3/8	9/16
1	3 1/8	7/8	3/4	1 1/2	5/8

only one cutting edge, formed by cutting away the metal down to the center of the tool, and relieving the beveled portion of the remaining half so that a cutting edge is produced. The second and later style is that shown in Fig. 26, which has four flutes or cuts. These cuts are straight, and the lands between the cuts are relieved on the beveled part. The inclusive angle of the point of the tool must, of course, be that used for lathe centers, or 60 degrees. These reamers are made with a straight shank. The dimensions of both styles are the same, and are given in Table XXII.

Flat-sided Reamers.

Very small reamers are sometimes provided with flats instead of actual flutes, the sharp intersection or corner between two flats acting as a cutting edge. These reamers are used for small dowel and taper pin holes, etc. The diameter of the reamer is, of course, measured over the sharp corners. If the reamer tapers, the taper of the flats will evidently not be the same as the taper of the reamer itself, and the milling machine head used when milling the flats must be set to a different angle than that which the cutting edge makes with the center line. A simple formula, expressing the relation between the taper per foot, the number of flat sides in the reamer, and the angle to which to set the milling machine head, was given in the "How and Why" section of MACHINERY, January, 1907. This formula reads:

Tangent angular setting =

$$\frac{\frac{1}{2}\text{ taper per foot}}{12} \times \text{cosine}\,\frac{360 \text{ degrees}}{2 \times \text{number of sides in reamer.}}$$

Adjustable Reamers.

In order to permit the diameter of the hole reamed to be slightly varied from the standard size, adjustable reamers are used. These may be of two classes, such as are adjustable but still have the cutting edges composing an integral part of the reamer, as shown in Fig. 27, and those which have inserted blades. The former are usually employed in smaller sizes only, while the latter are commonly used in sizes from 1 1/4 inch up to 5 inches diameter. On account of the construction of the class of reamers shown in Fig. 27, the reamer cannot expand uniformly its entire length; when that is desired, the reamer with inserted blades must be selected.

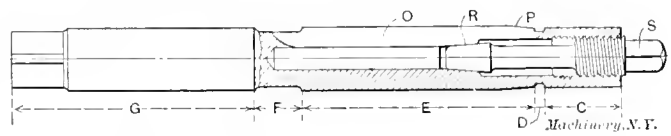

Fig. 27. Expansion Reamer.

Adjustable reamers are often called expansion reamers, and there is no real difference between the two kinds. If any distinction should be made, it would be advisable to call reamers of the type shown in Fig. 27 expansion reamers, as the change in diameter is actually effected by expanding the tool itself, while inserted blade reamers should be called adjustable reamers.

Referring to Fig. 27, the reamer shown is originally an ordinary hand reamer provided with a guide. The distance *C* represents this guide; *D*, a small neck or groove between the guide and the reamer body; *E*, the cutting edges; *F*, the neck between the cutting edges and the shank, and finally *G*, the shank. At the forward end of the cutting edges there is a small taper at *P*, the same as in ordinary hand reamers, and the diameter of the guide, which is not fluted, is in the same proportion to the full diameter of the reamer as for hand reamers.

The body of the reamer is hollow, and three slits are cut with 1/32-inch saw from the outside to the hole in the center. One of these slits is shown in the cut at *O*. The inside hole is tapered at *R*, and a tapered plug *S*, provided with a threaded part, serves as expander. The thread engages a threaded portion in the reamer guide, and, when the expander is turned so that the plug moves inward, on account of the taper at *R*, the cutting edges of the reamer are forced outward, a slight spring action being possible because of the slits being cut through the reamer body. The slits should extend into the neck, and end at the upper end of the guide, as shown. They should be cut in the bottom of a flute, so as not to impair the cutting edges.

Reamers of this type cannot be recommended for accurate work. It is evident that the expansion takes place opposite the tapered part *R*, and that the cutting edge is sprung up in an arc. The reamer will have no parallel cutting edges, and, unless the guide fits the original hole closely, will hardly be able to ream straight. For cheaper grades of work, however, the feature of a simple means of expansion may be deemed valuable.

Reamers of the inserted blade type were discussed in the July issue of MACHINERY, and it does not seem necessary to repeat the statements there made. In order to give an idea, however, of the dimensions which should be followed in

laying out any type of inserted blade reamer, Tables XXIII and XXIV are appended. The dimensions given in these tables are, of course, not intended to be followed too strictly, as varying designs may require modifications. The dimensions will, however, serve as a guide in laying out adjustable reamers, when required to be designed for special conditions, and will give an idea of the general proportions. They refer, of course, more particularly to reamers of a design similar to that shown in the article in the July issue, referred to above.

Inserted blade shell reamers should be ground with a back

TABLE XXIII. ADJUSTABLE HAND REAMERS.

$2\frac{3}{4}$	3	$\frac{1}{4}$	6	..	..	..	..

taper of 0.012 inch per foot. The shank of inserted blade hand reamers should be ground 0.002 inch smaller in diameter than the minimum size for which the reamer is intended.

The present article is the concluding one in the series of five articles on reamers which have been presented. It has been the purpose of the author to give such information as would be the most useful to the practical tool-maker. For this reason, the processes of manufacture, which the practical tool-maker is presupposed to be familiar with, have not been dealt with except in cases where reference to these processes seemed necessary to explain certain points, but the actual figures for dimensions, number of flutes, etc., have been the more carefully stated in every case, as there has never hitherto been published any systematized information on these subjects.

* * *

Not the least of the many notable applications of electricity in the arts which have effected substantial economies, is electric soldering. The gas-heated soldering iron was a decided improvement over the ordinary bit heated in a charcoal furnace, but it has faults very noticeable when compared to the electrically-heated iron. The flexible tubing, auxiliary air supply, waste heat and danger of poisoning by the escape of gas are all absent with the electric equipment. But aside from the convenience and flexibility of the system, the increased efficiency is in itself a deciding factor. A manufacturer of tin lanterns counted on five per cent of the day's output being "leakers" when using gas-heated soldering irons; with electric irons the percentage has dropped to one-half per cent, and the most of these defects are due to checks, cracks, and similar defects in the stock, largely caused by the forming dies. The practical result is that each man's daily output is increased nearly five per cent, with no added exertion; in fact, the conditions of working are easier than before.

THERMIT REPAIR OF STEAMSHIP STERN FRAME AND RUDDER POST.*

A remarkable repair was recently effected on the steamship *Corunna*, of the Canadian Lake Navigation Company, at Montreal. This vessel is of 1,296 tons register, 240 feet long, 35 feet beam and 21 feet in depth. In getting away from her pier in the Lachine Canal, the stern of the vessel was caught

Fig. 1. Rudder of Steamship "Corunna," showing new Stem Welded with Thermit.

by the current and swung against the stone walls of the canal, the shoe or skeg being broken off close to the heel, while the rudder post was broken at a point about eighteen inches from the top of the rudder. Owing to the serious nature of the injuries, it would have been necessary to tow the vessel to Cleveland, there being no adequate dry-dock in

Fig. 2. Showing Thermit in Shoe of Stern Frame, before Cutting Off Gate.

Montreal to make these repairs in the usual way, were it not for the fact that by the thermit process it is possible to effect such repairs without removing the stern frame from the ship or requiring the aid of machinery of any kind other than a compressed air blow torch and a few pneumatic tools. It was

* For other articles on thermit and thermit repairs see MACHINERY, March, 1901, "Some Future Possibilities of Aluminum," by C. Vickers; March, 1903, "The Thermit Process," by Frank C. Perkins, "The Use of Thermit for Repairing," and "Thermit and Its Possibilities"; December, 1903, "Lecture upon Thermit."

therefore decided that several thousand dollars could be saved by repairing the frame and rudder post with thermit, and the Goldschmidt Thermit Co., 90 West street, New York, was advised by telegraph to send an engineer to direct the operation.

On inspection it was found that the rudder post was broken off inside the tube, while the stern frame had been bent 12 inches out of line, the shoe being completely broken about 13 inches from the center line of the post. On account of the break in the rudder post being in an old scarf weld, fully 11 inches in length, it was not deemed advisable to attempt to

Fig. 3. Near View of Stern Frame Shoe Repair, showing Large Size Thermit Weld and Gate.

weld this again, so about 14 inches of the rudder post adhering to the rudder was cut off and a new piece of shafting, 8 feet long, was welded on in place of the old post, as shown in Fig. 1. In order to facilitate operations, the rudder was removed from the ship and the post welded on shore, this being done to prevent interference with the operation of welding the stern frame.

It was necessary to have a supply of compressed air in order to operate a gasoline torch and some pneumatic tools, so an old Westinghouse steam driven air brake compressor

Fig. 4. Showing Stern Frame Shoe after Gate was Cut Off.

was obtained and mounted on board ship, steam being piped from a donkey boiler. A receiving tank was placed on the edge of the dock and piped to the compressor.

With the apparatus in place, preparations were made to do the welding, the rudder being the first repair to be made. This was unshipped and welded in exactly two working days, the operation being in all respects similar, though on a smaller scale, to the method pursued in welding the stern frame. It is sufficient to say that the section which had to be welded was circular, 5¼ inches diameter, and was reinforced at the weld by a collar of thermit steel 8 inches long and 1 inch thick. For this operation 150 pounds of thermit, 25 pounds of steel punchings, and 3 pounds of metallic manganese were used. The results were extremely satisfactory, and when the riser and gate were cut off, the metal was seen to be of very fine grain.

The next operation was to straighten the stern frame, after which a series of holes were drilled along the line of the fracture, to provide for a free flow of thermit steel. As soon as this had been done, a collar of yellow wax was shaped around the fracture, the frame section being approximately 5 x 13 inches at the forward edge of the collar and 6 x 7 inches at the rear portion, while the section at the break was about 6½ x 7 inches. This collar was made 8 inches long with a middle ordinate of 1 inch; a sectional view would show approximately the segment of a circle. On the bottom, however, it was made only ¾ inch thick, in order that the draft of the vessel might not be made any greater than could be helped.

With the wax in position, a sheet iron mold box was placed around it, allowing for 6 inches of sand on all sides. Wooden patterns were constructed for a narrow gate and large riser, and provision was also made for leaving a small hole near the bottom of the mold, for the wax to run out when heated. After the mold was completed the flame of a strong gasoline blow torch was directed into this hole, and the heating continued until all the wax was out of the mold and the parts to be welded had been brought to a bright red heat. In the meantime a crucible containing 350 pounds of thermit, 70 pounds of steel rivets (1 inch x ⅜ inch in size), and 7 pounds of metallic manganese, was placed in position over the pouring gate.

It required about three hours to bring the sections to the proper heat, at which time the torch was removed, the hole at the bottom plugged up with a sand core, backed up with a few shovelfuls of sand, the thermit ignited in the crucible and the resulting superheated steel tapped into the mold, where it filled the space formerly occupied by the wax. The mold box was not removed for about 15 hours, in order that the thermit steel might become thoroughly annealed, but it was found, upon taking away the mold, that the weld was perfect in every respect, being inspected and passed on by Lloyd's surveyors, Capt. Reid and Mr. Calderwood. Figs. 2 and 3 show the thermit weld and large riser, which latter is characteristic of successful thermit repairs the same as of good steel castings. Fig. 4 shows the stern frame shoe after the riser was cut off.

The total time required for the two welds amounted to five working days, but there is no doubt that had the work been done in a properly equipped dry-dock, it could probably have been completed in three days or less.

* * *

We stated in a note in our December, 1906, issue that manufacturers of taps and cutting tools which cannot be ground after hardening did not consider it good policy to make these out of high-speed steel, on account of the high heat necessary when hardening, which caused the edges to fuse. We understand, however, that at the present time several firms are able to harden high-speed steel taps, hobs and similar tools in such a manner that the cutting edges are not impaired, and Wheelock, Lovejoy & Co., Boston, Mass., it is stated, have demonstrated that such hardening can be successfully accomplished by using a barium chloride bath in a standard gas-burning furnace. The investigations have been carried out in connection with blue chip high-speed steel, but equally satisfactory results may be secured with other high-speed steels. The application of barium chloride for hardening purposes was first developed abroad. Barium chloride in crystal form is placed in a crucible in the furnace, and melts into a bluish, milky fluid. When used as a hardening bath, the temperature varies from 2,000 to 2,300 degrees F., and very uniform results are claimed to be obtainable by this process; but the exact time during which each particular tool will have to be subjected to the treatment in the hardening bath will have to be established by experiments. It may be mentioned, however, for the guidance of those who are to use this process for hardening, that, according to the *Iron Age*, a ⅝-inch tap is subjected to a temperature of 2,100 degrees F. for four minutes when hardening by the process mentioned.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

DECEMBER, 1907.

PAID CIRCULATION FOR NOVEMBER, 1907, 24,096 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2 50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

TO MAKE MACHINERY OF PERMANENT VALUE.

Some of our readers seem to be under the impression that the frequent references to previous articles on machine design, etc., lately appearing in the form of foot-notes, were made to advertise back issues for sale. This is a mistake. We have scarcely any copies for sale, and, not infrequently, it has occurred that an issue was entirely exhausted before the next month's issue was published. The cost of clerical labor, storage, etc., makes it unprofitable for publishers of trade papers to print more copies than are required to meet the immediate demand. No; the reason for making references to what has gone before is simply to make MACHINERY of greater permanent value to those who keep its files. We feel that the reader who does not keep a file loses a large part of the value of his subscription. The subject which has no importance to you to-day may be what yields your bread and butter next year, and any literature on it will be very valuable. The text-books are indispensable, but they cannot cover everything, nor can they keep up to date. The side lights thrown on certain features of design by the published experience of contributors are most valuable, often being of a nature that the text-books ignore. There, too, is the matter of historical record of machine tool growth. The columns of MACHINERY present a most complete record of its development—a record that no one interested can afford to lose.

To those who feel that they cannot afford the cost of a permanent binding by a book-binder, we would suggest the use of a Shipman binder, 9 x 13 inches, price, about 80 cents. This binder will hold two years' issues. Place the indexes in front of each volume, and separate the two volumes with a sheet of heavy colored paper. In this way a large amount of valuable material will be put in shape for instant reference, and at a very low cost.

* * *

RESULT OF MECHANICAL FILE TESTING.

Something more than two years ago a British machine was developed for mechanically testing files and autographically recording the result. The autographic record shows the cubic inches removed by a file from a standard test bar, the number of strokes taken, the period when the file cuts most effectively, and when it ceases to cut because of being worn out. The publication of comparative results obtained from tests made on files purchased in the open market created a sensation among file makers and file users. The difference between the best files and the poorest files was so great that a manufacturer clearly could not afford to use the poorest files, even if supplied free of cost. This result, of course, merely confirmed what every intelligent shop manager already knew, but the mechanical record of the actual difference in cubic inches removed and strokes made was a more definite proof.

The valuable result of the file testing machine's work is the great improvement that has taken place since the file maker was given the means of accurately testing his product. At the advent of the file testing machine, the best files were able to remove about 12½ cubic inches, and the best files were about twelve times as effective as the poorest. In 1907, two years after, the file makers had so improved their product that the best file tested removed at the rate of eight cubic inches per 10,000 strokes, and 55 cubic inches of cast iron with *one side* of the file, or about 4 2/5 times the total removed by both sides, by the best files of two or three years ago.

If it was possible to produce such a remarkable improvement in the hand file, simply because of the use of an adequate testing appliance, what might be the result in many other lines of manufacture if rigid efficiency tests were impartially carried out? We all have learned that efficiency, so-called, is only comparative, and that no one can say anything has reached ultimate efficiency. Now that attention has been called to that simple yet perplexing tool—the file—it is entirely possible that its manufacture and action will not only be greatly improved but changed. In fact a radical change in file making has already been made by one British maker, which promises great improvement.

* * *

THE GROWING INEFFICIENCY OF WORKMEN.

A discouraging aspect of present industrial conditions is the inefficiency and general slackness of workmen in the building trades. The lack of the old-time pride in the mastery of a trade is very noticeable to one coming in contact with carpenters, plumbers, tinners, and others of the house-building trades. Not only do these workmen, in a great many cases, care nothing for their trades, but they rather pride themselves on being able to draw full pay for a minimum of knowledge and skill in their business. Not long ago the writer engaged a so-called carpenter to do a trifling job of interior work. The material cost at most 50 cents, and the time required was, say, two hours. The charge for the service was more than a first-class carpenter got for a full day of ten hours, ten years ago. The worst of it is that the job was of a grade that an amateur should have been ashamed of. This case is not merely individual; it is representative of a general state that is of grave import. The workman tries to do as little as possible for a maximum wage. Does he improve his condition by such action? No; on the contrary the general cutting down of productive capacity is one cause of the increase of cost of all building construction. Rents are higher because masons, brick-layers, carpenters, plumbers, tinners, roofers, painters, decorators, produce less. The consequence, of course, is a very substantial increase in the cost of living to all, for all must help pay.

The endeavor to better industrial conditions by reducing production is analogous to trying to lift oneself by one's boot straps. It is impossible to improve general conditions by reducing efficiency. *We believe in high wages and a full day's work.* The plumber who spends half a day putting a washer into a kitchen faucet is an encumbrance. He is essentially dishonest, and is a discouragement to the honest workman who would render honest service to his employer. It cannot be gainsaid, however, that the greed which would deny to workmen a just share of the profits accruing from their industry and general proficiency in manufacturing is largely responsible for creating the "ca-canny" spirit in America, a spirit which is the curse of Great Britain and which is reducing that country to a low level in the industrial scale. What will be the outcome here if there is no change for the better?

THEORY AND PRACTICE.

Many writers upon mechanical subjects, as well as many persons directly employed in mechanical work, treat the words theory and practice as if the ideas which these words signify were to be considered strictly apart from each other. They seem to consider that a distinct, clearly defined line can be drawn between the territories of theory and practice. It is a common error to speak of theory and practice as if they were in opposition to each other, the expression "right in theory, but wrong in practice," not being at all uncommon.

In the first place, there is really no defined line between theory and practice, and many a case could be cited where the theory of yesterday is the practice of to-day. Theory is nothing but an analysis of the laws which must be followed in practical work if that work is to be correctly carried out; and practice simply means the application of theory to the work carried out. Theory is nothing but common sense logically applied, and practice is the use of theory in productive work. In the second place, theory and practice can never disagree. If they do, then either the theory is incorrect, there is a flaw in its logic, and it ceases to be acceptable, or the common practice is wrong, and should be corrected to agree with the theory, logically arrived at by the application of common sense. While it is true that theory without practice would be useless, if it could be comprehended as existing in its extreme meaning, so practice without theory becomes next to useless, in our time at least, for it would signify only the rudest form of unskilled labor. While this is rather an unprofitable subject to discuss, still it is well to impress the idea that theory and practice cannot be considered apart, and that when it is done, it is liable to cause a confusion of ideas.

On the other hand, it is true that one may, with propriety, speak of things as being theoretically correct and commercially correct; the latter expression then simply signifying that a certain article, while produced in a way that really is not the best practice if one desires to arrive at extreme accuracy, still is such as to answer the purposes for which it is intended. Thus a screw thread may seldom be theoretically correct, but it may be commercially near enough to the exact form to serve its purpose. But this usage of these words does by no means imply that theory and practice are in opposition to each other. They are complements of each other, just as the work of the brain complements that of the hand. No man ever worked entirely by his brain, just as no man ever worked only by his hands. Brain and hands coöperate constantly, although in different degrees. So also do theory and practice. And in the same way as any work done mainly by bodily labor is always the better done the more the element of brain enters, that is, the more common sense is used, so also, the more true theory used in practical work, the better the result; for, as one of our European contemporaries says, *nothing is more practical than theory.*

* * *

THE FAILURE OF THE SMALL CAPITALIST.

One of the notable features of a period of great prosperity, such as that we have experienced, is the large number of new firms of comparatively small capital which spring into being at just about the time the wave of enthusiasm reaches its height. Most of these enterprises are wrecked when the wave breaks on the jagged rocks in the succeeding recession. They are short-lived at the best, and their increase forms one of the surest of the danger signals announcing the coming of reaction. The cause of this phenomenon may be coolly and dispassionately studied, though a vast amount of personal suffering is involved in the individual cases of which it is composed.

The condition is readily explained. When the tide of business begins to rise, following a preceding ebb of business, it finds men of small means with their resources nearly exhausted by the strain of the stringency through which they have passed. Men of great capital and foresight, however, carefully discerning the sign of the times, are gradually extending their operations, adding to their capital from time to time as fast as they can make money from their business, or borrow it from the banks. Business increases rapidly by such operations as these, and the new-found prosperity begins slowly to work its way downward from class to class, until finally the working man himself finds that his wages are somewhat larger than they have been for some time, and he is at last able to lay up a little store from the surplus left, over and above his living expenses. If the individual working man has a fertile brain and a little energy, this unwonted surplus acts as a stimulant, exciting his imagination, and urging him on in the venturous path of engaging for himself in a small way in some form of business in which he believes he can make a success.

Now, in all probability, at about the time this resolve has been reached, the climax of the good time has already been attained. Men of larger means and broader outlook have already begun to draw in their lines closer, fearing the coming stringency, and all of this is done so quietly and silently that the small capitalist never realizes that the best is passed, and the worst is yet to come. From such conditions as these result the great crop of pitiful failures which have marked every period of depression the country has passed through. It would seem wise for the small capitalist to store up his enthusiasm within his breast, and his money in the savings bank, until the next depression is passed and the country has again laboriously commenced to climb to a succeeding period of prosperity. It will take more courage to start in business then, but it will be an evidence of greater wisdom.

The acute thinker, on meditating the cause of this phenomenon, will easily conclude that it represents only one more example of the truth of that motto we sometimes see displayed for sale in the picture store windows: "Ain't it —— to be poor!"

* * *

LIABILITY OF EMPLOYERS.

In connection with the editorial entitled "Liability of Employers" in the November issue of MACHINERY, engineering edition, it may be deemed proper to quote some figures as to the average amount of expense due to accidents and injuries to employes, for which employers are held liable. The Fidelity and Casualty Co., of New York, has compiled some figures on this subject in its *Monthly Bulletin.* These figures cover the years from 1893 to 1900, and refer to the experience of the principal employers' liability insurance companies. It appears from these figures that, taking the United States as a whole, and the average of all classes of occupations, the average loss per $100 of wages paid was as follows:

Year.	Average Loss through Employer's Liability per $100 of Wages Paid.
1893	25.5 cents.
1894	27.6 "
1895	28.5 "
1896	29.9 "
1897	31.9 "
1898	33.6 "
1899	37.7 "
1900	36.2 "

The increase seen in these figures for late years does not depend on greater number of accidents, but is, undoubtedly, mainly due to new legislation tending to increase the liability of employers. The figures given express the average of all occupations, and it is stated that the figures are larger than those which concern manufacturers only would be, as the losses are greater for contractors than for factories. On the other hand, the figures given represent actual losses, and not premiums which are paid to the insurance companies. These are by necessity higher, but it has been estimated that 40 cents per $100 of wages paid would, in a factory of the ordinary class, cover the cost of insurance. In other words, the expense involved to insure a man earning, say, $600 a year would be $2.40 per annum, or less than 0.8 cent per working day. Considering this small amount, and as the insurance is, in fact, finally paid by the employes themselves, through their productive labor, it may well be repeated that employers should not place themselves in opposition to legislative measures of the kind referred to. The effect on the industries of the country as a whole cannot help but be greatly beneficial, and the movement for increased interest in safety appliances will receive all the more recognition.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

Consul J. I. Brittain, at Kiel, suggests that, when writing to German firms, American business men should enclose sufficient postage to pay for replies. If one has no German stamps, he should enclose American 5 or 10 cent stamps. This tends to create a better feeling in the matter.

A correspondent to the *Times Engineering Supplement* states that the German government railways have a fund for payment of premiums to employes who invent any appliance which may be useful in railway practice, and that during the last traffic year $3,700 was paid on that account to employes.

In our engineering review of last month we made mention of the very extensive use of American machine tools in Great Britain. In connection with this, it is of interest to note a statement made by Consul F. I. Bright, of Huddersfield, England. According to this statement, two large Huddersfield firms are equipped to an extent of 75 per cent. with American machines.

It has been claimed that the highest speed ever attained by an automobile was that accomplished at the Brookland motor track in England, where a 200-horse-power Darracq car attained a speed, for a short period, of 115.4 miles per hour. However, at Ormond Beach, Florida, on January 26, 1906, a mile was covered at a speed of 127.5 miles per hour, and at Ostend, Belgium, a speed of 117.5 miles an hour was attained for one kilometer, July 14, 1906.

It has been stated officially that the *Mauretania*, sister ship of the *Lusitania* frequently referred to in our columns, during her trials covered 300 miles at an average speed of 27.36 knots, and that she covered the full course of the trial run, 1,200 miles, at an average speed of 26.03 knots. These are by far the highest speeds ever heard of in connection with ocean liners. The record speed 27.36 knots equals a speed of about 31.5 statute miles per hour.

Some experiments by Prof. Ira Hollis, of Harvard University, says the *Magazine of Commerce*, show that cork has a distinct value for increasing the frictional resistance of metallic surfaces in contact. The coefficient of friction of materials usually used for brakes—leather or metal—is only half that of cork. Cork inserts may be used to advantage on the brakes of street railway cars, and also on pulleys to increase the grip of the belts. It is found that cork wears down no faster than the solid socket in which it is embedded. Its frictional resistance, apparently, is but slightly diminished by oil or moisture.

Attempts have recently been made at Stockholm, Sweden, says *Engineering*, with a view of devising a simple method of distinguishing between ordinary tool steel and the high-speed variety. The latter contains chrome and tungsten in considerable quantities, and as these elements form colored compounds with certain reagents, it was hoped that it might be possible to determine if a given sample of steel was of the common or high-speed variety by applying to a polished surface of it an indicating paper, previously moistened in a suitable reagent. No success was, however, attained, but it was afterward observed that while ordinary tool steel dissolves rapidly in dilute nitric acid with a copious production of nitrous fumes, high-speed steels are unattacked, at least so long as the content of chromium does not fall below four per cent.

In an article in the *Electrical Review* (London) the author discusses the question of electric *versus* hydraulic elevators. From the point of safety, it is contended, there is no difference between these two classes of elevators, if made by responsible firms; but a great difference is claimed as to running expenses. If power for both elevators be purchased from a power company, when there is but one elevator, the cost of hydraulic power is about $40, electric power, about $15. If there are several elevators in the same building, the charges for water power are reduced, and the figures then are $20 for the hydraulic elevator, and from $15 to $6 for the electric, according to the price of electricity. The author finally quotes Sir William Preece as saying that the London post office has found that the relative costs of working electric and hydraulic elevators are as one to five.

We mentioned in our engineering review of last month the success of steam turbines in a recently built German torpedo boat. It is now reported that the German government has placed a contract with a prominent ship-yard in Germany for the building of a large cruiser which will cost between $8,000,000 and $9,000,000. The new vessel will be fitted with Parsons turbines, a decision which shows that the prejudice which formerly existed in official quarters against this type of machinery is being overcome. The remarkable superiority in speed attained by the turbine-driven torpedo boat previously mentioned, over a sister vessel fitted with reciprocating engines, and the trial performances of the turbine cruiser *Stettin*, which developed a speed of 25.8 knots, have evidently fully convinced German navy experts that the turbines are superior, at least where high speed is the primary object.

According to the *Times Engineering Supplement* of July 31, one of the interesting exhibits at the Ironmongery Exhibition recently held at Islington was a new brazing flux, called "castolin," the invention of Messrs. Wasserman & Co., Lausanne, Switzerland. It is a preparation for brazing cast iron. The preparation is in the form of paste, and is rubbed into the pores of the broken surfaces. The pieces are then accurately joined together and tied; they are placed in a fire, and when as warm as the hand can bear, more of the castolin is rubbed into the grooves of the fracture. It is then covered with borax and "castolot" solder, and is placed in the fire again until red hot and the solder runs freely, when it is allowed to cool slowly and the piece is polished. It is said not to require a special plant, is always ready for use, contains no oxides, can be applied by any one used to ordinary brazing, is unaffected by time, and will not break again in the same place.

A recent report by a committee appointed by the British Board of Trade indicates, according to the *Mechanical Engineer*, that British manufacturers do not place great confidence in large industrial exhibitions. The same sentiment among German manufacturers recently gave the death-knell to an organized movement for a large world's fair in Berlin, to be held in 1913. American manufacturers, judging from the slight interest taken in the Jamestown exhibition, evidently have come to a similar conclusion, that is, that the matter of great, or so called international exhibitions has been largely overdone. After the failure of the Jamestown exhibition to arouse any interest worth mentioning, it is to be hoped that our government will, for a long time to come, refrain from aiding schemes of this kind, which so little benefit our industries. Specialized exhibitions on a smaller plan are of far greater value to both the manufacturer and the public.

Some newspaper writers like to tell a great deal about Europe being rather "slow" as compared with industrial America. A note in *Engineering*, however, seems to indicate that at times they perform over there some feats that have hardly ever been equalled here. The fitting of the machinery to the steamship *Peiho* by Barclay, Curle & Co., Ltd., is probably a record in its field. The machinery consisted of triple expansion engines having cylinders, 26 inches, 45 inches, and 76 inches in diameter with 54 inches stroke, and four single-ended boilers working at 200 pounds pressure. The boilers

were put in between 6:30 and 8:30 P. M., a Friday afternoon. The whole of the work in the stoke-hole, including the fitting of funnel and ventilators, was completed in less than eight hours on Saturday. On Monday morning the work of putting the engines in place was started, and at 5 P. M. in the afternoon the work was completed. This, it must be admitted, would make even our own "hustlers" work hard to equal.

A project of daring dimensions has, according to the *Oesterreichische Wochenschrift für den Oeffentlichen Baudienst*, been considered by the International Navigation Congress. This project involves no less an undertaking than a trans-Alpine waterway, consisting of a canal from the Danube at Vienna to the Adriatic at Triest. The initial expenditure has been assumed to amount to from $120,000,000 up to as much as $300,000,000, but as this waterway would be a link in a chain of waterways connecting the Baltic with the Adriatic, it has been estimated that it would accommodate an enormous freight traffic. The canal would have to be constructed with twenty-two tunnels of a combined length of nearly six miles. There already are, in Europe, some large canal tunnels, notably one on the Marne-Saone canal, where one tunnel is nearly three miles long and over 700 square feet in section, and one on a canal, at Condes, which is about 1,000 feet long and over 1,100 square feet in section. The cost of these tunnels is at the rate of about $1,000,000 a mile.

Consul-General R. J. Wynne, of London, in referring to the new British patent law, which goes into effect on January 1, 1908, quotes the following, which will be of direct interest to American machinery builders: If a patented article or process be manufactured or carried on exclusively or mainly outside the United Kingdom, then, unless the patentee prove that the patented article or process is manufactured or carried on to an adequate extent in the United Kingdom, or give satisfactory reasons why it is not so manufactured or carried on, the comptroller may make an order revoking the patent forthwith, or he may make an order revoking it after a specified interval if the patented article or process be not in the meantime adequately manufactured or carried on within the United Kingdom; but in the latter case, if the patentee give satisfactory reasons for the failure so to manufacture or carry on within the prescribed time, the comptroller may extend the period by not more than one year. To obtain such an order, application must be made to the comptroller at least four years from the date of the patent and one year from the passing of the act; moreover, any decision of the comptroller is to be subject to an appeal to the High Court, and no order is to be made that will be at variance with any treaty, convention, arrangement, or engagement with any foreign country or British possession.

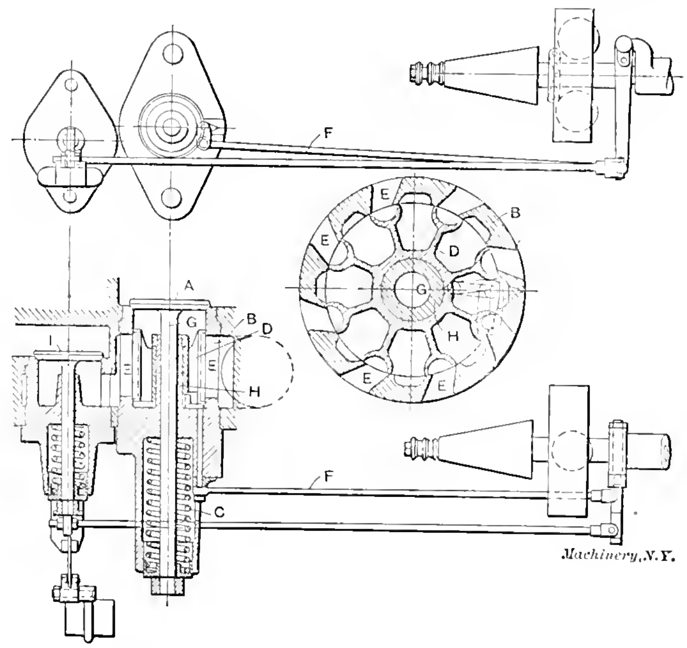
In an article on making steel and killing men by Mr. William Hard, published in the November issue of *Everybody's Magazine*, a terrible indictment is found against the managers of steel-making concerns for great loss of life and limb. During the past year, forty-six men were killed in the South Chicago plant of the United States Steel Corporation, and in no case was there a great casualty; there were forty-one separate accidents resulting fatally. But this is not all. One-hundred-eighty-four were disabled for at least thirteen weeks, and three-hundred-ninety-eight were disabled permanently. Of minor accidents, there were many hundreds more. The prime cause of these accidents is contributory negligence on the part of those injured and their fellow workmen. For example, it is a common practice to lift a slag-pot with the crane chains hooked to the rim of the pot rather than to lugs with which these pots are supposed to be provided. But, avers the author, if the company was made liable to pay a flat fine of $20,000 for every fatality, it is a moral certainty that slag-pots would not be lifted by their rims. Why? Because the company would make it a point of business to insist that this and all other similar dangerous practices be stopped. Now its business is making steel and the safety of human life is merely a secondary consideration. It is cheaper to kill and maim than to provide against accidents.

GOVERNING DEVICE FOR INTERNAL COMBUSTION ENGINES.

The Mechanical Engineer, October 19, 1907.

Internal combustion engines are commonly governed by throttling the admission of gas and air into the cylinder in such a manner that when working at full load the working fluid is admitted freely into the cylinder and practically a cylinder full is drawn in to form each working charge. As the load decreases the throttling of the admission causes a less quantity to be drawn in, and less than a cylinder full forms the charge for the next impulse of a reduced power, the degree of the throttling and the quantity drawn in to form a charge being varied by the governor.

An arrangement for obtaining the desired amount of throttling is shown in the accompanying cut. The admission valve *A* is arranged in a casing *B*, and is operated by a cam and lever, moved inward by means of the lever, and returned to its seat by means of a spring *C*, the opening of the valve *A* taking place during each suction stroke. The inner portion of the casing *B* is arranged with a number of parallel slots *E* through which the working fluid is drawn before passing



Governing Device for Internal Combustion Engines.

through the valve *A* into the cylinder. A light rotary valve *D* is provided, having as many arms as there are slots *E*, the outer edges of these arms being spread out so that in one position the slots are entirely covered. When in this position, although the admission valve may open in the ordinary manner, only as much of the working fluid can gain admission to the cylinder as will be allowed by leakage past the edges of the outer portions of the rotary valve *D*. The valve *D* will be moved into this position by the governor only when there is a light load on the engine. Should the load increase, the governor, by means of the rod *F*, rotates the valve *D* and opens the ports *E* to any desired extent. The outer end of the arms of the rotary valve *D* are hollowed so as to present only small fitting edges, thus reducing friction and risk of sticking. The ports *E* also have narrow fitting edges for the same reason. As it is not desirable to carry this method of governing down to very light loads, it is worked in combination with the ordinary hit-and-miss governing which comes into operation whenever the engine runs on very light loads, as indicated in the cut. It is not necessary therefore that the rotary valve *D* should do more than throttle the working fluid to a moderate extent, and it may therefore be left free in its movement, thus allowing the governor to move it with ease. The rotary valve *D* may either rotate upon the spindle *G* of the admission valve *A*, or upon a sleeve *H* through which the spindle of the admission valve moves, this latter arrangement being shown in the cut. The governor may be arranged so as to operate the hit-and-miss governing as well as the partial rotation of the valve *D*, as is also shown

TESTS OF EMERY GRINDING WHEELS.

Mitteilungen über Forschungsarbeiten, No. 43, 1907.

On behalf of the Verein Deutscher Ingenieure, and with the assistance of Messrs. Ludwig Loewe & Co., of Berlin, Germany, Dr. G. Schlesinger has conducted some tests on the durability and safety of emery grinding wheels. One of the objects of the research was to demonstrate that the regulations laid down by the Prussian Government in 1897 as to the maximum circumferential speed of such wheels—*viz.*, 82 feet per second—should be relaxed. The manufacture of emery wheels had at that time been taken up by incompetent and inexperienced men, and serious accidents had occurred, so that restriction was needed. The emery wheels and the grinding machines have, however, been so much improved of late that a revision of the regulations appeared opportune.

Dr. Schlesinger has, in his trials, adopted workshop conditions, except that he disregarded the safety regulations prescribed by law. Most of the twenty-eight wheels experimented upon were not especially ordered, but taken from the stocks of good firms. The wheel and the test-piece, of cast iron, wrought iron, or steel, were both rotated, and the experiments continued during ten hours for two or four days. The experiments lasted three months. No accident occurred, and in no case did the wheel fly apart, although the speed was raised to the maximum which the driving electric motor permitted. Under the continued strain the wheels began to crumble, emery grains breaking off. The wheels were cylindrical, 20 inches in diameter and 2 inches in width, and were revolved at speeds of 82, 99 and 115 feet per second. The test-piece was fed along at different rates, as a rule ½ to 1 inch per revolution of the test-piece, which was revolving at a maximum circumferential speed of 99 feet per minute. In extreme cases the grinding wheel absorbed 30 horse-power, while in practice 6 horse-power will hardly be exceeded.

The emery wheels were run wet during the experiment, and those wheels which allowed the water dripping upon them to percolate as if they were porous sieves answered, on the whole, best. In this respect the cement used for binding the emery grains is very important. In order to assist the purchaser, Dr. Schlesinger suggests that every emery wheel should bear a notice stating whether the wheel is to be used dry or wet, that it has stood a circumferential speed of 165 feet per second, but that it should not be used at any speed exceeding 115 feet per second.

INDUSTRIES OF BIRMINGHAM.

Derrick's British Report, August, 1907.

Birmingham is the third city in England, and her population has risen in a hundred years from 90,000 to 500,000, but within a distance of twelve miles from the town hall there dwell over a million people. It is built on an elevation, the huge teeming workshops, factories and warehouses, being in the lower parts of the town. It is the principal center of metal manufacture, the industry consisting of the production of an infinity of articles in gold, silver, brass, steel, etc. The manufacture of small arms has become a very important department of enterprise in recent years, hundreds of thousands of gun barrels being tested annually at the local gun-proof offices. The manufacture of engines and boilers has allocated to it a premier place in Birmingham's characteristic industries, the largest works being in a district known as Soho, lying to the northwest of the city, where Watt and Boulton made the first steam engines ever employed in British industry. There are extensive and flourishing chemical works, and the cycle trade competes with that of Coventry, the chief cycle center of Britain, distant but a few miles.

Birmingham has been termed the workshop of the world, as it has a greater variety of manufactures than any other city. These comprise iron and brass founding, rolling, stamping, plating and drawing of metals; manufacture of jewelry; pearl buttons; hooks and eyes; studs; cycles and cycle fittings; railway wagons and carriages, coach and railway lamps; cricket bats and sports outfits; perambulators and mail carts; wire; steel pins; metal bedsteads; art metal work; fenders; coaches; air guns and rifles of every kind; tools and machines; keys, screws, bolts, locks; plate glass; fancy leather goods; spectacles; umbrellas; furniture; gas and electric fittings; electro-plating and gilding; bell-founding; fancy aluminum goods; greenhouse and garden requisites, etc.

A great bulk of the bronze and copper coin of Britain is coined in the city for the Imperial mint. Birmingham also mints an important value of similar coin for other countries. The city also claims to be the largest hardware manufacturing center in the world. Within the place and its environs there is made everything from a pin to a hundred-ton gun, a pagan brass god to an anchor for a man-of-war. Birmingham has the distinction of being the world's metropolis for over a dozen distinctive branches of manufacture. The epithet "Brummagem," which at one time conveyed the idea of something cheap and unreliable, no longer has force or point.

A feature connected with the prosperity of Birmingham, and one that distinguishes it from other large industrial centers in the kingdom, is the absence of any marked contrast in the wealth of the people. In Manchester, Liverpool or Leeds you find merchants or manufacturers of immense wealth; a numerous and affluent middle class; the operative earning masses with sufficient to live in comfort and save money, the scale terminating with a sprinkling of shiftless, improvident non-productive people. Birmingham has been described as a place of small fortunes, the meaning being that there are more examples of the skilled mechanic or other operative who has, through some special knowledge of a branch trade or minor industry tributary to a large enterprise, succeeded in starting out in business as his own master and prospering therefrom. For instance, a large manufacturing concern employs in the building or construction of, say, a machine or other complex production characteristic of Birmingham, an infinity of processes, parts of structure or methods of treating material. It is competent for the mechanic or other artisan, who formerly undertook the mentioned work as an employe, having saved, or in other ways accumulated, a small capital, to establish himself on his own footing, his best customer not infrequently being his aforetime employer.

For example, suppose that a man has been engaged for years as an employe in turning out the bosses or the small rollers for bedsteads. The material and the necessary machinery perhaps are not expensive; the chief items of stock-in-trade are the skill and knowledge of the artisan himself; so that the whole circumstances are such as to enable the man of modest capital to become a master. Birmingham is noticeable for the prevalence of this class of manufacturer—the man of small fortune made out of a tributary industry.

THE PRESENT POSITION OF THE GAS ENGINE.

Paper by Mr. Dugald Clerk, read before the British Association.

In this paper the author first reviews the present condition of the gas engine industry in Great Britain. Engines of small and moderate powers are built in large quantities, and the principles that have to be followed in their design have been thoroughly investigated, and a type, almost standard, has been arrived at. The author understands small and moderate power gas engines to be those with less than 100 horse-power per cylinder. At the present time, about 300 such engines are turned out in Great Britain per week. These engines are recognized to be as reliable as the best steam engines of similar dimensions, and to be more economical. The small engines mostly use coal gas, and the larger, producer gas. With regard to large gas engines, British engineers have assumed the conservative attitude (and so, as we know, have American manufacturers as well), but experience in the design of larger units is constantly being acquired. English designers have always felt the desirability of keeping down cylinder dimensions as much as possible, on account of a general recognition of the fact that there are practical difficulties with large diameter cylinders, due to unequal expansions in the cylinder metal resulting in cracking, and also because of the appreciation of the fact that increase in cylinder dimensions and other details of the unit require an expenditure in metal and workmanship, the amount of which grows in a proportion having a far greater acceleration than the increase of the power obtained. The two main problems met with in large gas engine design may be stated as follows. The one is to build engines

of large power which will be reliable and be able to run economically for long periods without breakdowns, and the second is to be able to build such engines at such a cost as to enable them to compete effectually with steam engines, even in the matter of first cost. The first of these problems has been satisfactorily solved on the European continent, but it has been recognized that the solution of the first problem has involved weights of material and cost of construction which have almost left the second problem out of consideration. The author stated as his personal opinion that he did not think that the tremendous units of gas engines which of late have been designed on the Continent were commercially desirable, and he thought that there were difficulties preventing a successful competition of gas engines with steam engines of greater power than about 500 horse-power, excepting in cases where the gas engines could be operated with blast furnace gas, in which case the cheapness of the fuel made these engines desirable. If gas engines are to be run with producer gas, the fuel is rather expensive for large units, if it has to be produced out of anthracite, and no really satisfactory producer has been constructed for producing gas from bituminous coal.

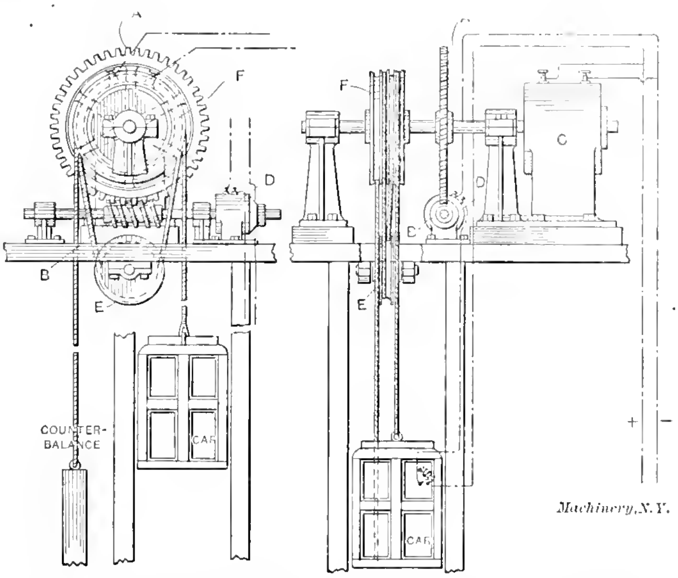
One of the main difficulties in the design of large gas engine cylinders is the contradictory conditions required for obtaining sufficient strength, and at the same time permitting the cooling of the cylinder. The enormous pressure in the large units require thick castings, but, in order to allow the heat to be carried away from the cylinder walls to the water in the water jacket, thin castings are called for. Engines of small dimensions do not present this difficulty, but where the metal is required to be about three inches thick in order to resist the internal pressure, the difference between the temperature on the inside of the cylinder and on the water side becomes serious, and great stresses are set up in the walls, which finally lead to the cracking of the casting. It has been found that cylinders 50 inches in diameter are too large in ordinary gas engine design, and nothing but the highest skill in designing, and the greatest care in choice of material, enable such cylinders to withstand, for any length of time, the severe stresses to which they will be exposed when in use.

[In this connection, it may be proper to call attention to some figures in regard to the operation of gas and steam engines as stated in a late issue of the *Practical Engineer*. Here the author, in discussing the commercial efficiency of high power reciprocating steam engines compared with that of gas engines for driving electric generators, points out that the efficiency of the gas engine, unlike that of the steam engine, does not increase in proportion to the increase of power, and that above a certain power, the cost of gas engines, per horse-power produced, is almost independent of the number of units adopted. If, therefore, a plant of 4,500 horsepower be taken as an example in order to make a comparison between two types, while the steam engines may be properly made in say three units each of 1,300 horse-power, the best results for gas engines may be obtained with six units of 750 horse-power. The following figures tend to show that a gas engine installation is the cheaper, as the cost per kilowatt hour, including depreciation and working expenses, for the steam engines varies between 0.524 cent and 0.742 cent, while for gas engines supplied with high-temperature furnace gas, the same cost would amount to only 0.178 cent, and that for a gas engine with producer gas supplied with coal at $3 per ton would be 0.406 cent. Of course, these figures refer to British conditions. The figures for American conditions would surely be considerably higher, but there is no reason why there should be any difference in the proportion between the costs of the steam engines and gas engines.]

HIGH-SPEED ELEVATORS.

At the regular monthly meeting of the American Society of Mechanical Engineers, held November 12, Mr. Charles R. Pratt presented a paper on high-speed elevators in which he called attention to certain dangers existing in gearless 1-to-1 traction electric elevators as now built, and described the construction of his new elevator machine, designed to overcome the dangers pointed out. The type of elevator selected for the new Singer Building and the tower of the Metropolitan Life Insurance Building, is of the older gearless 1-to-1 traction type, the driving mechanism being a motor located over the hoistway with a traction sheave and a brake pulley mounted on its armature shaft. The ropes from the car pass over the traction sheave down under an idler sheave and again over the traction sheave, thence to the counterbalance, thus giving two half traction turns over the sheave to drive the car and counterbalance. The accompanying cuts, Figs. 1 and 2, illustrate the general scheme so far as the arrangement of the sheaves and motor is concerned.

The diameter of the traction sheave is about 40 inches, which is the least permissible for proper wear of the size of ropes used. The diameter gives a circumference of about 10½ feet. Running at normal speed a motor of about 50 horse-power is required to handle a net load of 2,000 pounds, lifting at a speed of 600 feet per minute. However, if it runs at the low speed of 57 revolutions per minute a motor of about 200 horse-power size, cost and weight will actually be required. The loss of motor efficiency, however, is more than compensated for by the elimination of friction. This elevator



Figs. 1 and 2. Elevator Machine of the Type to be used in the Singer Building, showing Pratt's Safety Device, which is not part of that Installation.

machine is a product of elimination throughout, all unnecessary frictional parts having been discarded, and it eliminates:

a. Friction of worm, spur, screw or rope and sheave gearing.
b. Excessive size of winding drums.
c. Dependence upon automatic limit stops.
d. Inertia of large moving parts of metal and water in hydraulic elevators.

Experiments made by the author on this form of traction rope drive using iron wire hoisting ropes running in smooth round grooves in the traction sheave with from 1½ to 7½ half traction turns demonstrated that the least traction obtained is with new dry ropes on new dry grooves. After considerable use there is not 5 per cent difference in traction between a dry rope and a rope flooded with lubricant. Thus, the fact is established that if this elevator will handle its full load when first started with new ropes, it will always handle its full load safely.

This type of elevator has two distinct advantages over all others, being, unlimited rise and safe normal limit stops. Its unlimited rise is obvious. Its safe normal limit stops are due to the landing of the car or counterbalance on buffers. When either the car or the counterbalance reaches the bottom of the hoistway the tension on its rope leading to the traction sheave is so reduced that all traction is lost and the motor and sheave can keep on revolving with no further travel of car or counterbalance.

The new Singer Building and the Metropolitan Life Insurance tower call for a speed of 600 feet per minute at a rise of 500 feet and over. The selection of the elevators of the Metropolitan Life Insurance building was referred to a most distinguished board of engineers, *viz:* Messrs. Mailloux, Knox, Spangler, Knight and Duenkle, and the gearless 1-to-1 traction elevator was selected. The author then stated that although

the gearless 1-to-1 traction electric elevator has been used in high-class passenger elevator service but a few years, its success proves the merits indicated in theory. There have been no accidents to suggest danger, but in his opinion there has been two most important elements of safety neglected, *viz:* positive speed control and holding power. The brake pulley, being of the same or but little larger diameter than the traction sheave, must have a frictional resistance at the brake shoes, when the brake is on, equal to the net load. The brake and motor are alternately deprived of their motive and holding power every few seconds. Should one happen to let go before the other takes hold, the car falls free to the bottom of the hoistway unless checked by some safety device. There is no positive means to hold a car or prevent it attaining a dangerous speed.

Mr. Pratt's patent No. 865,205, dated September 3, 1907, is designed to take care of these danger elements. The safety feature consists briefly of a worm-wheel *A*, Figs. 1 and 2, mounted on the armature shaft. Meshing with this worm-wheel is a worm *B* driven by a small auxiliary motor *D*. The main and auxiliary motors are worked from a common controller, and start and stop together. The pitch of the worm is such that the worm-wheel cannot over-run. If the small motor does not run, the main motor cannot turn the armature shaft. The effect is obvious. The auxiliary motor must run in step with the main motor, although it does little or no actual work in lifting or lowering the load. It simply operates as a positive lock, the lock always being in engagement with the worm-wheel yet running at such speed as to offer no retardation save at starting and stopping. The auxiliary motor working under no load tends toward perfect acceleration, and it tends to stop the car without jolt.

The advantages claimed for the gearless 1-to-1 traction electric elevator, with the Pratt improvements, are as follows:

a. Positive limit stops.
b. Absolute limit of speed.
c. Perfect acceleration.
d. Shortest possible distance in starting and stopping.
e. Perfectly smooth action.
f. Dead lock at stop position.
g. Highest possible rise and speed.
h. Little space occupied.
i. Low cost of installation.
j. Low cost of operation.
k. Perfect safety.

The difficulty with this device lies in controlling the auxiliary motor so as not to consume a great deal of energy in friction and lost work. The author states that two electric motors can operate without interference when positively geared together, as witness the design of the Central London Railway elevators by Mr. Frank J. Sprague, and intimates that no real difficulty exists in securing coördinate action in this case.

STANDARD PROPORTIONS FOR MACHINE SCREWS.

Abstract of Report presented before the Americon Society of Mechanical Engineers, May Meeting, 1907.

A committee appointed by the American Society of Mechanical Engineers to investigate the subject of machine screw proportions and to recommend standard specifications for machine screws, made its first report at the December meeting, 1905. Some criticism, however, of this report made it necessary to call for a second, and what was intended to be a final, report at the May meeting, 1906. (See June, 1906, issue). In the discussion that followed this report there were, however, several diverging opinions expressed on this subject, and the committee was therefore continued and was supposed to report at the December meeting in the same year. For some reason the report, however, was not accepted by the Association before the Indianapolis meeting in May of this year. In connection with the tables given in the present data sheet supplement, we herewith present some of the most important points of consideration in the new standard for machine screws which has been accepted by the American Society of Mechanical Engineers.

The standard diameters of machine screws are to be 21 in number. The included angle of the thread is 60 degrees, and the flat at the top and bottom of the thread for the basic standard is ⅛ of the pitch. The uniform increment between all sizes from 0.060 inch to 0.190 inch is 0.013 inch, and for larger sizes 0.026 inch, making the largest size 0.450 inch in diameter. The number of threads is made a function of the diameter as expressed by the formula

$$\text{Number of threads per inch} = \frac{6.5}{D + 0.02}.$$

This formula, however, gives the results approximately only, as even numbers of threads are chosen in order to avoid fractional or odd numbers.

In regard to the limits for variation from the basic standard, the maximum screw shall conform practically in all respects to the basic standard. The minimum screw shall have a flat at the bottom of the thread of 1-16 of the pitch, and the difference between the maximum and minimum root diameter will allow at the bottom of the thread any width of flat between 1-16 and ⅛ of the pitch. (See cut). The maximum tap shall have a flat at the top of the thread equal to 1-16 of the pitch, and the difference between the maximum and the minimum external diameter will allow at the top of the thread any width of flat between 1-16 and ⅛ of the pitch. The minimum tap shall conform to the basic standard in all respects except in diameter, as plainly shown in the cut. The difference between the minimum tap and the maximum screw is settled upon in order to allow for errors in pitch, and for the wear of the tap in service. The formulas in Table I give the relation between the various dimensions determining the sizes of taps and screws in this standard.

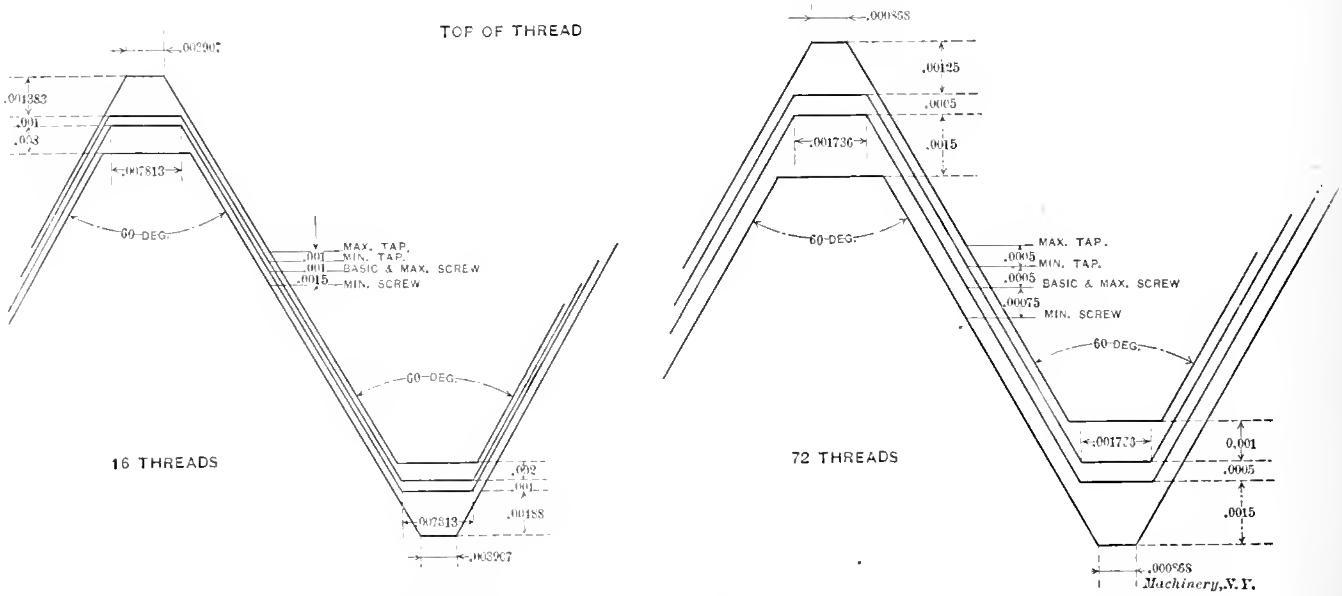


Diagram showing Relation between Diameters of Taps and Screws.

The reference thread gages should be made from unhardened steel, 0.35 per cent carbon, and a set should include both reference thread gages for screws and reference thread gages for taps, each of these to represent the maximum and minimum diameters. Table II gives the thickness of double end

templet thread gages, for each pitch of the standard screws recommended, for the practical inspection of machine screws. The formula

$$\text{Thickness} = \sqrt{\text{pitch}} \times 1.443$$

provides a limit for the error in lead on screws and taps. These templet thread gages are to be made of steel, hardened, and being double ended and having maximum and minimum limits, respectively, are to represent at the largest end the pitch and root diameters of the basic standard, while at the small end they should represent the minimum limits for the pitch and root diameters of screws. The threads of these templet gages should be made by taps having the thread enough larger than the standard in the outside diameter to insure clearance at the top of the thread of the screw. In addition to the threaded holes, these gages should have plain cylindrical holes representing, respectively, the external diameter of the maximum and minimum screw.

BALL BEARINGS. 1.

Abstract of Paper by Henry Hess, presented before the American Society of Mechanical Engineers, May Meeting, 1907.

Although the field of usefulness of the ball bearing is as wide as the domain of mechanical engineering, but little information on ball bearings can be found in the engineering hand books or text books. Generally the subject is dismissed with occasional reference. Sometimes a formula for carrying capacity is given, but this is usually wrong. There is of course much matter scattered through the technical press giving isolated experiences with a few bearings that happen to come within some one's observation. But, undoubtedly, the insufficient information on the elements of ball bearings is responsible for the directly contradictory statements to be found, and the generally accepted opinion that ball bearings are suitable only for comparatively light loads. This was the situation found by Prof. Stribeck, a German investigator, who has been experimenting with ball bearings for the German Small Arms and Ammunition Factories, of Berlin. The present paper is a résumé of Prof. Stribeck's report, together with a number of notes based on the author's experience.

The Wear of Ball Bearings.

Sliding bearings wear out by abrasion of the carrying surfaces, but ball bearings do not give out on account of wear. In fact, they do not wear. They may be ground out by admitting grit, but that is an abnormal condition for ball bearings, the same as it would be for sliding bearings. The only normal cause for the giving out of ball bearings is the stress on the material, when this stress exceeds certain limits. Lightly loaded bearings can be so designed as to eliminate this cause altogether, and to insure practical indestructibility. In heavily loaded bearings this condition may not be possible to realize within practical dimensions, but the proportions may be so chosen that the stress will not cause a break-down within the lifetime of any mechanism to which the ball bearing is applied. An important principle in the design of ball bearings is that the balls may be subjected to loads, increasing as the shape of the supporting surface more nearly becomes complemental to that of the ball. A ball running between races having a flat or straight line cross section will not support as great a load as if the section were curved, or in other words, if the balls were running in a groove. The groove, of course, must never have a curvature equaling that of the ball, as that would substitute sliding for rolling contact.

Formulas for Loads on Ball Bearings.

The frictional resistance of a ball bearing is lower the less the number of balls. Bearings should be designed to have between 10 and 20 balls. For this number of balls the equation

$$P_a = \frac{5}{z} P_b \qquad (1)$$

should be used. In this equation

P_b = total load on the bearing consisting of one row of balls, in kilograms.

P_a = greatest load on one ball, in kilograms.

z = number of balls.

The load carrying capacity of a ball is $P_a = k\,d^2$, in which

d = the ball diameter, in eighths of an inch.

k = a constant depending upon the material and shape of the ball supporting surface. This constant should vary between 3 and 5 for common materials for ball bearings and between 5 and 7.5 for improved steel alloys.

As balls are usually made to English measurements, one-eighth inch has been selected as unit for the ball diameters.

From equation (1) we have

$$P_b = P_a \frac{z}{5}, \text{ and substituting } k\,d^2 \text{ for } P_a, \text{ we have}$$

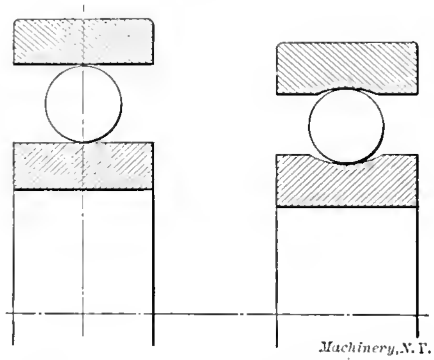
$$P_b = k\,d^2 \frac{z}{5}$$

Speed rotation, in as far as it is uniform, does not affect the carrying capacity of a ball bearing. This applies, however, only to radial bearings, but not to thrust bearings of the collar type. In these, the carrying capacity decreases with the increase of speed. Variations in load reduce the

carrying capacity, the effect increasing with the amount of load change and the rapidity of the change. Uniformity of ball diameter is very essential as the calculated carrying capacity can be realized only if each of the balls sustains its share of the load. High finish on both ball and ball sustaining surfaces is also essential. The presence of grinding scratches will very materially cut down the load carrying capacity.

Frictional Resistance of Ball Bearings.

The frictional resistance of ball bearings has, by actual measurement, been found to vary from 0.0011 to 0.0095. These are the coefficients of friction referred to the shaft diameter, thus permitting direct comparison with coefficients of sliding friction. Ball bearings having a coefficient of friction materially above 0.0015 under the greatest allowable load should not be recommended, because they are too short-lived. The high resistance indicates the presence of too large an element



Figs. 1 and 2. Example of Simple Radial Bearings.

of sliding friction. The coefficient of 0.0015 for a good ball bearing under its greatest load, independent of the speed within limits, will, however, rise to approximately 0.0030 under a reduction of the load to about 1/10 of the maximum.

The Requirements of a Good Ball for Ball Bearings.

The requirements for a good ball are, in the first place, truth of shape and size. The permissible limit of error will vary with the character of the material. It is evident that where a ball is larger than the other balls in the bearing, it must be capable of a deformation sufficiently large so as to permit the others to carry part of the load, and for that reason, the smaller the deformation, the more accurate to size must the ball be. In the second place, a high degree of surface finish is essential. What is usually considered a very good finish is in a ball bearing totally inadequate. Grinding and polishing marks must not only not be recognizable by the naked eye, but, if detected with an ordinary pocket lens, the balls should be condemned. This, at least, is true of balls for bearings expected to have long life, and to carry heavy loads under high speed. The third condition for balls is that the material out of which they are made has an elastic limit as high as can be had. The uniformity of

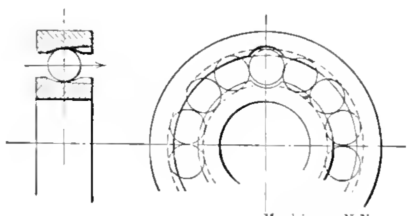


Fig. 3. Objectionable Filling Groove in Ball Bearing.

hardness throughout the mass of the ball is also very essential. General uniformity, in fact, is one of the most important factors, for it will not do to say that because some balls in a lot are better than the others, the design may be based on the poorer ones. Such reasoning would result in the better balls carrying more than their share of the load, producing too heavy a stress, and possibly breakage, of these balls. Lower quality, provided it is uniform, is better than such a condition. The limits of error in regard to the truth and size should not exceed 0.0001 of an inch.

Radial Bearings.

Other things being equal, it is always best to arrange sustaining surfaces at right angles to the load direction. That gives a design of bearing such as shown in Fig. 1, but a better carrying capacity is to be had from the modifications shown in Fig. 2, in which the ball races have curved cross section instead of straight lines. The grooved races have the advantage of greater sustaining capacity, as has already been mentioned. Cutting a local groove from one side into the races, as in Fig. 3, for the purpose of assembling the balls between

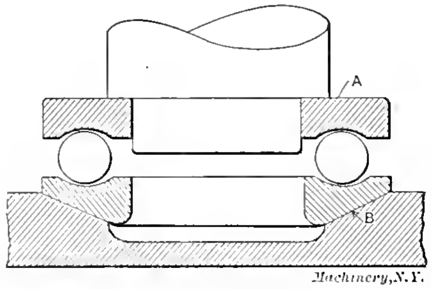

Fig. 4. Collar Thrust Bearing.

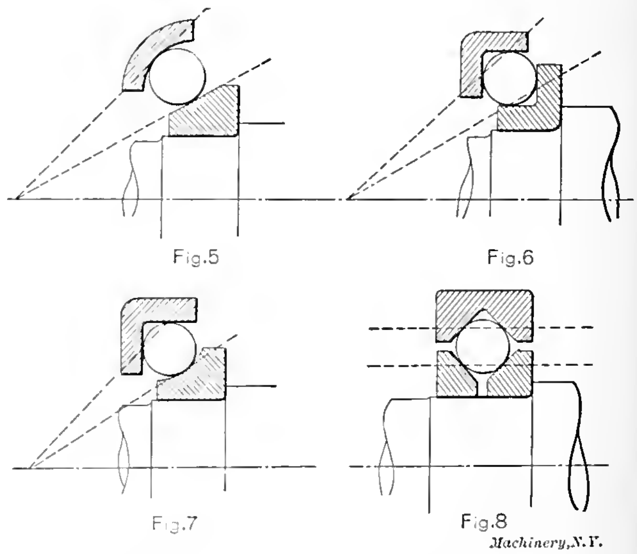
the two races, is common practice, but it is not good practice. So long as the loads are low enough, a filling opening may be of no account, but at high speeds and loads this groove is objectionable, since then the catching of the balls at the junction of the filling groove results in damage to the balls and through these to the race surface.

Thrust Bearings.

In thrust bearings, of the type shown in Fig. 4, the requirement that the sustaining surface should be at right angles to the direction of the load is provided for. These bearings are frequently made with the surfaces *A* and *B* parallel. Providing that these surfaces are made truly parallel, that design is good, but in practice it is seldom possible to get these surfaces truly parallel, because even if such parallelism were



Figs. 5, 6, 7 and 8. Example of Angular Bearings.

possible of attainment, it could not be maintained under the deflections due to the load. It must be remembered that initial errors or deflections of a thousandth of an inch will cause the balls on one side to carry the entire load. For a given case this would demand bearings of larger size than otherwise necessary. By seating one plate on a spherical surface as shown at *B*, Fig. 4, the lower plate can adjust itself in such a way as to distribute the load over the entire number of balls. The speed at which these bearings are run enters decidedly into the carrying capacity of this type of bearing. The utility of these bearings is greatly reduced when speeds exceed 1,500 revolutions per minute.

Angular Load Bearings.

The shapes and modifications of angular load bearings are innumerable. Figs. 5, 6, 7, and 8 may be taken as typical instances of these bearings, representing 2, 3, and 4-point contacts. In order to secure rolling contact, the contact points

of balls on races should form points on a cone of rotation whose apex lies in the center line of the shaft, or they may form points on the surface of an imaginary cylindrical roller that would be parallel to the shaft. The defect in all these forms of bearings is their adjustable feature. This places them absolutely at the mercy of every one capable of handling a wrench. A bearing properly proportioned with reference to a certain load may be enormously overloaded by a little extra effort applied to the wrench, or on the other hand the bearing may be adjusted with too little pressure, so that the balls will rattle, and the results consequently be unsatisfactory. The prevalent idea that angular ball bearings can be adjusted to compensate for wear is erroneous. The wear will form a groove on the loaded side of the race, deepest at the point of maximum load, and adjusting the cone endwise will only cause

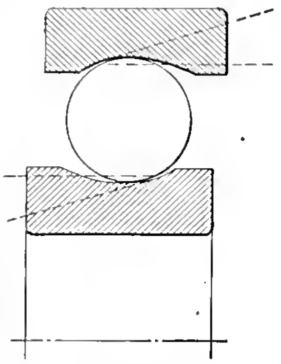


Fig. 9. Radial Bearing used as Thrust Bearing.

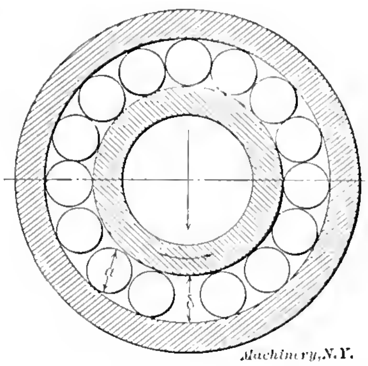

Fig. 10. Diagram used in Analyzing Condition of Sliding Friction.

the balls to be more tightly pinched between the sound portions of the races, which will most likely cause overload. The rough surface of the groove previously worn will attack the balls, and in due time the entire race and bearing will be destroyed.

Theoretically, it would seem that a radial bearing would be incapable of carrying thrust load, owing to the wedging of the balls between the races. In Fig. 9, however, is shown the condition of a ball bearing where the ball does not entirely fill the space between the races if the bearing is not under load, and which, when under load, will assume the position shown. The ball does not come in contact with the race grooves where these are deepest, but so that the tangents to the race curvature at the contact points form angles with the line of thrust. A calculation of the amount of the wedging action in Fig. 9, with the radial freedom of ball permissible in these bearings, indicates an inadvisably large amount of wedging. Actual running tests, however, as well as a large fund of accumulated experience, have absolutely proved that these bearings will carry much more thrust load than the

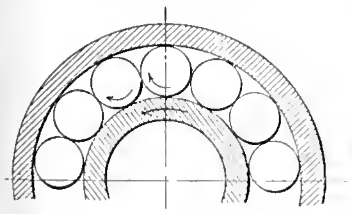

Fig. 11. Diagram showing Direction of Rotation of Balls, indicating Sliding Friction.

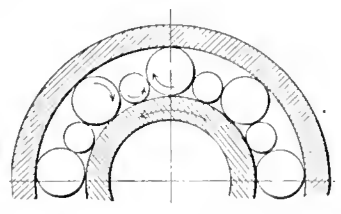

Fig. 12. Fallacious Means for avoiding Sliding Friction between Balls.

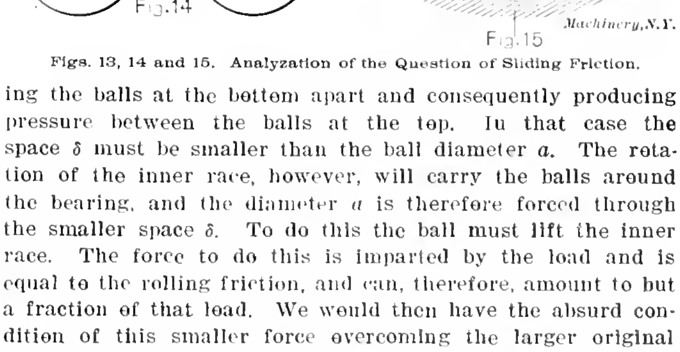
calculation of the theoretical wedge angle indicates as possible. It is probable that the deformation which occurs at the point of ball contact, which results in small surface *areas* of contact, instead of mere *points*, has a mean tangent to the compression surface of greater inclination, and that the wedge is therefore more blunt. It has been experimentally determined that the thrust carrying capacity of the uninterrupted type of annular bearings is to the radial capacity as 0.1 is to 1, and may be as great as 0.25 to 1, the variation depending upon the ball diameter, race curvature, and number of balls. It has been experimentally found that speed has but a slight influence on the thrust carrying capacity of this class of ball bearings, and for speeds above 1,500 revolutions per minute, these radial bearings are more efficient thrust carriers than the collar type.

The Supposed Sliding Friction in Ball Bearings.

Many designers have supposed that in ball bearings adjacent balls press against one another with considerable force. With the inner race in Fig. 11 running as indicated, the balls will also rotate as shown. The surfaces of the balls run in opposite directions, and therefore rub against one another. This is assumed to be a serious defect by those who reason that these surfaces are in contact under pressure. The same general cure in innumerable forms, as shown in Fig. 12, has been proposed time and again. This cure consists in the provision of smaller balls interposed between the larger ones, so that all the contacting surfaces roll in the same direction relative to one another. This remedy is, however, fallacious, in that it brings about the very condition it seeks to avoid. If two large balls, Fig. 13, compress a smaller one between them, and the three have their centers connected by a straight line, they will retain their relative positions, but if the interposed ball has its center to one side, as in Fig. 14, then this ball will be forced outward. The resort to a cage for retaining the interposed roller or ball results in the latter being pressed against the sides of the cage, and keeps the ball in forcible sliding contact, the very thing that it was intended to avoid. In another design, Fig. 15, the interposed member is brought into contact with the race, and while the various balls have a rolling contact in relation to one another, the interposed member has a wrong direction with reference to the race against which it is forced, and thus a sliding contact is produced. All these designs are based on a failure to recognize that axiom in mechanics according to which a force whose direction is normal to the supporting surface has no component in any other direction.

Analyze the conditions in a ball bearing, and, referring to Fig. 10, suppose that the shaft is loading the inner race, and that the latter is fallaciously assumed to act as a wedge, forc-



Figs. 13, 14 and 15. Analyzation of the Question of Sliding Friction.

ing the balls at the bottom apart and consequently producing pressure between the balls at the top. In that case the space δ must be smaller than the ball diameter a. The rotation of the inner race, however, will carry the balls around the bearing, and the diameter a is therefore forced through the smaller space δ. To do this the ball must lift the inner race. The force to do this is imparted by the load and is equal to the rolling friction, and can, therefore, amount to but a fraction of that load. We would then have the absurd condition of this smaller force overcoming the larger original force. Were we to assume that the inner race is not raised by a ball in passing, but that the ball is compressed sufficiently to get through, it would mean the absurdity that the small force represented by the rolling friction would be sufficient to deform the ball. The author concludes this portion of his paper by the remark that it may seem unnecessary to dwell so much on this fallacy of ball bearing design, but its surprising prevalence seems to justify the emphasis laid upon this phase of the subject.

[Having given space to the theoretical considerations in ball bearing design in this issue, a coming issue of MACHINERY will contain that portion of Mr. Hess's paper which deals with the practical side of the subject—the correct mounting of ball bearings.—EDITOR.]

* * *

It is stated in the *Brass World* that lead which contains a small quantity of tin and antimony does not corrode as readily as pure lead. When exposed to a damp atmosphere, the surface will not turn white as rapidly.

ERECTING MACHINERY FOUNDATIONS.*

J. A. PRATT.†

Machinery foundations are built usually of stone, stone and brick, and concrete. The principal characteristics of these materials are briefly as follows.

Stone is a very strong and durable material, and has great vibration-absorbing power but it is quite costly. Brick is not so durable as masonry, but it is cheaper and is everywhere available. In a brick foundation, stones are usually placed under the parts of the machine which rest on the foundation. Good bricks should have plane faces, parallel, sharp edges,

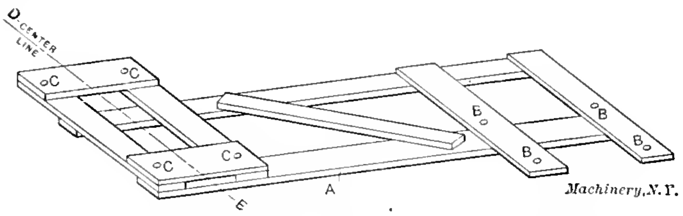


Fig. 1. Templet for locating Bolts for a Simple Engine.

and sharp angles; their texture should be compact, and free from holes. Concrete is a mixture of cement, sand, and broken stone, or gravel. Portland, Rosendale, and Black Diamond cements are used as the first ingredients; if Rosendale or Louisville (Black Diamond) cements are used in mixture, the foundation should not be put in use for two weeks after it is completed.

Method of Testing Cement.

Soundness and setting qualities of a cement are important, and tests of stock can be obtained from the mills. The following is a brief outline of the method of testing: Make four or five pats about 2 or 3 inches in diameter and about ½-inch thick at center, and thin at the edges. Put them on glass plates for the tests. The initial or first set is determined when this pat will bear a wire 1/12-inch diameter loaded with a ¼-pound weight. This should not take place in

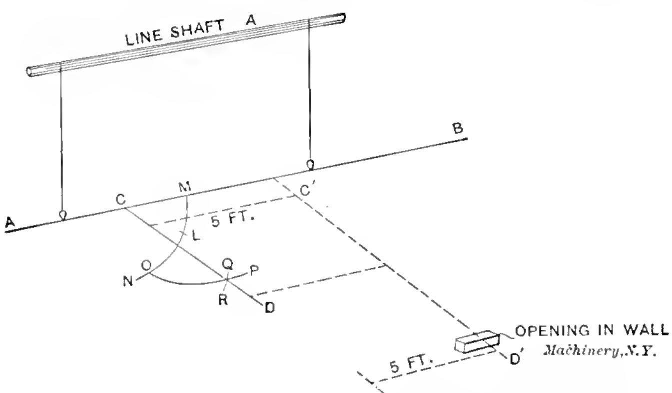

Fig. 2. Illustration of Method used for locating Reference Lines.

less than half an hour. The final set is determined when a pat will bear a wire 1/24-inch diameter loaded with a 1-pound weight, which it should do in less than eight hours.

Preparation of Lime Mortar.

Lime mortar is made by slaking lime entirely covered with water, to keep it from burning. Make of 1 part lime and 5 parts clean sand, and mix a day or so before using. If cement is used in the mortar, the cement should be thoroughly mixed with water and added just before using. Lime cement mortar is mixed as follows: One part cement, 3 parts lime, 5 parts sand.

Pure cement mortar is used a great deal at present and is mixed as follows: One part cement, 3 parts sand. Be sure to use this before initial set takes place.

Size of Broken Stone.

The broken stone, or gravel, should pass through a 2-inch screen and over a ¼-inch screen, and neither "tailings" or "fines" should be used in the concrete. It is best to avoid using limestones or stones of slate formation in foundation concrete. A typical mixture for concrete is 1 part cement, 3 parts sand, and 5 parts broken stone.

Mixing Concrete.

In mixing, the broken stone should be wet down before using; throw sand and cement on mixing board first, and mix well together in dry state; add sufficient water by sprinkling, so that water can be squeezed from a ball of the mixture in the hand. Do not mix ahead of needs, as cement concrete must be in place before initial set has taken place.

Preparing Foundation Pit.

Let the foundation pit be deep enough to go below the frost line of the locality. On the bottom of this pit prepare the foundation bed, by first going over the whole bottom of the pit with rammers, and thus tamping it down. Place on this surface good sized stones about a foot apart, and fill the

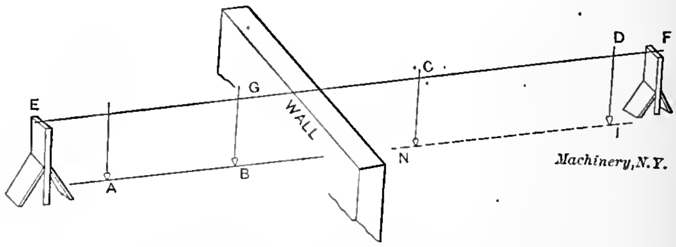

Fig. 3. Locating Reference Line by carrying the Line through a Wall.

spaces between these with concrete of the mixture given above. This bed may be from 1 foot to 18 inches thick.

Construction of Templet.

The next step is the making of the templet by which all the holding-down bolts are correctly located. This templet should be solidly built of good pine boards about 1 inch thick, and, say, 1 foot wide. Lay out accurately on it all bolt holes and all center lines.

Fig. 1 shows a templet for a simple engine. The edge of the board shown at *A* should be planed straight, as it is used as the main center line of the engine. From this edge or center line are located all other center lines on the templet. From the foundation drawing lay out the main shaft center line *D*, *E*, perpendicular to edge *A*. Next lay out the centers of all holes from these two lines, taking dimensions from the drawing. Bore holes about 1 inch larger in diameter

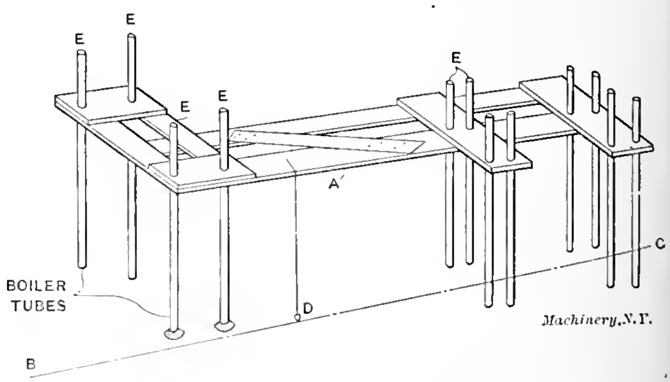

Fig. 4. Leveling and setting the Templet true to Reference Lines.

than the foundation bolts. These large holes will permit the use of pipes as centers for the holes when building the foundation.

Locating Reference Lines.

The next step is the getting of reference lines from the center line of the shaft to which the engine is to be connected by belting or gearing. Figures 2, 3 and 4 will give some idea of the methods used in such layouts. Fig. 2 shows at *A* what we assume to be the old line-shaft, over which we drop two plumb-bobs. Hang these so they will be about 1 inch from the floor, and when they are perfectly steady, let them drop, making a slight dent on the floor. Make this mark as deep as required by the use of a scratch-awl. Then stretch a chalked line, and snap a line on the floor, passing through these points. We now have a line parallel to the line-shaft to which we must connect. If some present installation of machinery is in the way on the floor, transfer this

* See also MACHINERY, January, 1903, engineering edition: Shop Construction—4, Foundations; August, 1903, engineering edition: Concrete Foundations; and March, 1907: Foundations for Machine Tools.

† Address: Pratt Institute, Brooklyn, N. Y.

line to the ceiling overhead, where it will serve the purpose just as well.

Since the engine center line will usually be perpendicular to the shaft line, we must establish a perpendicular to this line, and the method of doing it is shown in Fig. 2. Select the point from which the perpendicular is to be drawn, which, of course, will be taken at the position where the engine must finally line up. This point C is taken as a center, and with any radius—the longer the better—swing arc $M\ N$.

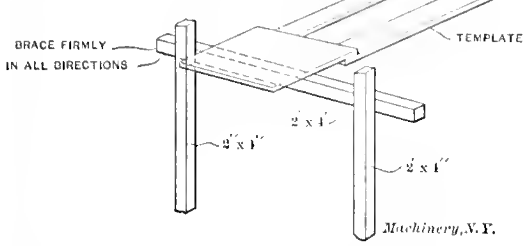

Fig. 5. Frame for supporting Templet.

Next take M as a center and swing short arc L, intersecting $M\ N$. Now from L as a center swing arc $O\ P$. Take O as a center and swing arc $Q\ R$. The point of intersection of $O\ P$ and $Q\ R$, and the selected point C on the given center line, will determine the required perpendicular. Notice that the radius for striking the various arcs is not changed from the start to the completion of the operation. Trammels should be used when describing these arcs. The line $C\ D$ may be extended indefinitely, so the engine can be located at such distance from the shaft line as conditions of belting or gearing require.

A machine to be installed, possibly, may be in another room with a partition between the engine shaft and the shaft to be driven. In this case we have to carry the line through the partition. Fig. 3 shows the method followed in getting the lines located. Two stiff wooden uprights are erected at any selected distance from the wall in question, and the line is stretched tightly between them.

Assume that line $A\ B$ is the portion we have placed on the floor, while the dotted portion shown on the farther side of the wall is the portion we desire to locate. Set the two uprights or targets E and F, and stretch the line. Adjust the line by letting two plumb-bobs hang so they touch the line struck on the floor. Bring the target line $E\ F$ so it will just touch the plumb-bob strings. Now the portion of the target line, $E\ G$, is exactly over the perpendicular, which was located as described in Fig. 2. The portion of the target line $G\ F$ now becomes an extension of $E\ G$, and by dropping plumb-bobs as shown at $C\ D$, so they just touch this line, we may locate a second section of line, either parallel to $A\ B$ or in direct continuation of it on the farther side of a wall.

This line may be struck on the ceiling as well as on the floor if obstructions are in the way. It is usually extended through a convenient window, which may or may not be in

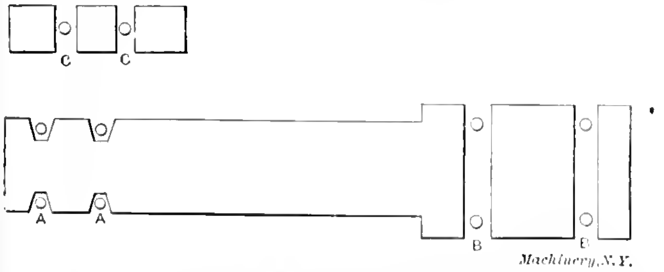

Fig. 6. Laying Out the Foundation.

direct line with $C\ D$, Fig. 2. In such a case, we measure off in perpendiculars from the first line such a distance as the opening through which we wish to pass the line may require (in this case 5 feet), and after passing the line through the wall, measure back again. This work is indicated in dotted lines, Fig. 2. All perpendiculars are struck as directed in connection with $C\ D$, Fig. 2, using trammel points and large radii.

Locating the Templet.

The templet should be slung from the roof timbers if they are in place, and, if not, a good stiff framework of 2 x 4's should be put up. A portion of such a frame is shown in Fig. 5. There should be one at each end of the foundation, and they should permit the templet being slung high enough to complete all work without cramping the masons for room.

In concrete work it is not always necessary to keep the templet in place till the foundation is up to full height, as the setting of lower layers of cement will hold any centers for bolt holes firmly in place, and there is no necessity for a support at the top.

After the templet is hung, it must be carefully leveled up, and the edge A, Fig. 4, set perfectly true with the line $B\ C$ which we placed on the floor of the pit. To do this, drop plumb-bobs over the edge A, and move the templet until they are true with $B\ C$. Now nail the templet firmly to the framework. Next cut some pieces of boiler tube long enough to reach from the foundation bed to 6 inches above the templet, and of same diameter as the holes bored in the tem-

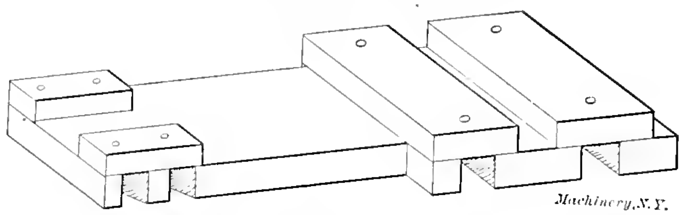

Fig 7. Appearance of Pocket Covers in Place.

plet. Slip these tubes through the holes and set them plumb. As each tube is set, build a little wall of cement around the lower end to keep it in place. See tubes at E, etc., in Fig. 4.

The foundation should be larger at the top than the base of the machine for which it is built. The "batter," or inclination of the sides from the vertical, should be from 1½ to 3 inches per foot. See Fig. 8.

Locating the Bolt-head Pockets.

Now lay out the form of the foundation on the base as shown in Fig. 6. The various pockets are shown at A, B and C. These pockets usually should be placed in a foundation for convenience in tightening up the bolts. In small work, however, the bolts are often set in the templet (instead of using tubes and masonry built around them) leaving them solid in foundation. In such cases pockets are not needed. Pockets should be high enough to permit the bolts being dropped below the upper surface of the foundation while placing the machine. The pockets should be covered with

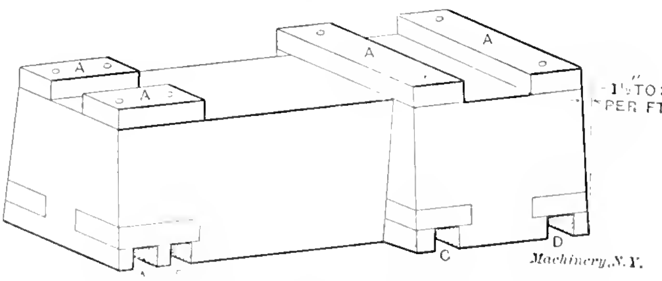

Fig. 8. Foundation with Cap Stones in Place.

a stone or iron slab as indicated in Fig. 7. In placing these stones, slide the boiler tubes up through the templet and set the covers so the tubes can be freely turned when held by the templet and cement guide on foundation bed.

Leveling Cap Stones.

The feet of the machine should rest on stone slabs about 8 inches thick. All brick or stone used should be wet down before placing, unless the weather is freezing, in which case mortar may be mixed with hot water and the work protected with boards at night.

Fig. 8 shows a foundation with the cap stones in place. Be very careful that all cap stones are set level, and all in the same plane or parallel planes.

Fig. 9 shows the method of leveling stones with each other by use of a pair of cast iron cubes, straight-edge and spirit level. Level the stone which is placed at the highest part of the foundation first. After setting the cap stones, the foundation is complete. Then transfer the center line from the foundation base to its top face, and it is ready for the machine.

Advantages of Concrete for Foundations and Method of Construction.

Concrete makes an ideal foundation material, since, when it is set it becomes practically one solid piece. The method of construction is much different from putting up a masonry foundation, and much less expensive. The bed is prepared and the templet is carefully set to center line as described before. All concrete work is molded in forms. The timber for these forms should be about 1 inch thick, dressed on one side for the purpose of getting a smooth surface on the work, and braced about every 2½ feet. Fig. 10 shows a foundation form set up and braced for filling. Two methods of external bracing are shown. At *A* the braces are carried horizontally to the side of the excavation; at *B* a piece of timber is firmly set in the ground, outside the base, and all bracing brought to it. The inside of the form should be braced about every foot in height; the upper brace of one of these sections is shown at *C*. Such braces are placed inside for the entire height of the foundation, spaced as just mentioned. As the concrete is put in place the braces are removed.

The form should be carefully placed to the layout of the foundation, and pocket molds set. Fig. 11 shows a pocket mold and Fig. 12 a top view of the form set ready for filling. The pocket molds are simply wooden boxes of the same outside dimensions as the pocket is required inside, and finished smooth. These molds should be soaked in water 2 or 3 hours before using to prevent their swelling and sticking in the concrete. They may be nailed to the main mold, or wires may be fixed to them, which pass through the main mold, and tightened by means of wedges in a manner similar to that used by a molder in holding suspended cores. These pockets must be firmly fixed in place.

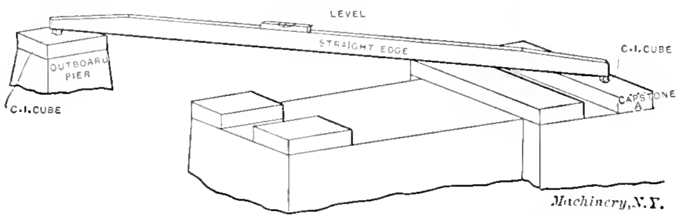

Fig. 9. Method of leveling Stones with each other.

The next step is filling the form. Do not use concrete that has stood mixed much over 20 minutes. Ram with rammers weighing about 1 pound per square inch of face area, and ram until water just shows at the surface. Put down in layers about 6 inches thick, and work down next to forms with a shovel to get a smooth surface. The foundation may be filled with good sized stones, about the size of a man's head, about 1 foot apart and at no place less than 1 foot from foundation surfaces. Wet these stones before laying. If the work is stopped at night, make grooves in the surface, and when starting next morning sprinkle and dust over with dry cement.

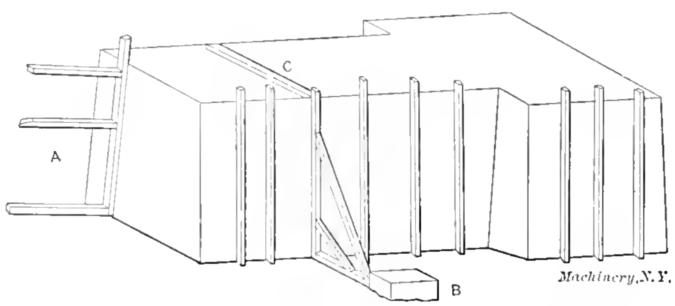

Fig. 10. Foundation Form set up and braced for Filling.

As soon as the cement has set, strip off the forms, as it is much easier to patch when cement is somewhat green.

Foundation work is sometimes "slushed" instead of being rammed. In this case, the concrete is mixed just wet enough so it cannot be piled up. The concrete is then dumped into molds, and worked in them to prevent air bubbles. The first method gives a more homogeneous structure, as there is no chance for the broken stone to settle. Turn the pipes occasionally as the foundation goes up, to prevent their becoming set, if they are to be removed. Sometimes they are left in the foundation as a sort of lining to the foundation bolt holes. When the machine is set approximately true, the space around the foundation bolts may be filled with liquid cement, lead, or melted sulphur.

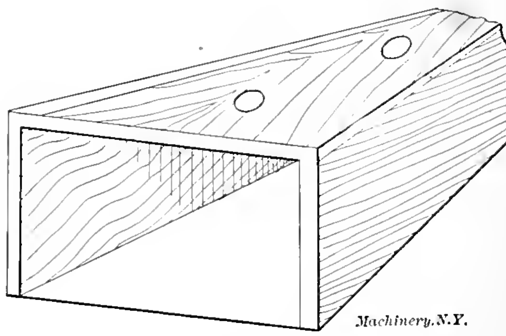

Fig. 11. Pocket Mold.

* * *

An Austrian journal, *Technische Neuerungen*, has published some computations, taken, it states, from an English source, which give an idea about the cost of our inventive age. Not counting trade-marks, copyrights or registration of labels, there have been 3,500,000 applications for patents since the patent system was inaugurated, and about 2,500,000 of the applicants have been granted letters of patent, the United States having granted almost one-half of these, or about 1,000,000. The government fees for this alone have amounted to about $180,000,000. This, however, is only small part of the expense incurred for patents. Solicitor's fees and the expense incidental to maintaining the granted patents may be estimated to at least $1,100,000,000. A conservative estimate places the total cost of litigation for protecting patents to $1,700,000,000, and the promoters' rake-off to $1,200,000,000. The total cost of development has been estimated at more than $6,000,000,000, so that the grand total of all these various items, all incidental to patenting and exploiting patents, is about $10,200,000,000, and with a reasonable interest for an average of thirty years, the total cost to the world for its patented inventions should be placed at about $30,000,000,000. Now, the main question is if individual inventors, for the protection of whom we must consider that many of these charges have been paid, actually were benefited to any amount in the least proportionate to the stupendous sums expended.

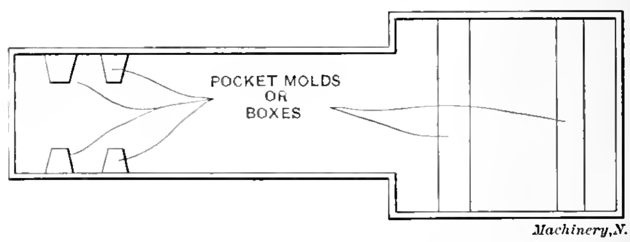

Fig. 12. Top View of Form ready for Filling.

* * *

The Northern Pacific Railway Co. has recently built a novel roundhouse at Dilworth, Minn. This roundhouse contains 44 stalls, having pits so arranged that the ashes from the engines can be dumped into them, thus avoiding the delay which is often caused by sending the engines to an outside ash pit. There is a depression in each roundhouse pit, which contains perforated pans for receiving the ashes. These pans, which are about 72 by 30 inches, are submerged in water for the purpose of cooling the ashes. There are two pans in each pit so that two engines can use the pit before the ashes need to be removed. The pans, when filled, are lifted by an electric hoist which travels on an overhead track, and carried to a cinder shed where the ashes are dumped from the pans into cars. This arrangement will make it possible to clean and bank the fire without delay, which will mean a saving in coal, and a reduction of the terminal expenses.

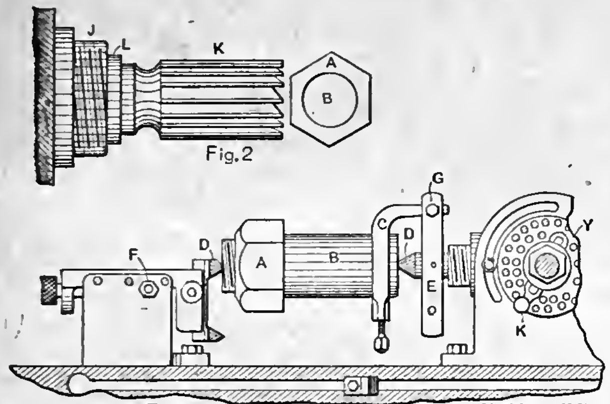
SHOP OPERATION SHEET NO. 46.

W. S. Graffam. MACHINERY, December, 1907.



To Set Up the Job of Milling the Faces of a Hexagonal Nut.

NOTE.—A simple and elementary operation is here chosen, for the reason that the principles and mechanical details by which it is accomplished are practically applicable to many milling machine jobs of a much more complicated nature. The most accurate milling may nearly always be done with an end mill. Consequently the various steps in connection with milling the flats of a hexagonal nut, will be given. Let it be assumed that the nut to be milled is to finish 1.5 inch short diameter, or the diameter across flats. It is supposed to have been drilled, tapped, faced, and chamfered. The threaded nut arbor upon which it is held is 1.25 inch diameter across the body. The milling machine is supposed to be provided with graduated dials reading to thousandths of an inch on all feed screws.

1. Screw the nut A tightly against the shoulder of the nut arbor B.

2. Clamp a lathe dog C upon the opposite end of the arbor B.

3. Bring the tail-stock up to the proper position and clamp it. Place the nut arbor B on the centers D of the machine, with the tail of the dog C in the slot of the carrier E, and clamp it with the set-screw G. Bring up the tail center and clamp it by nut F.

4. Clean the taper hole in the main spindle J (Fig. 2). Select a reducing collet L, wipe it clean, and place it in the hole in the spindle J. Wipe clean the hole in the collet L. Select an end mill K, of sufficient diameter to entirely cover one of the faces of the nut A. Wipe the taper shank clean and place it in the collet L, fixing it with a light blow from a lead hammer.

NOTE.—The importance of thoroughly cleaning the collets, and wiping the shanks of all mills clean before using, cannot be overestimated, as small chips which are scarcely visible will cause the mill to run out of true.

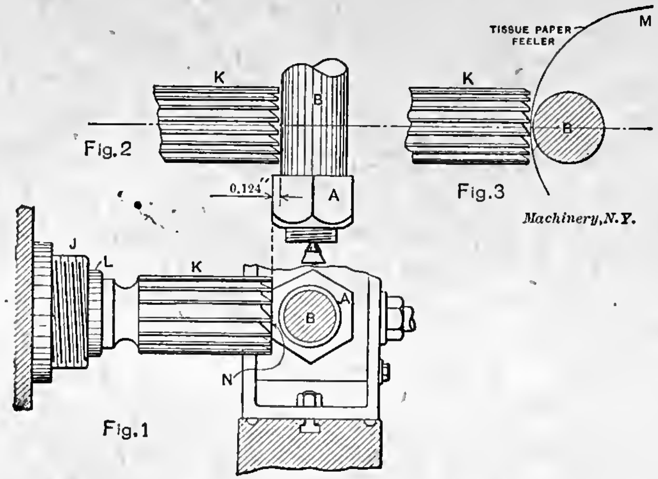
SHOP OPERATION SHEET NO. 47.

W. S. Graffam. MACHINERY, December, 1907.



To Set the End Mill for Milling the Faces of a Hexagonal Nut.

NOTE.—The short diameter of the finished nut is assumed to be 1.5 inch. The body diameter of the nut arbor upon which it is held to be milled is 1.25 inch. The thickness of the tissue-paper feeler is .001 inch.

1. Place a tissue-paper feeler M over the arbor B (Fig. 3), and bring the cutting end of the end mill K, lightly against it, not hard enough to cut the paper.

2. Caliper the diameter of the arbor B (in this case 1.25 inch), add twice the thickness of the tissue paper ($1.25 + 0.002 = 1.252$). Subtract this from the finish short diameter of the nut A ($1.5 - 1.252 = 0.248$), and divide the result by 2 ($0.248 \div 2 = 0.124$). This may be expressed thus:

$$\frac{1.5 - (1.250 + 0.002)}{2} = 0.124.$$

It may be done thus: Subtract one-half the diameter of the arbor B ($1.25 \div 2 = 0.625$), plus one thickness of paper ($0.625 + 0.001 = 0.626$), from half the short diameter of the nut A ($1.5 \div 2 = 0.75$) to obtain the distance to move the work from the end of the mill K ($0.75 - 0.626 = 0.124$). The machinist will probably favor taking the diameter thus: $1.25 + 0.002 = 1.252$, and

$$\frac{1.500 - 1.252}{2} = 0.124, \text{ the distance required.}$$

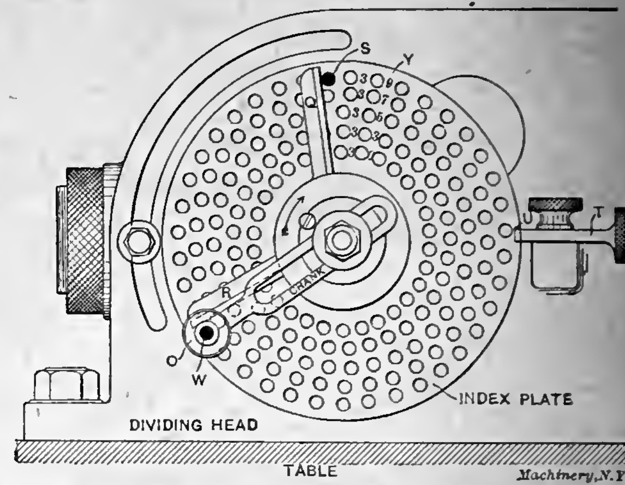
3. Set the pointer on the cross-feed dial at 0.124, as obtained in step 2.

4. By turning the cross-feed crank, draw the work somewhat farther away from the end mill K than necessary (to take up back lash). Reverse the motion and move the work up until the dial reads zero.

Published by THE INDUSTRIAL PRESS, 49-55 Lafayette Street, New York, and sold only with subscriptions to MACHINERY. Binders holding 150 sheets sent postpaid for 25 cents. Back numbers may be obtained by new or old subscribers. Copyright, 1907. THE INDUSTRIAL PRESS, New York.

SHOP OPERATION SHEET NO. 48.

W. S. Graffam. MACHINERY, December, 1907



To Set the Indexing Device and Take the Cuts for Milling the Faces of a Hexagonal Nut.

NOTE.—Ordinarily the dividing head of a milling machine is so arranged that 40 revolutions of the index crank rotate the spindle through one revolution; that is, it has a ratio of 40 to 1. This ratio is here assumed.

1. Select an index plate Y having one or more circles of holes whose number is divisible by 3 (in this case 39), and put it in place on the dividing head.

2. Find the indexing thus: The ratio being 40 to 1, and the number of sides of the nut being 6, we have $40 \div 6 = 6\ 2/3$ turns of the index crank O to change from one face to the next.

3. Set the sector arms Q, R, so as to include two-thirds of a circle of 39 holes, plus one hole, or 27 holes ($2/3 \times 39 + 1 = 27$), and clamp them together.

4. Insert the stop-pin T in the slot U of the index-plate Y, and set the crank O to bring the pin W to the radius of the 39 row of holes, if this has not been done.

5. Turn the index crank O a portion of a revolution, in the direction of the arrow, to take up back lash, and insert the pin W in the hole at S. Bring sector arm Q against pin W.

6. With the lateral and vertical movement feed cranks bring the work directly over the cutting surface of the end mill K.

7. Start the machine. Feed the work down past the end of the mill K, making the first cut. Return the work to its original position.

8. Give the index crank O six turns in the direction of the arrow, and, in addition, move it from the sector arm Q to R, making 6 2/3 turns in all, as per Step 2. Swing the sector arm Q around against the pin W.

9. Proceed with the remaining cuts as described in Steps 7 and 8.

NEW SHOP OF J. E. SNYDER & SON.

H. P. FAIRFIELD.*

Since 1892, and up to recent date, the shop of J. E. Snyder & Son was located in a large power building on Beacon St., Worcester, Mass. Owing to a steady increase of business, which made the old quarters too small, and because of a wish for more convenient and better lighted shop conditions, the company has built and moved into the building shown by the accompanying photographs. The new shop is located at the intersection of Parker and Dewey Sts., convenient to car lines running to all parts of the city and to the union station.

In selecting this location, attention was paid to the needs of the workmen, and the reader will note that the shop is surrounded by residences, making it an easy matter for the workmen to secure a home within an easy walking distance of his employment. This is a feature too little thought of by some firms when choosing a site for a new works. The construction is of concrete blocks, giving a building which is not only substantial for its purposes, but pleasing in appearance, an essential point when it is remembered that the location is residential. Special attention was paid to uniform lighting, and Figs. 1 and 2 demonstrate the means employed, the walls consisting largely of windows, and the central area of the roof of glass monitors.

The views showing interiors also show the method of lighting. There are four bays from north to south, those on either side receiving light from the wall windows, while the two central ones are lighted by the roof monitors.

The shop is so well lighted, that when taking the interior photographs shown, no difference in the time of exposure was found necessary, and the writer has never before found this to be true.

Fig. 3 is a view taken near the shipping door at the north end of the building, and shows the erecting bay with a portion of the shipping floor. The offices and drafting rooms are located at the right of this view.

Fig. 4 is taken from the north end near the offices, and shows the gear cutters, milling machines, and lighter lathes, and looks out toward the setting-up floor.

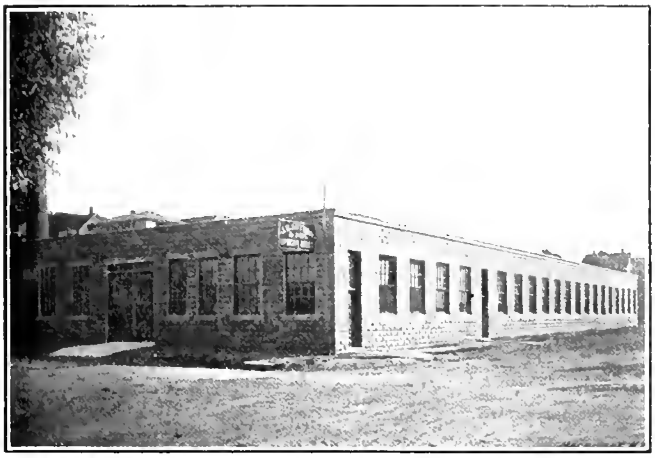


Fig. 1. View from the North.

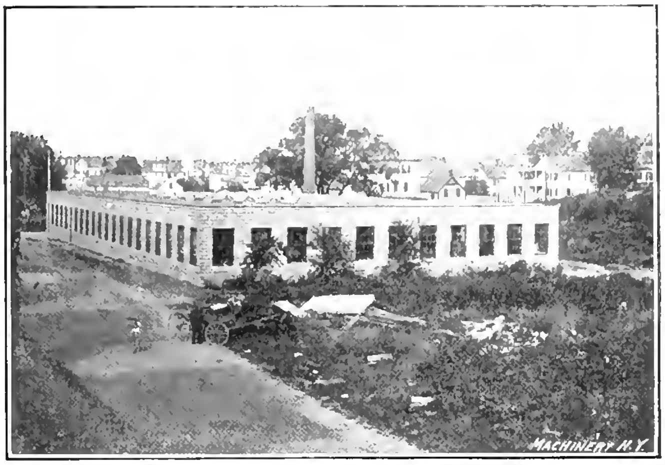

Fig. 2. View from the South.

Fig. 3. Shipping Floor and Erecting Department.

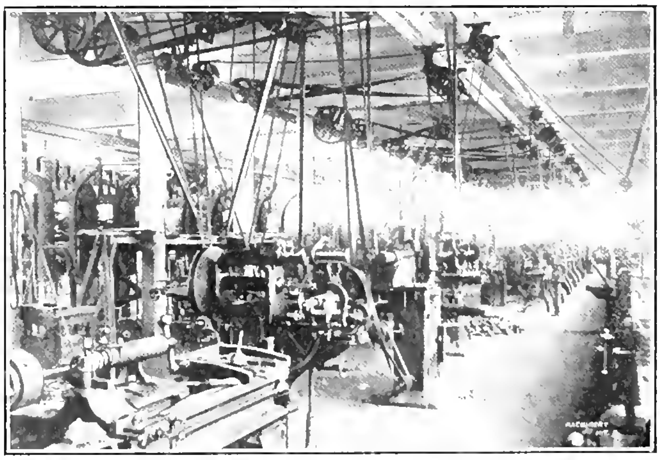

Fig. 4. Gear Cutting and Small Lathe Work.

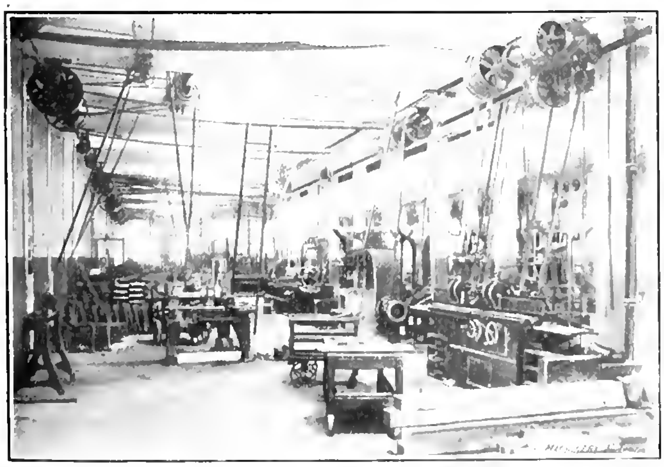

Fig. 5. Grinding, Boring and Heavy Turning, also Tool-room in Middle Distance.

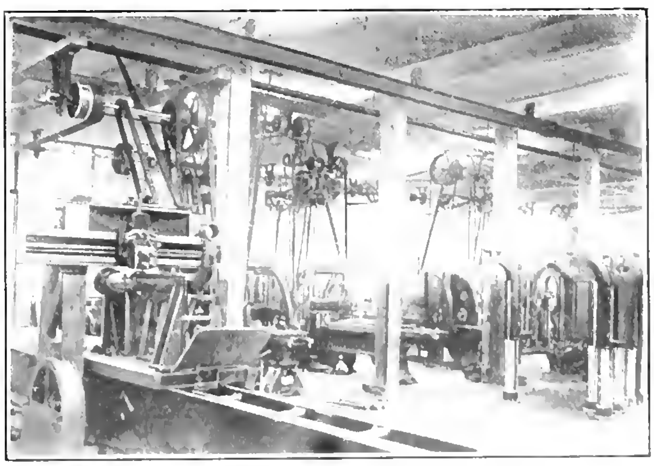

Fig. 6. Planers as seen from Erecting Floor

* Address: Worcester Polytechnic Institute, Worcester, Mass.

In Fig. 5 is shown the grinding, boring, and heavy turning machines, and in the middle distance the wire netting surrounding the tool room can be seen. A view of the planers from the setting-up floor is shown in Fig. 6.

About 1882, Mr. J. E. Snyder first began to manufacture, in a small way, the drilling machines for which he has since become so well known. Then the firm name was Currier & Snyder, and the shop was located on Central St. In 1884, the firm removed to Hermon St., and in 1892 to Beacon St. Mr. Snyder bought out Mr. Currier's interests in 1894, and his son entering the business with him in 1902, the present firm name of J. E. Snyder & Son was adopted.

Like many machine tool builders, they have deemed it best to concentrate their efforts in manufacturing a single, straight line of machines, namely, drilling machines in all sizes from small lever machines to those of the largest back-geared drive and geared feed machines. These are built in lots of forty, sixty, eighty and one hundred, according to size. Their products go to all parts of the world, and foreign orders are now booked for months ahead. At the present writing the company has about sixty machinists in its employ, having very recently moved into its new quarters.

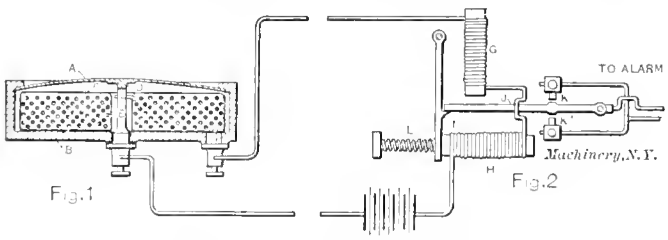
* * *

THE BURGLAR AND THE SAFE MAKER.

GEORGE P. PEARCE.*

The fight between the burglar and the safe maker is very similar to the fight between the armor plate manufacturer and the gun builder. First one is ahead, and then the other. The only difference is that the safe maker has never been far enough ahead to make himself prominent. The burglar is very enterprising in his bad way, for he was among the first to use the electric current for burning holes in a plate. He took advantage of "Thermit," and now, according to October MACHINERY, he is getting quite handy with the oxy-acetylene blow pipe. Any attempt to discourage him with ethyldichloracetate fumes, or other noxious or dangerous vapors, as suggested, would surely be a failure, for a modern safety helmet would enable him to attend to his business without much inconvenience. The following is a description of an attachment for protecting safes, which in my opinion would possibly check successful attempts at burglarizing for some time at any rate.

Let an electric contact device be made along the lines suggested in Fig. 1. The top plate *A* being a sheet of thin springy brass, and the frame *B* a casting. The coil *C* is a resistance, the contacts *D* and *E* are of platinum, and the connections are as shown. In assembling, the plate *A* should be slightly sprung out, as shown, so as to cause a good contact between *D* and *E*, and then the whole box hermetically sealed. This device would be suspended inside the safe, the



Device for making a Safe Burglar proof.

wires brought out through air-tight joints and connected to the alarm, shown diagrammatically in Fig. 2, which could be placed in any desired location. In operation, the safe would be closed as usual, and the current switched on. This would cause a large current to flow through the contacts *D* and *E*, and the electro-magnets *G* and *H*. This current would cause *G* to attract *J*, closing contact *K* and thus throwing in circuit the auxiliary current and ringing the alarm. Next it would be necessary to obtain a partial vacuum in the safe by means of a small pump. This would cause the air confined in the contact device to push the spring surface *A* outward, thus breaking the contact between *D* and *E*. The current will still be able to flow through the resistance coil *C*, but it will be greatly weakened, and the electro-magnet *G* will not be powerful enough to hold *J*, which will fall and catch on step *I*. Magnet *H* will still be magnetized enough to just overcome the tension of the spring *L* and thus keep *I* in position; thus contact at *K* will be broken, and the alarm will cease to sound. The partial vacuum will also cause the door to be tightly drawn against the rubber packing and thus prevent leakage.

Now as soon as a burglar makes a hole in the safe, the air will rush in, and spring plate *A* will return to its first position and close the short circuit. The extra current will magnetize *G* to a greater extent and cause it to pick up *J*, closing its contact with *K*, and operating the alarm. Should the burglar cut the wires, the magnet *H* would lose its magnetism, and *I* would be drawn back by the spring *L*, allowing *J* to fall and make contact with *K'*, thus again operating the alarm. A resistance could not be inserted between the line wires to balance the resistance coil *C* while the wires were cut, because the resistance of *C* would be unknown. If the new resistance was too great, or too small, it would either cause the magnet *G* to lift *J* and ring alarm through the contact *K*, or it would decrease the power of magnet *H*, which could not then overbalance the spring *L*, which would pull *I* back and let *J* fall and close the contact *K'*, and again ring the alarm. Any attempt at testing the wires would also disturb the balance in the alarm box and cause the signal to be given, and thus it would certainly be a difficult matter to get the valuables without sounding the alarm.

* Address: 384 Prospect Ave., Buffalo, N. Y.

* * *

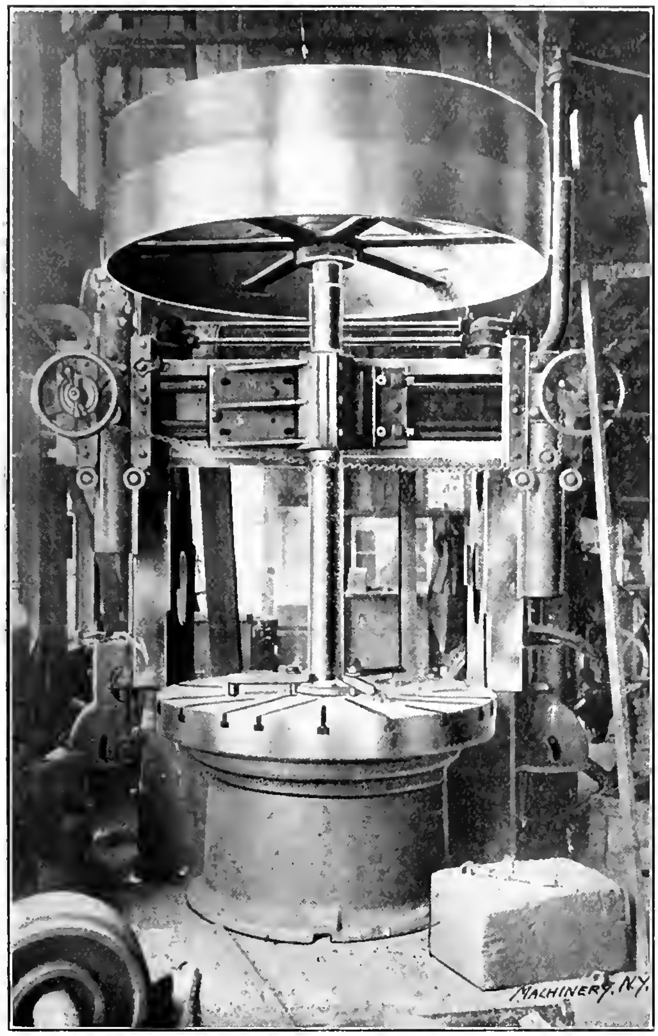
TURNING A 76-INCH PULLEY ON A 60-INCH BORING MILL.

R. C. PORTER.*

The accompanying half-tone shows the manner in which a 76-inch pulley was successfully finished at the shops of the California Iron Works Co., Eureka, Cal. The shops in question are not equipped with lathes or other turning machinery to finish work of a larger diameter than 60 inches, as the ordinary run of work in this shop does not call for machinery of larger sizes. A case came up, however, in which a pulley 76 inches in diameter and 21 inches wide was required to be turned. After some meditation, it was concluded that by rigging a 60-inch Colburn boring mill as shown in the cut and as described below, it was possible to finish the pulley on this machine. In the first place, the casting shed was searched for some old 6-inch post boxes, which were then planed on the back and bolted to the cross rail of the boring mill. In order to enable these boxes to be used for the same kind of work in future jobs, dowel pins were also provided, so that the boxes could be located in exactly the same position if wanted for use again. These boxes were, of course, not as yet babbitted. A piece of 6-inch shafting was now turned on one end to fit the hole of the pulley, which had previously been finished to size in a radial drill press, and key seated. The other end of the shafting was turned to fit the center hole in the face-plate or table of the boring mill. The length of the shafting, of course, had to be made such that when the pulley was placed on its upper end, and the lower end fitted into the table, the shaft would reach fully through the hub of the pulley, so as to give a satisfactory bearing. An extra heavy piece of pipe flange was then keyed to the lower end, and faced true with the shaft, after which the arbor was erected on the mill, the flange bolted to the table, and the shaft located in the center by means of placing the end to fit the center hole in place in the table. The machine was then started, and the arbor was trued up until it was running perfectly correct for its whole length. The boxes bolted to the cross-rail were then babbitted, so as to give an upper bearing to the shaft. As in this case it was necessary to feed the tools upward instead of down, the tool-holder heads were detached from the machine and reversed, the left-hand head being put on the right-hand side and *vice versa*. The pulley was then hoisted in place by a crane, and was keyed firmly to the upper end of the arbor. Tool-holding bars were now placed in the heads, one on each side of the pulley, one taking a roughing and the other a finishing cut. On account of the width of the pulley it was not possible to finish the whole face at one setting, and, therefore, when one-half of the pulley was turned, it was reversed and the other half

* Address: California Iron Works Co., Eureka, Cal.

finished. The face was crowned the same as any ordinary pulley. Novo steel was used in the tool-holding bars or cutting tools, and a feed of 0.043 inch, and a 1/4-inch depth of cut for the roughing cut was used. In order to prevent the chips from falling down into the tool-holder heads and injuring



View showing the Way in which the Pulley was attached to the Boring Mill.

the ways, burlap was thrown over the heads and the guides. This arrangement worked very satisfactorily, so much so, in fact, that it was concluded to finish two 96-inch diameter by 10-inch face band mill-wheels in the same manner.

AN OLD-TIME APPRENTICESHIP.

BACK-NUMBER APPRENTICE.

The apprentice who starts in nowadays to learn the greatest of all trades (though by no means the best paid), the machinists' trade, has a much easier time in a great many respects, than he would have had fifteen or twenty years ago. Now he works so many weeks, or months, on various machines, and so many more at the bench, or on the floor, and passes through a regular course, often having a special foreman to look after him, and see that he learns all that he should in each branch.

They used to start us snagging castings, cutting bolts, and sweeping up the shop. Happy were we, when the boss came around and told us to help some one do a little repair job over in the mill, or out in the yard somewhere. The erecting floor, so called, was a space between the drill-press and the wood planer, in the "wood butcher's" end of the shop, and directly in the passage to the blacksmith shop and the pattern shop. Here were brought pumps, engines, water-wheels, or anything else that couldn't be repaired where it stood, and the apprentices, sometimes assisted by some superannuated pensioner, would scrape off the accumulations of grease and dirt, while some of the handy-men, who did anything, and everything, would take it apart and stack up the pieces in some out of the way corner, until they were needed. Here the "cubs" reveled in dirt, hoping that they might get a chance to bore out a bushing, or plane up a pillow-block cap, or do any other little job that called for a "pretty fine fit," or a "light drive," as the case might be. One man in the shop had worked "down country," and was used to seeing men who used micrometers every day, but to us, they were a useless extravagance, and if anybody had attempted to use one, he would have been considered as putting on airs. How we did look up to a man who could take his calipers over to the mill and caliper a shaft, and then come back and bore out a gear to fit "just right," without any worry or fussing. We would stand beside his lathe, when the boss was out, and watch the boring tool chattering its way through the pulley, or gear, while he leaned carelessly against the ways, and explained that *he* always set his inside calipers just a "feel" to his outside calipers, and of course couldn't make a mistake.

I recall an experience of my own which may be of interest. I was told to turn the bolts for a flange coupling, and make them a light driving fit, and, of course, I wanted to make a record, so I rushed the job along until the bolts became heated. They were finished, and driven into the coupling while in this condition, and after a while the boss came around to inspect the job. In the meantime the bolts had become cool, and the boss was able to drive them out with his hand. I learned more about the expansion and contraction of metals from this simple experience, than a year's study of physics would have taught me.

The variety of work that we had was not as great as it is in a job shop, but it was varied enough to keep it from being monotonous. Once there was some difficulty with one of the Westinghouse single-acting vertical engines, which made it necessary to send an expert up from Pittsburg to investigate. The engine had to be rigged up so that indicator cards might be taken, and I had the pleasure of helping on the job. The expert, a gray-bearded, white-haired old man, seemed to me to be the smartest man I had ever seen. He would take a card, and then taking it off the drum, would study the, to-me-meaningless curve, and nod his head wisely, and mutter something about the valves or eccentric. At any rate, he located the trouble, and repaired it, or had us do it, and sent in a nice little bill, I suppose. It was whispered around that he got five dollars a day, and expenses, for his services, which looked mighty big to an apprentice getting seventy-five cents a day, and paying his own expenses at that.

My experience after going into a railroad shop was somewhat different. Not having served my time, I was considered an apprentice still, and as the other apprentices didn't know that I had had any shop work at all, I was the object of many remarks, when the boss put me on a bolt lathe. When I passed over several others and got this job, there was a good deal of feeling, which gradually disappeared when they found that I could turn bolts to fit, without filing off the last 1/64 inch, as seemed to be the custom. Sometimes I was given a planer job, which was rated as a "snap," because I could sit and watch the machine run, and no one came along and told me to take a heavier cut. Work on the pits was harder and more disagreeable, but the apprentices all got their share of it. That branch of the work was managed a little better as regards supervision, as each pit was in charge of a gang boss, and there was considerable rivalry between them, to see who could turn out the most engines; so they would show the apprentices the best way to do things.

Things are much better in connection with railroad work now, and railroad shops are rapidly being put on a commercial basis; and it is to be hoped that some adjustment of the apprenticeship problem will be reached, which will put railroad apprentices on a footing approaching that in the best manufacturing shops.

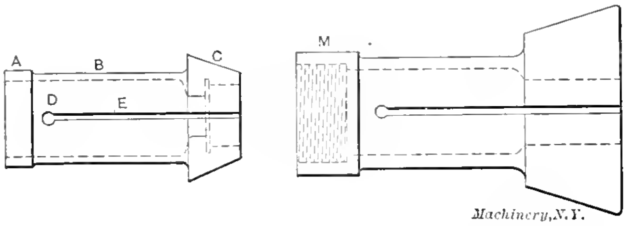
* * *

Do not lose heart and get discouraged. Your success does not lie in the hands of others, but in your own. Do not think that the world is down on you or that, because you merely work hard, you should succeed. The man who works hard building ice ponds in Florida or planting orange groves in Maine is not entitled to victory.—*William F. Forbes, in Stevens Institute Indicator.*

LETTERS UPON PRACTICAL SUBJECTS.

MAKING SPRING COLLETS.

Spring collets are now used in nearly all shops, and there are many varieties, depending on the work they are required to hold, and the machine in which they are used. I will describe how three kinds that are used at our shop are made. The one illustrated in Fig. 1 is the smallest, and this collet is used on a small nut machine, while drilling, facing and tapping small solid cast brass nuts. This collet is closed on the work by being thrust forward into a taper collar. The



Figs. 1 and 2. Showing Collets of the Push-in and Draw-in Types.

collet is made heavier at A, because the plunger strikes it there, and also because it will keep its shape better while being tempered or case-hardened. The collet has three slots, 1/16 inch wide, which allow quite a little spring. These collets are now made of machine steel. They were formerly made of tool steel, but it was found that by using machine steel the original cost was much less, and the wearing qualities were very much better. Tool steel crystallizes from constant springing, and owing to their shape, the collets were frequently broken in tempering.

To make the collet, a piece of machine steel just a trifle larger than the finished collet is chucked, and the end A faced. The smallest size hole of the collet is bored clear through, and the large hole is bored as deep as the head C. The piece is then put on a mandrel, which only fits into the

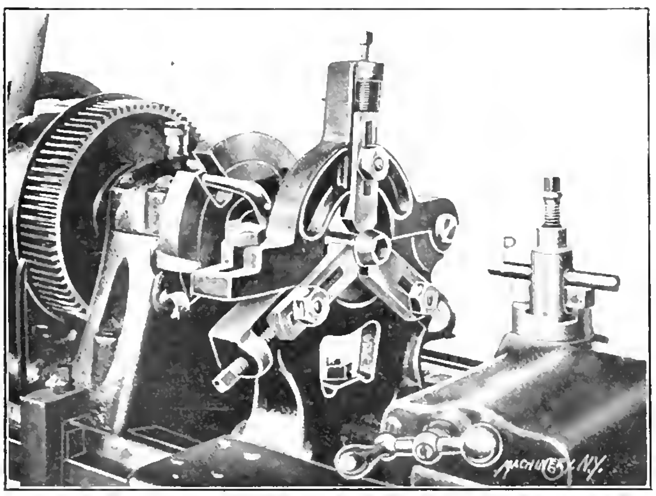


Fig. 3. Method of broaching a Collet in a Lathe.

collet as far as the head C, and the other end is faced. The parts A and B are turned, and then the compound rest is set, and the head C is turned to the required taper. The steady-rest is now placed on the lathe, and adjusted to the work just back of the head C, as shown in Fig. 3. A hole is then bored, the diameter of which is equal to the short diameter of the hexagon nut which the collet is to hold, and the depth about 3/64 inch less than the length of the nut. At the bottom of this hole a narrow recess is cut. The diameter of this recess should be a little more than the distance across the corners of the nut to allow the broaching tool to cut through. The broaching is done in the lathe, and when this is being done, it will be necessary to rotate the lathe through one-sixth of a revolution, as a hexagon is to be formed. This can be done by laying off six equal spaces on the face-plate, and measuring with a pointer from some fixed point on the bed to the spaces; but if the number of teeth on the large gear is right, this will not be necessary. For example, the gear shown in Fig. 3 has seventy-eight teeth. These are divided into six equal divisions, or every thirteenth tooth is marked. A steel stop, which rests on the bed of the lathe, is made to engage with these marked teeth, and in this way the necessary divisions are obtained. The broaching tool is shown at D. The broaching is done by moving the carriage back and forth by hand. Several cuts are taken, then the work is rotated through one-sixth of a revolution, and the operation is repeated. This is continued until the hexagon is nearly to the required size. The tool is then set to make the hexagon the finish size, and the six cuts taken without moving the tool. The back gear should be in when doing this work, in order to steady the spindle. We formerly laid out these hexagons, and cut them in the shaper, but it is very much better to broach them, using the lathe. After the hole is broached out, three 1/8-inch holes D (see Fig. 1) are drilled. These holes are spaced so as to be in line with every other corner of the hexagon. The collet is now driven on a man-

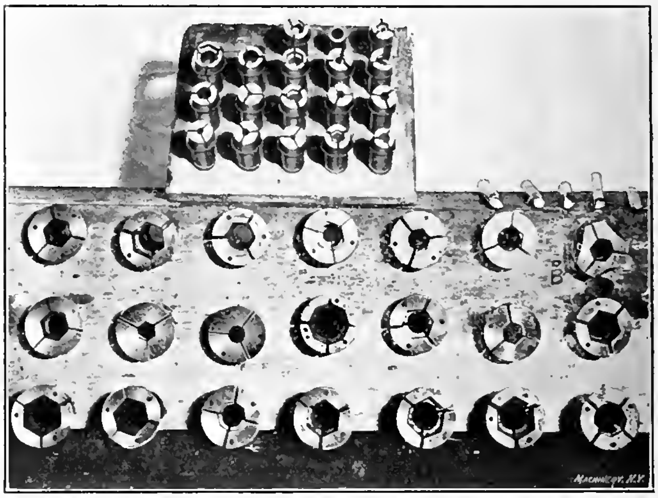

Fig. 4. Collets of Various Sizes and Broaching Tools used in making them.

drel, and the slots E cut. This is done on the milling machine, a 1/16-inch slitting saw being used. After the collet is slotted, the burrs are filed off, and it is ready to be case-hardened. Pieces are then inserted in the slots to spread them open, and they are case-hardened while in this position, which permits the work to be inserted easily.

The collet shown in Fig. 2 has an internal thread at M, and it is screwed onto the plunger or quill. This collet is closed by being pulled into a taper collar. It is used for holding round and hexagon bars, brass fittings, etc. This collet has three holes drilled into its face, and a wrench having three pins which fit into these holes, is used when screwing the collet onto the quill.

The collet shown in Fig. 5 also has an internal thread, and it is much heavier than the other two. It has four 1/8-inch slots, which allow it to spring, and there are four grooves cut into it, which engage with keys, making a positive

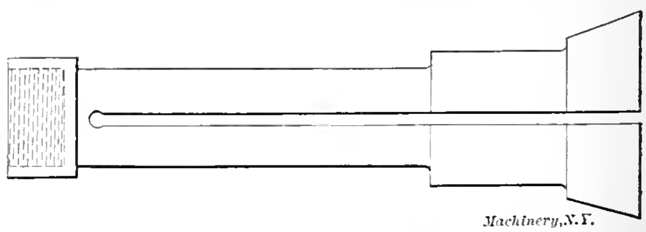

Fig. 5. Large Collet of the Draw-in Type.

drive. The collet is opened and closed by compressed air, and it is used for holding compression cock stems, and similar pieces, while they are being box-tooled and chased with a die. An 8-pitch, square thread is cut on the stems referred to, which shows how well this collet holds the work. That part of the collet which comes into contact with the work, is corrugated to prevent the work from slipping. These corrugations are also made by broaching.

A number of these collets are shown in Fig. 4. The small

collets shown at the top are the same style as the one illustrated in Fig. 1, and the larger ones below, are the same as the one shown in Fig. 2. The collet marked *B*, which is seen in the upper right-hand corner, illustrates the way in which they are sometimes broken in tempering. The tools shown just above this broken collet are the broaching tools. Two of these are used for cutting hexagons, one for squares, and the other two for corrugating the collets.

Decatur, Ill. J. J. VOELCKER.

TOOLS FOR BORING AND TURNING SPACING COLLARS.

The tools shown in the accompanying illustrations are used for the boring, reaming, and turning spacing collars. By using these tools the collars can be bored, reamed, and faced, while in the chuck, which is a decided improvement over the method formerly employed. This method consisted of first boring and reaming the collars in a chuck, and then driving them on a mandrel to be faced. As a rule the width of spacing collars must be within a certain limit, as they are used in strings of from thirty to sixty on one shaft, and any variation in width will be multiplied according to the number used.

When using the tools shown, these collars can be bored, reamed, and faced in a turret lathe. Fig. 1 shows the com-

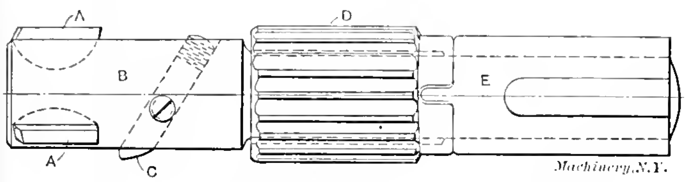

Fig. 1. Combination Drill, Boring Tool and Reamer.

bination drill, boring tool, and reamer used. Three high-speed steel cutters *A* in the shape of a Woodruff key, are set into the soft steel shank *B*, forming a three-lipped drill. The boring tool *C*, which follows the drill, trues up the hole and makes it the proper size for reaming. The reamer *D* is of the "floating" type, and it is kept from turning by the projections on the sleeve *E*. This sleeve, which is split, fits into a socket, and acts as a holder for the drill and reamer. With this arrangement, it is not necessary to swing the turret-head around, as would be the case if three separate tools were used. The only requirement is that the speed be changed when using the different tools. After a collar has been bored and reamed, it is faced to the required width by using the straddle-tool shown in Fig. 2. The shank *F* of this tool fits into the cross-slide of the turret. The cutters *G* fit into a

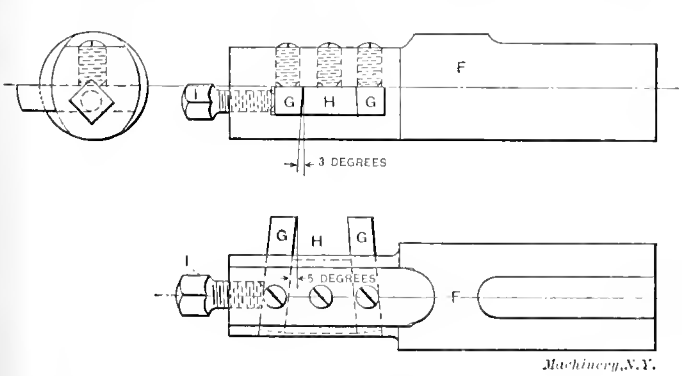

Fig. 2. Straddle-tool for facing Collars.

slot as shown, and the distance between their cutting edges is regulated by the adjusting wedge *H*. The wedge and the cutters are each held by a separate set-screw, to allow independent adjustment. After they are properly set, they are fastened securely in place by the set-screw *I*. A side clearance of 3 degrees, and a back clearance of 5 degrees, is given to each cutter. That part of the shank containing the cutters is made oval, as shown in the end elevation, Fig. 2, so that the tools can have sufficient lateral movement for facing the work.

After the collars have been bored, reamed, and faced, they are strung on a special mandrel (which holds eighteen at one time) and splined. They are now ready to be turned to the required outside diameter. The collars are splined before turning the outside, because the mandrel shown in Fig. 3 is provided with a feather *L*, which acts as a driver. A heavier

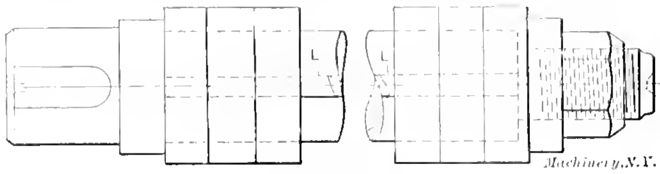

Fig. 3. Mandrel for holding Spacing Collars.

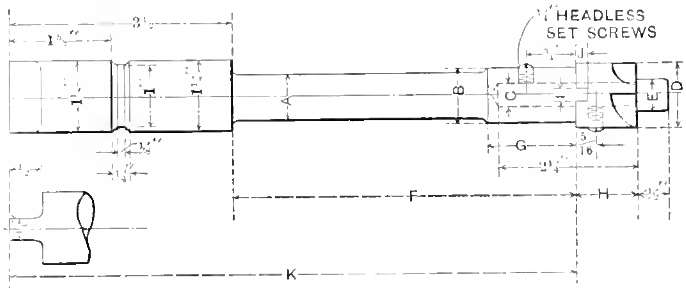
cut and a coarser feed can be taken when driving in this way, and a number of collars can be securely held and turned at one time. CHARLES THIEL.

Lawrence, Mass.

TABULATING DIMENSIONS OF TOOLS.

The cut shown herewith shows an idea which will be very acceptable to all tool designing rooms, and also to all regular drawing rooms making tool-room drawings. The foreman of the tool-room wanted sketches of a number of sizes of counterbores, having various sizes of pilots, and all fitting the same spindle. To save time in drawing, tracing, and blue-printing, I have standardized a sheet, as shown in the cut. All dimensions which are constant are given in their proper places on the drawing itself, while all those which differ for different



No.	A	B	C	D	E	F	G	H	I	J	K		
1	3/4"	3/4	5/16	3/4	3/8	4		1	3/16	3/16	7 1/2		
2	3/4	3/4	5/16	5/8	5/16	4		3/4	1/8	1/8	7 1/2		
3	3/4	7/8	3/8	1	3/8	4	1 3/8	1	3/16	3/16	7 1/2

Machinery,N.Y.

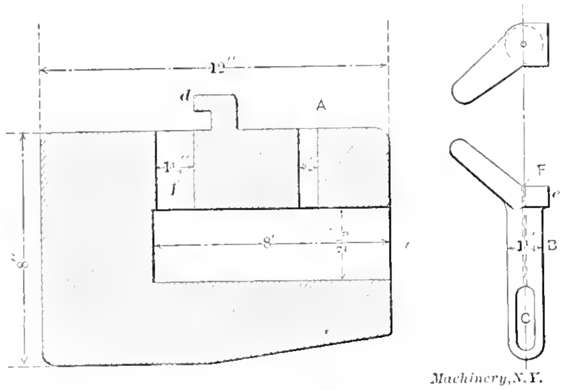
Example of Tabulated Tool Dimensioning.

sizes are indicated by letters, and tabulated. Vacant columns are left in the table of dimensions, and the tool-maker foreman can now supply the required figures for any new sizes he wishes to make, and turn the print over to his workman without waiting for another sketch. This idea can be used for a great variety of tools and fixtures, and we find it a great saver of time. TOOL DESIGNER.

[A system that in some respects is even better than the one mentioned by our correspondent is in use in some drafting-rooms. Instead of inserting letters for variable dimensions and tabulating them, the spaces where the variable dimensions are to be given are marked on the tracing with circles filled in with india ink, thus producing on the blue-print a white spot on which the dimensions can be conveniently and plainly filled in with ink. The work of filling in the dimensions on the various blue-prints is hardly more than that of tabulating; but the advantage gained of having one distinct blue-print for each tool aids greatly in preventing mistakes in the shop, due to reading the dimensions wrong in the table.—EDITOR.]

CANNON FOR SHOP USE.

The cut shows a cannon which is used principally for driving large keys. It is a breech-loader, and because of this, has an advantage over the one shown in September MACHINERY. This device, which has been in use for many years at the Portland Company's shops, Portland, Me., was designed for driving the keys on the paddle wheels of side-wheel steamers. The barrel *A* is of cast iron, and of the dimensions given. There are four ¾-inch eye-bolts tapped into the sides, to facilitate handling. Three ⅝-inch holes are drilled as shown, for the escape of the gases. The powder is placed into the cavity *C* of the breech plug *B*, and covered with a piece of tissue paper which has been moistened to make it



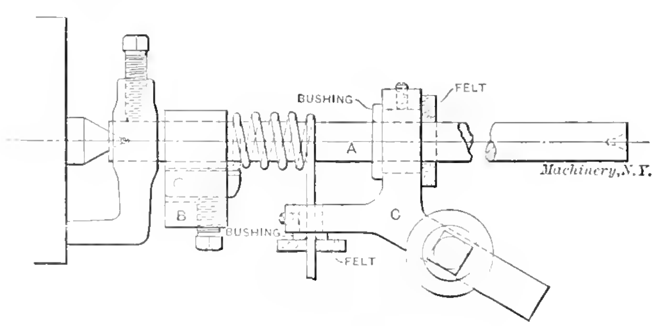
Cannon and its Breech Plug.

stick. The breech plug is then inserted in the hole *f*, and the handle turned so that the lug *d* engages with the projection *e* on the plug, holding it securely in place. The shot, which consists of a hardened piece of steel, about six inches long, is placed in the muzzle, and the cannon is fired with ordinary cannon primers, which are placed in the ¼-inch hole *F*, in the breech plug. A string about five feet long is attached to these primers, and in this way they are exploded. In driving keys, coupling bolts, etc., it is not necessary to chain the cannon, as its weight will take care of the recoil. There is very little danger attached to the use of this device, if the breech plug is cooled before it is reloaded. After firing, the barrel should be swabbed out, first with wet, and then with dry waste. Of course, the usual precautions in handling gun powder should be observed. H. K. GRIGGS.

Portland, Me.

TOOLS FOR WINDING SPRINGS IN AN ENGINE LATHE.

The manufacturing concern by whom I am employed use a great many small compression springs, made of red bronze spring wire, in a variety of sizes and lengths. As it has not been possible to buy springs of sufficiently accurate or durable quality, it fell to my lot to make them on something like a



Tools for Winding Springs in a Lathe.

commercial basis, and at the same time without spending much money for tools, as it was hoped we could buy them outside when the demand became greater. It is necessary that these springs be set, or squeezed together once only, after being wound, since they are never compressed again to that extent in service. It is thought that they will then fill the space they are supposed to occupy for a longer period of time. By referring to the accompanying sketch it will be seen how they were wound and compressed, or set. *A* is the mandrel which is made of drill rod, in a variety of sizes to suit the springs to be wound. Each size mandrel has fastened at one end a piece *B* in which is pivoted a beveled edge tool steel piece, which in connection with the set screw shown holds the end of the wire being wound.

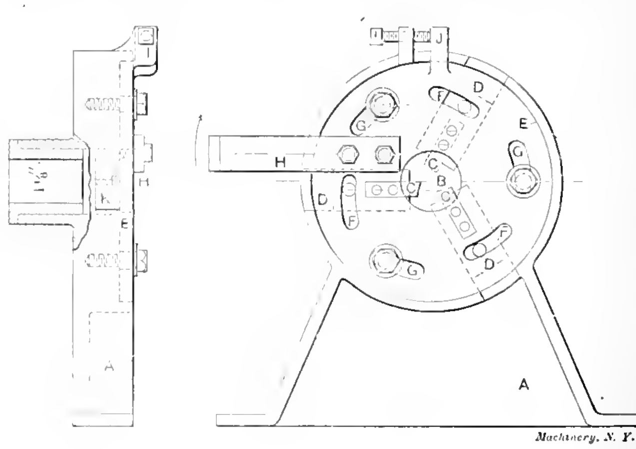
This method of fastening is a great improvement over the usual hole in the mandrel, as the wire never breaks off, as it does with the hole, and the spring can be taken off the mandrel without cutting the wire at that end, as is necessary when a hole is used.

Piece *C* is a forked piece which is held in the tool post of the engine lathe. One end of piece *C* is bored to receive guide bushings for the different sizes of wire to be wound. The other end is bored to receive bushings for the different sizes of mandrels. The end which passes over the mandrel serves a double purpose. It acts as a follower rest, making it possible to use long, slender mandrels. It is also used to compress the springs. By releasing the nut from the lead-screw, the lathe carriage can be moved by hand toward the head-stock until the spring is closed up solid, and then released again and taken off the mandrel, and the operation repeated. The springs are then cut up into short lengths on the punch press, using a stop so that each spring will have the same amount of wire in it. As there was formerly a short piece wasted on each piece wound, the saving in winding as long as possible will be apparent. Eighteen per cent was scrap wire. We now lose less than two per cent. It will be noticed that the holes in the bushings are rounded at the ends, also that pieces of felt kept filled with oil are fastened where the wire and mandrel pass through them to keep from roughing up the wire and mandrel. These little points are very important, as they often spell success or failure for tools.

C. G. H.

CUTTING TRIPLE THREADS.

The accompanying cut illustrates an economical device for cutting triple threads. The frame *A* is bolted to the lathe carriage, and it is of such height that the center *B* is in line



Device for Cutting Triple Threads.

with the lathe centers. The cutters *C* are held in slides *D*, which slide in grooves planed in the circular part of the frame *A*. These slides are held in place by a circular plate *E*, which also serves to move the slides in and out, through the medium of the cam slots *F* acting on pins in the slides. Plate *E* is held in place by bolts in the slots *G*. A handle *H* serves to rotate plate *E*. A set screw *I* in a lug cast on frame *A* bears against a lug *J* on plate *E* and acts as a gage to vary the depth of cut.

The tools or cutters *C* are set in the slides *D* so that the top surface is in line with the center *B*. They are fastened to the slides by screws as shown in section at *K*, and they are all set in the same plane so that each one cuts a different thread. At the head-stock end of the lathe a slide is bolted, which engages with arm *H* and throws it up in the direction of the arrow thus drawing the cutters back at the end of the cut. A removable bushing provides adjustment for cutting threads on rods of various sizes. With this device four feet of triple square thread 1¼ inch diameter and ¾ inch pitch can be cut in twenty minutes. FRED SEABURG.

Chicago, Ill.

GRINDING THREADING DIES.

In the November issue of MACHINERY appeared an interesting article on the subject of grinding threading die chasers. The points brought up in this connection were rather interesting, but the same trouble as met with by the author of that article may be caused in other ways than the one which he mentions. While not disputing the former writer's opinions, or his remedy, my own experience in regard to the grinding of threading dies has been that they cause trouble on account of not being ground or chamfered in a common sense manner. The die may be to all appearances in perfect condition for doing good work and have an equal chamfer on every land, but the chamfer may not be of a kind that actually does much good. In nine cases out of ten, in manufactured dies, one will find that the chamfer is made on the lines indicated in Fig. 1, which is, to any one analyzing the subject, entirely

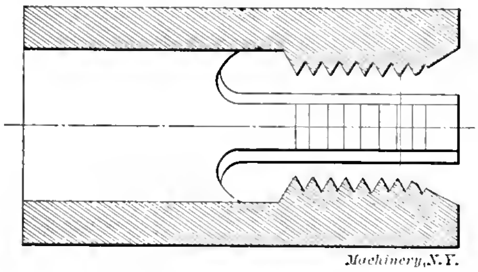


Fig. 1. Die not chamfered properly.

wrong. This die has the appearance, when examined, of having a very liberal chamfer, but the actual fact is that this die has only about 1 to 1½ threads chamfered. Now, whether ground in one way or another, these 1½ threads will have all the cutting to do, and, consequently, will have a tendency to "dig in." The land that digs into the metal first will, of course, leave little or nothing for the other lands to cut. I think that it is right here where the difficulty lies. That would coincide with Mr. Cleverdon's experience, as he says that on dies with a long chamfer, that is, where the chip is distributed over several threads, the difference in the total lengths of the cutting edges becomes negligible, and the remedy he mentions would not be necessary to apply. All his trouble

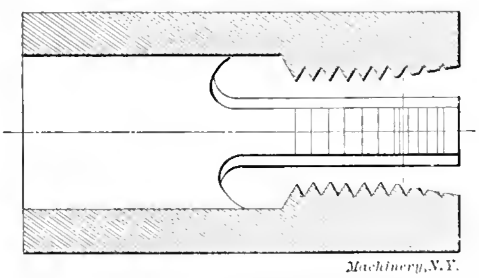

Fig. 2. Die correctly chamfered.

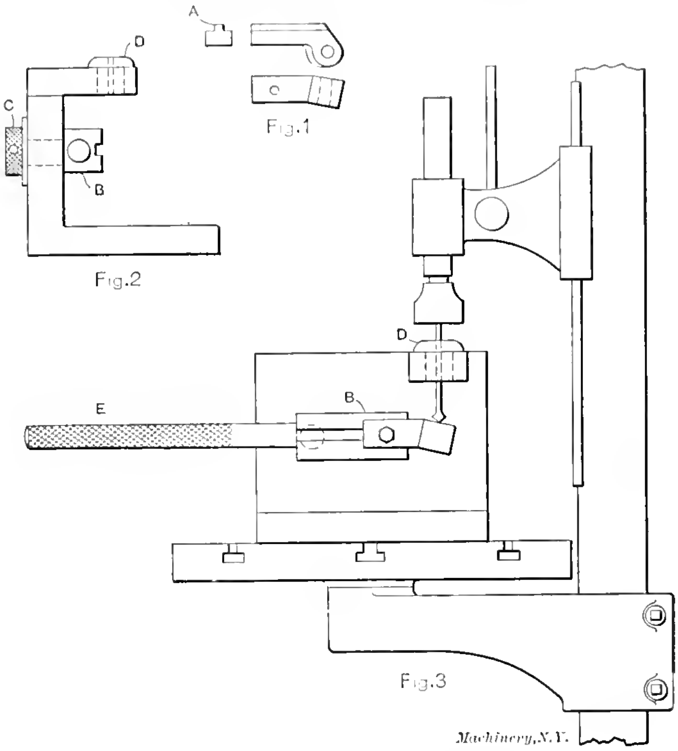
has been met with in dies with but short chamfer. My personal experience indicates that if a die is otherwise well made in all respects, and then has a chamfer like the one shown in Fig. 2, there would be no difficulty. The thread of the die should never be chamfered more than to the root of the thread. Whatever chamfer is made above this line is absolutely useless unless it be that the turret and spindle of the screw machine in which the die is used should be so much out of line that the die would have to act as a guide for the blank, in which case a chamfer like that shown in Fig. 1 would come in quite handy. It might also be argued that a die held in a *loose* die holder must have a chamfer like that shown in Fig. 1, in order to start properly, but even in this case a chamfer as shown in Fig. 2 should be used, and the blank to be threaded should be chamfered before it is presented to the die.

A.

METHOD OF DRILLING CURVED HOLES.

The accompanying cuts illustrate a method of drilling holes through needle guides, the holes following the arc of a circle. Fig. 1 shows the guide after it is finished. The tongue-piece *A* is milled so that it fits into the groove of the holder *B*, Fig. 2. This holder fits closely into a hole in the angle plate, and it is held against the plate by the nut *C*, which is just loose enough to permit the holder being turned on its axis. The drill bushing *D* is located above the work as shown. The hole through the bushing which guides the drill is made to fit the shank of the drill instead of the point. The drill is flat pointed, and its shank is much smaller than the point, so that it will allow the work, when being drilled, to turn without rubbing against the shank. The reamer is of the



Drilling a Curved Hole in a Needle Guide.

ball type, and it is essential that the ball be round, if the hole is to be accurate. The shanks of both drill and reamer are ground and lapped to fit the hole in the bushing *D*.

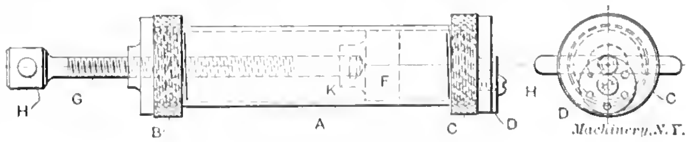
Fig. 3 illustrates the way in which the jig and the work are placed on the drill-press. The work is fastened to the holder by a bolt, as shown, and its position located with a height gage. By pressing down on the handle *E* the work is fed against the drill, and the hole is drilled on an arc, the radius of which will depend upon the distance from the axis of the holder to the drill.

K. R. CROSS.

S. Boston, Mass.

DEVICE FOR MAKING WAX FILLETS.

The accompanying cut shows a device for making wax fillets, which I came across the other day. As a good method of making the various sizes of wax fillets used on wood pattern work, at the time and in the exact quantity needed, I think this tool will be acceptable to any up-to-date pattern shop owner or pattern maker. The device is nearly self-explanatory, but a short description will serve to make its work-



Device for making Wax Fillets.

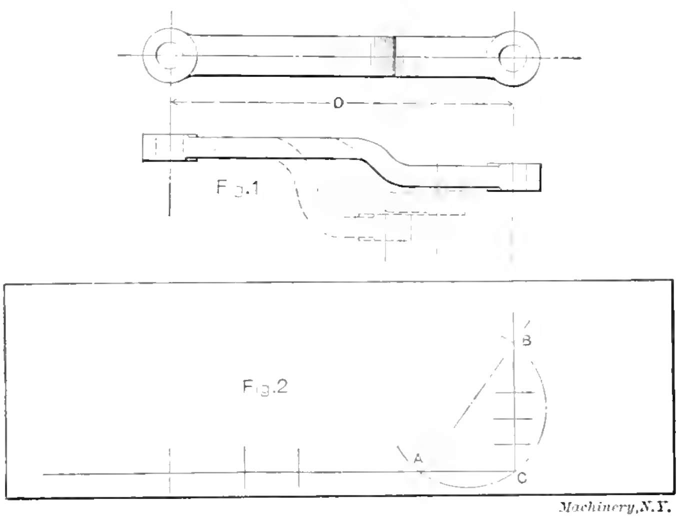
ing more clear. The barrel *A* is a piece of seamless brass tubing. The cap *B* is made of soft machinery steel, tapped to fit the compression screw *G*. This screw is fastened to the plunger *F* by the pin *K*, allowing the screw to turn without turning the plunger, but preventing its withdrawal in backing off. The cap *C*, also of soft machinery steel, has a hole in the center slightly larger than the largest size of fillet it is desired to make. The circular plate *D* is made of sheet steel, and drilled with different sized holes to correspond with the sizes of fillets wanted. It is screwed to the cap *C* so that

the holes will coincide with the central hole in the cap. The working of the device is obvious. By warming the barrel after filling it with odd pieces and scraps of wax, and setting the plate *D* for the size wanted, the fillet is made by turning down the compression screw with the handle at *H*.

Detroit, Mich. M. R. KAVANAGH.

LAYING OUT OFFSET LEVERS.

During my stay with an automatic machinery company in the East, I had a number of cast iron levers with various offsets to lay out. These levers were made as shown in Fig. 1, and the distance between centers was given on the blue-print as indicated. It was important to get these dimensions within close limits, so I went about the work as follows. I took a piece of sheet iron, Fig. 2, and with scale and scriber drew a base line. With the dividers I erected a perpendicular at the end of this base line, in the manner shown, and stepped off on this perpendicular the offsets of the different levers. Then, from the intersection of the perpendicular and the base line, I measured off the distance between the centers of the levers. It now only remained for me to set the dividers on the proper center dimension on the base line, and the corresponding offset point on the



Offset Lever, and Method of making Lever to Required Dimensions.

perpendicular, and transfer this to the right lever, estimating with my eye the location of the center of the bosses at the same time. E. R. SEITER.

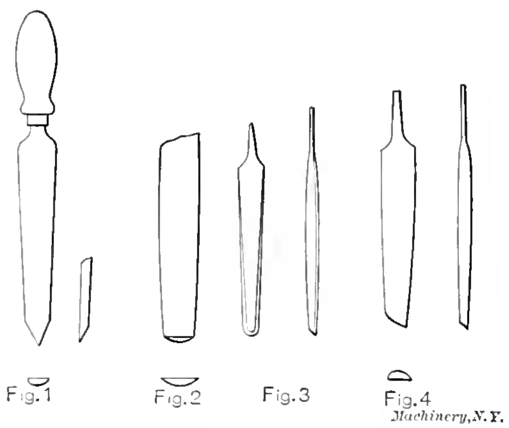
Chattanooga, Tenn.

[The manner in which our correspondent erected a perpendicular to the base line may not be clear to all readers of MACHINERY. The detailed procedure is as follows: Draw any circle with its center outside of the base line, so that its periphery intersects the base line. From one of the intersecting points *A* draw a diameter through the circle, intersecting the periphery again at *B*. From *B* draw a line to *C*, the other intersecting point between the circle and the base line. The angle *A C B* is then a right angle, or, in other words, *B C* is perpendicular to the base line.—EDITOR.]

TOOLS FOR SCRAPING.

Every once in a while it becomes necessary to scrape out a hole in order to true up a certain surface, or clean up a bearing and leave it as large as possible. Almost everything from a chisel to a file is used with varying degrees of satisfaction. The proper tool is a half-round file, ground on the flat face and pointed to an angle of about 60 degrees. One edge is sharp, and the other rounded slightly, as shown in Fig. 1. All the pressure that is put on the end of the handle goes to the cutting edge, and the hole is not marred nor does the tool slip. Another job is the scraping of semi-cylindrical holes in steel, such as drop forge dies, etc. The ancient hook or draw scraper is generally used, in spite of the fact that one cannot see the cutting edge. The proper tool to use is an end-cutting scraper made of a half-round file, Fig. 2, ground to a smaller radius than the work. The great fault with most scrapers, in steel work especially, is too great a length of cutting edge, requiring too great a pressure to keep it cutting. Therefore, slightly round the face and edge of the tools, and keep them always sharp, and stone as soon as they slide or tear. A coarse India stone and a bit of waste soaked in turpentine is often as essential on fine steel work as the scraper itself.

For plane surfaces, sharp corners, etc., the tool shown in Fig. 3 is handy and useful. This is also made of a half-round

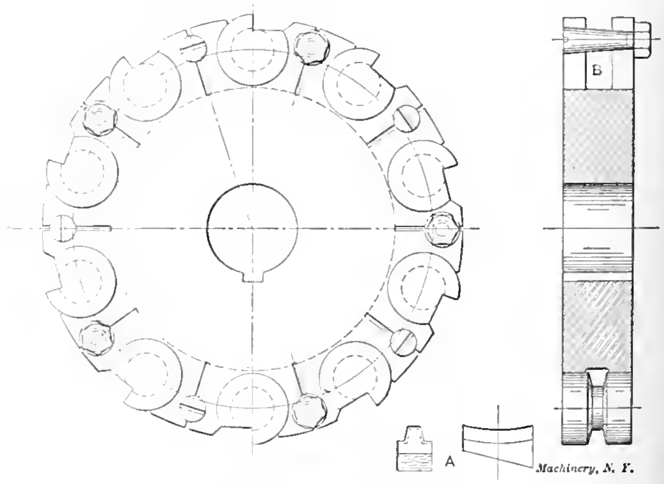


Scraping Tools of Various Kinds.

file. It is sometimes given quite a relief, as compared with the usual end cutting tool, the cutting edge being ground to about 70 degrees. These tools will stand up for a long time on unannealed tool steel and saw steel. Fig. 4 shows a half-round scraper used for the last thousandth in cylindrical work in the lathe, especially steel, and for smoothing out holes. The back edge is rounded so as not to mar the work and the long curved edge avoids chatter from too long a cutting edge, and permits cutting where it is needed. SIRIUS.

INSERTED TOOTH MILLING CUTTER.

The accompanying cut shows an inserted tooth milling cutter, designed to manufacture the brake shoes shown at *A*, in which it is necessary to keep both the form and the radius of the cut to gage. The principle of the inserted teeth is the same as that of the circular forming tools used on screw



Inserted Tooth Milling Cutter.

machines, the teeth being sharpened radially. The taper studs are used to secure the teeth in place by forcing the slots open and binding the body of the cutter on the teeth. The cutter-holding body is grooved in the center to reduce the body of metal to be sprung out in order to bind on the outer edges of the teeth or cutters. As the teeth become dull, they can be ground while in place a few times, before being loosened and again set radially. The advantage of this form cutter is that the teeth can be ground to shape after being hardened (because they are circular) which is impossible with the ordinary form cutter, but often very necessary when the pieces milled have to be correct within small limits. This permits the use of Novo or other high-speed steel, which

ordinarily cannot be used for form cutters, as the outside is burned in hardening. Broken teeth can be easily replaced. No backing off machine, or fixture, is needed for making the formed teeth, which will appeal to small shops which get an order to make a few thousand duplicate parts. The cost of material is considerably reduced as compared with a solid form cutter. Within its limits different kinds of teeth can be used in the same body, but this is only recommended when the removed cutters are of no further use.

Candiac, Canada. S. A. McDonald.

[One weak point in this design of cutter seems to be the cutting of the central groove *B*, which naturally permits the outer edges of the cutter body to bend inward when the nut on the tapered pins is tightened for binding the blades. Another objection is the projection of the nuts outside of the cutter body, as it is never good practice to have projections of this kind on rotating bodies if it can be avoided. These objections, however, are mere details, and can easily be overcome. The principle of the cutter itself is very commendable, and may also be of value as suggestive of similar adaptations for a multiplicity of work.—Editor.]

FACING WORK BETWEEN CENTERS.

After reading in the October issue of Machinery the criticisms of my article on facing work, I called on an expert machinist and tool-maker and inquired as to his practice. He stated that his practice had been for some years past exactly in line with what I stated in the article, and that he had never considered the half-center necessary in lathe work. Mr. Simonds wants to know how I would cup the center of an arbor. Well, if only one arbor was to be cupped I might use the same side tool that was being used to face the end of the arbor. To demonstrate that there is no difficulty in doing this, the expert referred to, in my presence, faced and cupped an arbor with a side-tool without slackening the tail spindle; and he used less time than Mr. Simonds would probably use to change centers and do the work. When there are a considerable number of arbors to center and cup, it is better to use a universal chuck and steady rest. By this method, each center may be drilled, reamed, and cupped, at one setting of the work. The material that arbors are usually made of is nearly enough round to be run in the steady rest. Lapping the centers after hardening the arbors corrects minute irregularities.

I admit that a side-tool used in connection with a half center may be of such a shape as to stand more crowding than will the side-tool I described, and I am glad that Messrs. Simonds and Allan pointed out the advantages of the half center. But Mr. Allan is certainly far from the truth in intimating that the tool I advocated would fail after facing one piece. If he got such poor results, possibly the fault was in the quality or temper of the steel. In using poor steel we have the same trouble with the point of a V-thread tool.

Anticipating questions as to the method of cupping the arbor, it may be explained that the side-tool used in the example cited was of a sufficiently sharp angle to admit of setting the tool around to the right for cupping. To get a smooth job, high speed and fine feed were used. While the tool is stronger than it looks in the sketch accompanying my previous article, for ordinary facing its strength could be increased by making the angle at the point just a little less than 60 degrees, a center gage being used to test it by. The tool should not be used for end cutting, except for a light finishing cut. W. S. Leonard.

Atlanta, Ga.

The letters written by Messrs. Leonard and Allan which have appeared in recent issues of Machinery are timely. They bring up a subject which, though simple, is well worth consideration. I differ with Mr. Allan as regards the efficiency of the tool described by Mr. Leonard. I find that it does all that he claims for it. Allan says this tool does not hold its edge. I gave a tool, ground as Mr. Leonard describes, a month's trial, and I am well pleased with the results. One reason that the tool dulls quickly, in common practice, is due to improper care in feeding the tool toward the lathe center. The work at the center is turning very slowly in comparison to its outer edge. For this reason the speed of travel of the tool should be decreased as the tool comes nearer the center of the work, else the tool will be moving faster lineally than the work is revolving. This will cause the work to tear, spoiling its finish, as well as dulling the point of the tool. It is also essential to the life of the tool that its point be in line with the lathe center. Should it be above or below the center, it will be subject to a rubbing or scraping action that will quickly dull the tool. It may be well to say, that the test I gave the tool described by Mr. Leonard, was made on high-grade carbon steel. Wm. H. Addis.

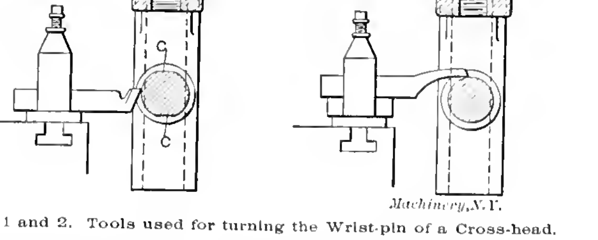
Decatur, Ill.

I have noticed several suggestions in the August, October and November issues of Machinery about facing work on lathe centers. Why face the work on centers at all? This is my method: One end of the work is held in the chuck and trued up roughly; the other end is put in the steady rest. Then the end is faced with an ordinary diamond point tool. A tool shaped like a flat drill, with an angle of 60 degrees, is clamped in the tool post and brought up to the center of the shaft where a slight cut is made for the center drill to enter into. After drilling the center hole to a sufficient depth, the flat drill-shaped tool is again brought up, and the center is cut to the right size, using only one cutting lip. A center formed in the foregoing manner is bound to be perfectly true with the periphery. G. E. Daniell.

Augusta, Ga.

TURNING THE WRIST-PIN OF A CROSS-HEAD.

Turning a wrist-pin which has been cast solid with the cross-head is a job that a few years ago was much more common than at present, although even now it is sometimes necessary to do work of this kind. To turn the pin, and get it round and smooth, requires considerable skill on the part of the one doing the work. Before the wrist-pin is turned, the cross-head should be bored and planed. It should then be carefully centered in such a way that a line passing through the centers will be at right angles to the hole for the piston



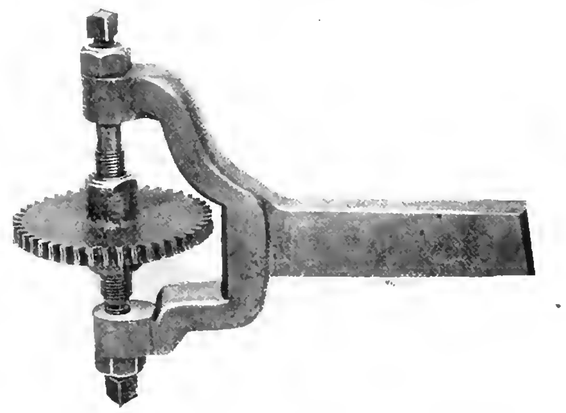
Figs. 1 and 2. Tools used for turning the Wrist-pin of a Cross-head.

rod. After the cross-head has been placed between the lathe centers, a wooden handle should be inserted in the piston rod hole. This handle enables a man behind the lathe to turn the cross-head back and forth on the lathe centers, while the operator feeds the tool for every forward stroke. For the first cut an ordinary round nose tool is used, as shown in Fig. 1. Of course it is necessary to take light cuts. From 120 to 180 degrees of the circle can be reached with this first turning. The position of the cross-head is then reversed, and a cut taken over the opposite side of the pin. It is well to cut clearances *C* for the tool at the beginning and the end of the cut. These clearances can be chipped by hand, but if there is much metal to remove, a slotter should be used. After as much of the pin's surface as can be reached with the ordinary tool, has been roughed out, another tool, shown in Fig. 2, is used to remove the remaining metal. The tools are now ground for finishing cuts, and the above operations repeated. The rough spots, which will be found at the points where the tool marks intersect, can be smoothed off with a fine file. If this part of the work is done properly, the job will be entirely satisfactory. W. L. McLaren.

Ottawa, Ont.

WORM-CUTTING TOOL.

The half-tone herewith illustrates a worm-cutting tool which does away with a great amount of work. When using this tool, the worm thread is first roughed out in a lathe, so that the depth of the thread is about one-quarter of the depth of thread wanted in the finished worm. The worm is then put on an arbor and finished with the tool shown, which is held in the tool-post and permitted to revolve freely. The advantage of this method is the ease of sharpening the cutter,



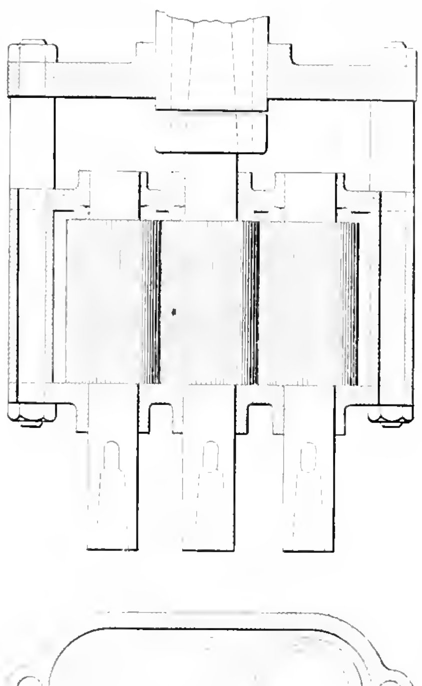
Worm-cutting Tool.

combined with the true shape obtained in the worm thread, it being cut by the generating process. The method of making the cutter is exactly the same as that used for hobbing an ordinary worm-wheel, except that the edges are not beveled off as in a worm-wheel. Instead, the upper side of the cutter is slightly concaved, so as to produce a better cutting edge on the teeth. ALBERT ANDREWS.

Chicago, Ill.

MULTIPLE SPINDLE DRILLING DEVICE.

In a large number of gears three pin holes were to be drilled through one of the arms, comparatively close together, too close, in fact, to permit the use of an ordinary multiple spindle drilling machine. For this reason, the device shown in the cut was designed to be attached to an ordinary drill press. The three pinions are made of steel, and drill sockets and pinions are made in one piece. Ball bearings at the end of the pinions take the end thrust. In order to prevent the device from revolving with the drill press spindle, a yoke clamped to the spindle sleeve is secured to the gear case by short, stiff tie rods. The drills used with this device are of the inserted blade type, having soft steel shanks with four high speed steel blades, one of the drills cutting right-hand, and the other two left-hand. Y. Z.



Multiple Spindle Drilling Device.

SHOP LIGHTING.

It is announced regarding the construction of a certain new manufacturing plant that the windows will *not* be frosted, and that the workmen will be able to see the beautiful park adjoining by simply looking up from their work. Such a view is not obtainable from every shop, but the adverse effects of the translucent pane are much more clearly realized now than when this style of glazing was first installed. A man may work in front of a blank wall without serious protest, but there is something peculiarly irritating in being compelled to stand day in and day out before a window, with a mental realization, but not a visual perception, of the view without. If the human interest to see the world outside is not satisfied, there seems to be a deadening influence which has its effect in reducing efficiency. Of course, there are conditions where only distraction can result; when the view becomes a motion picture, a sort of continuous show. Broadly speaking, however, experience has shown the unwisdom of setting the entire sash in translucent glass, and the advantage of the shop in the open country, with its touch of nature in the view. In so far as ribbed or prismatic glass may be essential to the better illumination of the interior, it may be set in the upper part of the sash, leaving the lower portion clear, but the idea of the prison cell should be removed from the mind of the workman. Incidentally, the difference in lighting value between a clean and a dirty window should not be overlooked. In a certain shop, lighting up was not necessary for an hour later in the day, after the windows were washed. W. B. S.

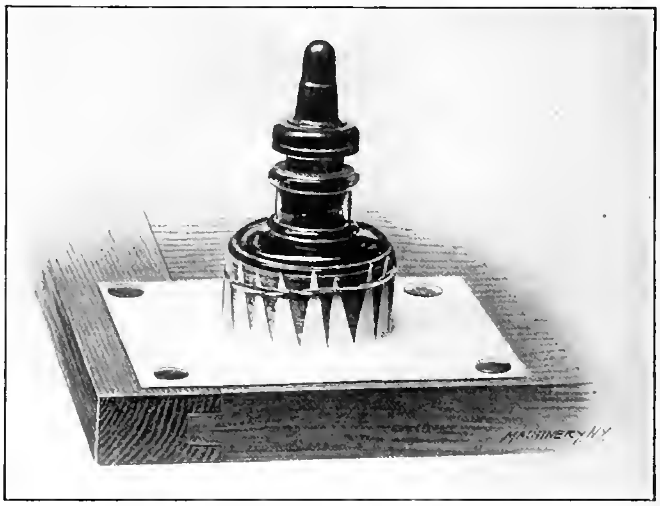


Fig. 1. Securing the Ink Bottle.

SECURING THE INK BOTTLE.

The greatest efficiency often lies in the greatest simplicity. The illustration, Fig. 1, shows one of the most effective means of preventing what has always been a source of great annoyance to the draftsman, *viz*, the overturning of the ink bottle. In the center of a four-inch square of ordinary drawing paper, scribe a circle equal to the diameter of the ink bottle. Divide the circle into about twenty-four parts, as shown in Fig. 2, then with a sharp knife, cut the paper from each of these twenty-four points to the center, following a radial line. Press the paper down over the neck of the bottle. Around the paper points, which stick up around the bottle like a picket fence, put six or eight ordinary elastic bands. Thumb tacks in opposite corners will securely hold the entire outfit to any part of the board desired. C. H. RAMSEY.

Paterson, N. J.

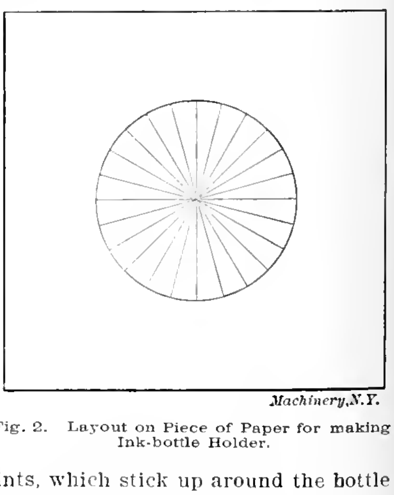

Fig. 2. Layout on Piece of Paper for making Ink-bottle Holder.

CONTOUR GAGE.

The accompanying cuts illustrate a special tool which we have found of great value in certain classes of work. The need of some such device became apparent when patterns and core boxes were required to be accurately checked with the drawings of a certain brass specialty concern. The tool

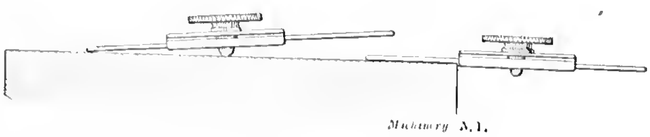

Fig. 1. End View of Contour Gage.

is applied to the work, and the wires pressed down onto the contour by using the side of a lead pencil. Of course, patterns parted on the center could have their halves laid directly on the drawing without using the contour gage, but our patterns were carded and inseparable. Such a tool proves a relentless check upon the patternmaker, who, by

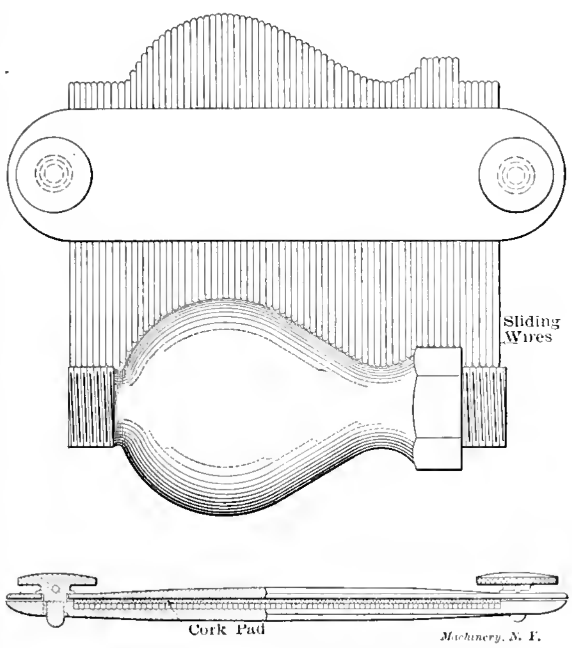

Fig. 2. Setting Gage to Turned Semple.

making the patterns larger than necessary, can cause a considerable loss in a business where thousands of casts are made yearly from the same patterns. As a ready and universal templet it is the best I have seen. Howard D. Yoder.

GALLING OF METALS.

There is rarely any little mishap in shop practice that will cause more annoyance than the galling of a shaft, or mandrel, in its enveloping piece. This is most likely to happen when the inner and outer pieces are of the same material, but it occasionally occurs when the materials are different. Such a mishap is nearly always due to the lack of oil. When cutting a thread in a casting, which is to be fitted to a screw by the cut-and-try method, oil should be used on the screw very sparingly, because it would otherwise be transferred to the internal thread, making it difficult to dislodge the fine chips. For this latter reason, a certain machinist in making a new face-plate, tried it on the lathe spindle without any oil. He succeeded in screwing it up against the collar, but on unscrewing the plate, it galled to such an extent that it became necessary to split the plate in two parts to save the thread on the lathe spindle. When trouble of this kind is caused by the fine chips which are apt to adhere to the threads of a face-plate, it can be almost entirely eliminated by cutting two shallow key-ways, one through the hole in the face-plate, and the other on the threaded part of the spindle. These key-ways scrape the thread clean, and they are also a receptacle for the dirt.

A peculiar example of galling, and one which the writer has observed but three times during a long experience, is that of the lathe center galling in the work. A case of this kind happened in connection with a "hurry-up" job, which a certain man had charge of a few years ago. He was very nervous, and impatient, and generally underestimated the time required to do any piece of work. Being dissatisfied with the progress of some lathe work that was being done for his job, he requested the foreman to let him do the turning, declaring that "he could do the work while Jim Slowcoach was getting ready to do it." He was given a lathe and told to go ahead. He started in with a heavy cut, and coarse feed, and

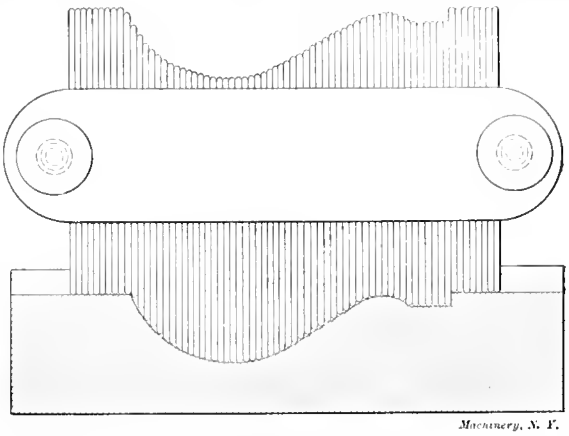

Fig. 3. Testing Core-box with Gage.

was so busy in trying to keep the belt from slipping, that the insignificant matter of oiling the lathe center was overlooked. Suddenly the work dropped to the floor, and he was surprised to find that about half of the conical part of the right-hand center had been sheared off. On examining the work, he discovered that the end of the center had galled in the work so tightly that it appeared to be welded. This could not have been the case, however, as the heat caused by the lack of oil was certainly below that of fusion. Nevertheless, the center had to be cut out with a chisel.

A large boring bar or mandrel should have an oil hole drilled from the periphery to the extreme end or bottom of the center, and this hole should be tapped and fitted with a small plug. If, in addition to the oil hole, three equidistant shallow oil grooves be cut in the conical part of the center, without extending quite to the outer end, the combination would make a perfect self-oiling arrangement. A single groove in the conical part of the lathe center will enable the workman to oil the center without slackening the tail-spindle, but the plugged oil-hole has an advantage, as it provides a reservoir of oil, and a continuous feed. One objection to slackening the tail-spindle for oiling is that oil thus applied is likely to wash fine chips between the lathe center, and the work center, and cause the work to run out of true.

For heavy lathes, a very efficient center oiling arrangement may be made by drilling a small hole axially in the outer end of the dead center, and then drilling a larger hole at right angles to, and meeting the small hole. To insure an ample supply of oil, the large hole might have an oil tube or an oil cup. W. S. Leonard.

Atlanta, Ga.

* * *

Pure putty is usually made in what is known as a "chaser," of whiting and linseed oil. The proportions are about eighty-five pounds of whiting and fifteen pounds of raw linseed oil. Bolted American paris white is commonly used in this country for the purpose, though imported whiting may also be used. Of course these proportions are only tentative, and must be varied according to the consistency of the mass produced. For quick drying putty, boiled linseed oil is used instead of raw, and about ten per cent of dry white lead is added to the whiting. This is the old receipt for pure putty. At the present time, however, very little commercial putty is made according to this formula, large proportions of crude cotton seed oil (known in trade as "putty oil") being substituted for some of the linseed oil, and boiled linseed oil being used instead of raw to counteract the slow drying qualities of the cotton seed oil. Instead of fine paris white, common whiting with varying proportions of fine marble dust is used. G. R. Heckel in *Trade Press List*.

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

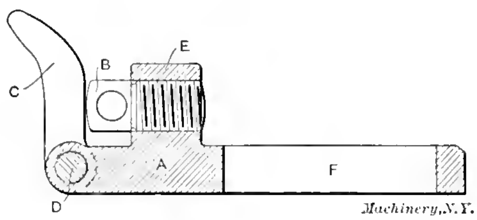
SUBSTITUTE FOR THUMB-TACKS.

It is very exasperating to have a triangle or T-square catch on the head of a thumb-tack, when making a drawing. In the drafting room where I am employed, we have the regular thumb-tacks, but very few of them are used. We use instead a very small iron carpet tack, being the size used to fasten window shades to the rollers. A magnetic tack hammer is employed to drive them. These tacks can be driven in until the head will not catch on the triangle or T-square, and, being very short, are easily extracted. Five cents' worth of these tacks will last as long as a dollar's worth of thumb-tacks, and they have the additional advantage of *not* standing point upwards on the draftsman's stool. A DRAFTSMAN.

[In some drafting rooms small copper tacks are used as a substitute for thumb tacks. The copper tacks, being softer than iron carpet tacks, have the advantage of flattening out entirely to the surface of the paper, presenting no projection whatever. They, of course, are at a disadvantage as compared with the carpet tacks as they cannot be handled with a magnetic hammer.—EDITOR.]

HANDY PLANER DOG.

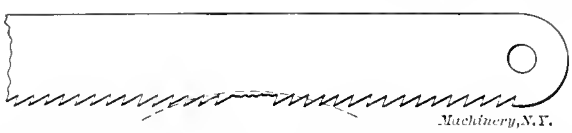
The accompanying cut shows a simple planer dog, which can be used to advantage on almost any class of work. On very heavy work, however, the relative proportions of the body *A* are rather light, and should be increased. The design of the appliance is very simple, and is plainly shown in the



cut. A body *A* is provided with a lug *E*, into which is threaded screw *B*, the other end of which bears against the binder *C*, swiveling around pivot *D*. The body *A* is clamped in the T-slots in the planer table, a long slot *F* being provided for adjustment. A drilled hole in screw *B* makes it easy to turn the screw when binding the clamp *C* against the work. O. G.

SAVING A HACK-SAW BLADE.

Most machinists have doubtless noticed that when one or two teeth break from the blade of a hack-saw others soon follow. This is especially true when the piece being sawed is narrow, because the saw drops when the space made by the

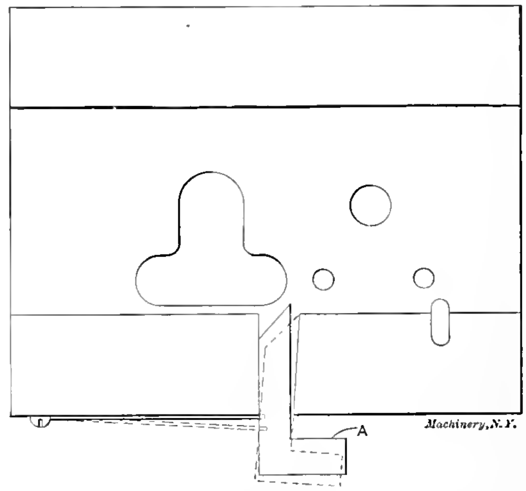


broken teeth passes over the work. Other teeth can be prevented from breaking out, by grinding two or three teeth on each side of the broken part, as shown by the dotted line in the cut. This will prevent the teeth which are next to the broken part from striking abruptly against the work. This kink may not be of interest to the man in a large shop where saw blades are plentiful, but it may be useful to those working in small jobbing shops, where very often the blade being used is the last one on hand. A. E. FISH.

Denver, Col.

STOP FOR STOCK IN BLANKING AND PROGRESSIVE DIES.

The stops which we use on all blanking and progressive dies are of the automatic type. The cut shows a die with stripper removed, but with guide plates and stop in place. The stock is fed up to the stop, which is so located as to give a whole blank the second stroke. As the punches descend, a pin engages the stop at *A*, and forces it out, but not until the pilot pin in the blanking punch has engaged the perforated hole in the stock. On the up stroke, the stop is released and is resting against the edge of the stock in a position indicated by the dotted lines. When the stock is pushed forward by the operator, the point of the stop engages a notch cut

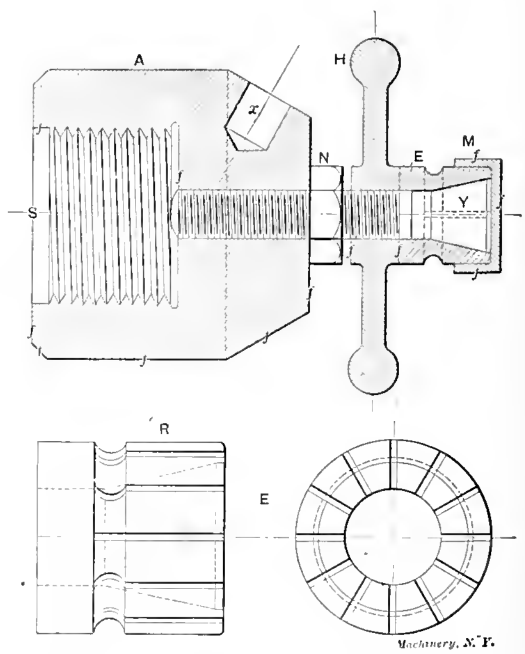


in the side of the stock, bringing it to a full stop when the back of the stop gets a bearing against the side of the slot in the die in which the stop is placed. As the punches descend, this performance is repeated. The pin, which acts as a trip, is made of ¼-inch cold rolled stock, filed to an angle on the end, and case-hardened. K. L. ROSS.

St. Louis, Mo.

EXPANDING CHUCK.

A simple, but very effective, expanding chuck can be made as shown in the accompanying cut. The part *A* is made of machinery steel, and screws onto the lathe spindle at *S*. A rod of suitable diameter is inserted in the hole *x* when it is desired to screw the part *A* on or off. A lock nut *N* and a hand-wheel *H* are screwed on the expander *Y*. The expanding chuck *E* fits over the expander *Y*, and is made to expand by being forced against the taper part of the expander by



the hand-wheel *H*. The expander *Y* and the chuck *E* should be made of tool steel, and hardened. The surface *R* (see enlarged detail) of the chuck can be roughened for small, smooth work. This simple arrangement can be varied to suit any case where work must be held internally. The small piece *M*, which is to be finished as indicated by the finish marks *f*, is an example of the kind of work held by this chuck.

TOOL DESIGNER.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

TO LOOSEN PULLEYS WHICH ARE RUSTED FAST ON THEIR SHAFTS.

Referring to the "How and Why" question in the October issue asking how to remove pulleys rusted fast on their shafts, I would suggest heating the hubs and melting beeswax into the joints. Then drive the pulley with a heavy sledge, while hot. In this way I have been able to loosen pulleys and gears which could not be loosened in any other way. JOHN M. KUPEL.

Peoria, Ill.

In answer to N. M.'s inquiry in "How and Why" department of the October issue for a practicable method of removing pulleys rusted fast on their shafts, when a hydraulic press is not available, I would suggest that the hubs be wet with kerosene oil, and then fired. The quick heat will cause the hubs to expand sufficiently to loosen the rust and permit the pulleys to be driven off with a sledge. I have followed this method with success. WM. DAVIS.

Philadelphia, Pa.

In your October issue, under "How and Why," N. M. asks how to loosen some 48-inch pulleys which are rusted fast on their shafts. If he will heat the shaft and hub of a pulley to a temperature, say, that will turn the shaft blue and then place beeswax around the joint and let it run well, the pulley will loosen "as slick as grease." Beeswax congeals at a comparatively high heat, but when melted it is very thin and will run into any place that oil can reach, and is a better lubricant for a condition like this. E. W. NORTON.

North Tarrytown, N. Y.

In the October issue, under "How and Why," the question of how to loosen a pulley on a shaft was considered. If the shaft is mounted horizontally, I would build a wooden box around the hub, using as many pieces A as there are spokes, less one to leave an opening on top, and four pieces B clamped together (See Fig. 1.) I would heat the hub by pouring this box full of hot babbitt. The small pieces C, Figs. 1 and 2, serve to part the babbitt. Chalking will make the wood fireproof. This is the quickest way of heating, and therefore the one that leaves the shaft cool. Instead of forcing the pulley endways only, I would also apply a turning force. I once had to remove heavy bolts on a marine engine. The sledge alone would not make them budge. I then thought of how, when moving a loose-fitting pulley along the shaft, we nearly always turn it at the same time. Acting on this idea, I applied a wrench to the head of the bolt, and this time the combined efforts of sledge and wrench made the bolt move. It seems to me this action can be explained by a parallelogram of forces, but there may be a better explanation. J. SCHURING.

Bangor, Pa.

FITTING KEYS IN KEYWAY.

N. R. T.—How should keys be fitted on engine cranks, flywheels, gears—especially gib-head keys? Is it not best practice to use gib-head keys where there is nothing else to keep the part from shifting endwise on the shaft, and to give it an ordinary sideways fit in the keyway, and a *good, strong driving* fit top and bottom?

A.—A key should be fitted first on the sides, as the sideways fit is the most important, but it should fill the keyway and bear lightly top and bottom. It is a mistake to fit top and bottom in preference to the sides. A key strongly driven, which fits on top and bottom only, tends to spring the hub and reduce the contact with the shaft. A key is much more likely to work loose when fitted thus than when fitted sideways, and it is in a far less effective position to resist the twist of the shaft. The use of a gib-head key is simply to facilitate removal when the inner end is not "get-at-able." It has no greater holding power because of the shape of the head.

TO OBTAIN THE HEIGHT OF THE MIDDLE ORDINATE OF AN ARC.

G. C.—Tell me how to find the height of an arc at its middle ordinate, having given the number of included degrees and the length of its chord.

A.—The height of the arc may be found by simple arithmetical calculations, if a table of sines is at hand. All engineers' handbooks, and many other books on engineering subjects as well, contain a table of sines. Inasmuch as we know the number of degrees in the arc, we know the angle subtended at the center. Suppose that the arc is 36 degrees, then the angle is that measured by 36 degrees. Half the chord is the sine of half the angle. Half the chord is to the radius of the circle as the sine of half the angle (ratio as given in the table) is to 1. From this proportion the radius is calculated, using the given numerical value for half the chord length. Suppose the length of the chord is 10 feet, then half the chord length is 5 feet. Also suppose that the angle is 36 degrees. In a table of sines we find the sine of 18 degrees (half of 36 degrees) is 0.30902. Then $5 : R = 0.30902 : 1$; or $0.30902\ R = 5$. Then $R = 16.55$. The cosine of 18 degrees is 0.95106, and the difference between it and 1, or 0.04894 is the versine or height of the middle ordinate with a radius of 1. We have found the radius of this circle to be 16.55; hence, the height of the middle ordinate for a radius of 1 must be multiplied by 16.55 to obtain the middle ordinate for a radius of this length. $0.04894 \times 16.55 = 0.81$ foot, the height of the middle ordinate on an arc of 36 degrees, having a chord length of 10 feet.

* * *

By the way, we are all excited over the records of the high-speed steels. But a glance around us seems to show that most of it ends in excitement. Is it the fault of the new steels, the machines, or the men that handle them? After the noise and smoke clear away, we find that things have a tendency to settle back into the easy-going run of ordinary practice. The machine tool manufacturers, however, are always ready to give to the trade any advantage that their long experience shows is worthy of serious attention. So we have to-day become so used to what were called new-fangled devices a few years ago, that few buyers would consider any machines not fitted with all these latest improvements, that have shown their value as cost-reducing elements in the manufacturing plant.

* * *

In our June, 1906, issue, engineering edition, we referred to the evil of employing female labor in foundries, and we now find that the delegates of the Iron Molders' Union, at their session in Philadelphia this summer, pronounced themselves as opposed to the employment of women and children in core-rooms and foundries, as being detrimental to the health, and contrary to the station in life for which they are intended. Here is a territory where upright employers and fair-minded employes may well coöperate, for it certainly is, in the long run, but a loss and a disgrace to the country, if the standard of our women is permitted to be lowered so as to be required to perform such work as is in the highest degree incompatible with American ideals.

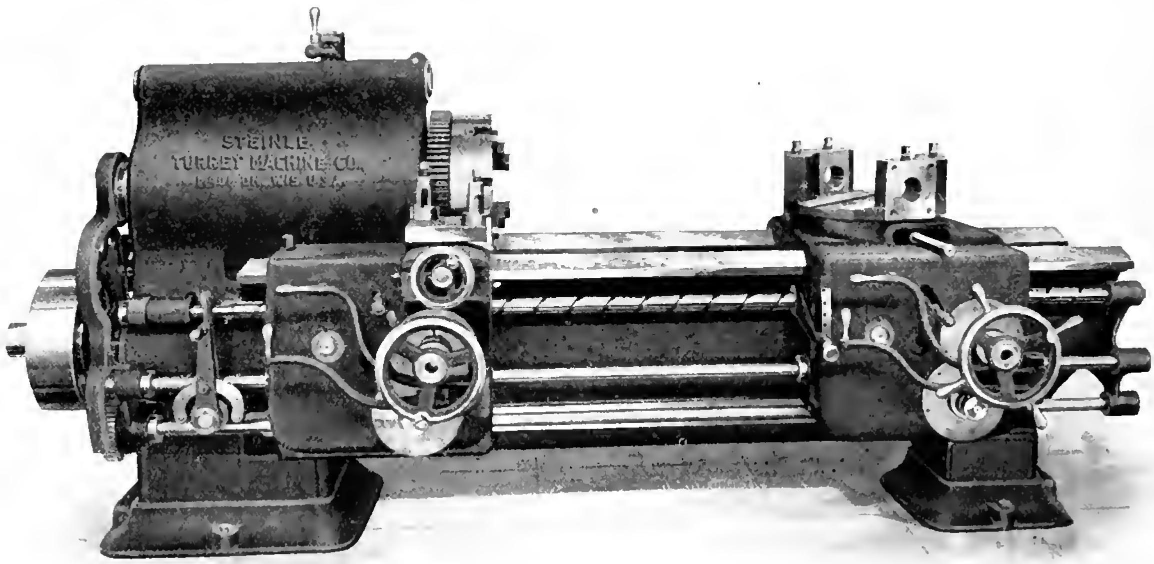
NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

THE FULL SWING SIDE-CARRIAGE TURRET LATHE.

The principal innovation in this interesting tool is indicated by its name. It was the experience of the designer of the tool, who has been connected with turret lathe work for more than twenty years, that the greatest objection to the two-carriage type of turret lathe has been excessive over-hang of turret tools required to reach the chuck over the width of the tool carriage. This great length of tool has resulted in weakness and vibration as well as inaccurate indexing. In the machine shown in the half-tone, this difficulty has been overcome by making the carriage of such a form that it may be in under the chuck, entirely out of the way of the turret slide, when it is necessary to bring the latter close to the face of the chuck.

This cross-slide carriage is supported at the front of the bed instead of extending across the top of the vees. It is speeds. The doing away with the bolted connection between the head-stock and base allows these speeds and feeds to be used even with multiple broad shaving cutters fastened in the turret. Another advantage resulting from this one-piece design is the arrangement for driving mechanism it is possible to obtain with all the shafts and gearing beneath the spindle. This brings the driving shaft as close to the base of the machine as possible, and overcomes the vibration which is prevalent in the type drive belt mechanism. The spindle mechanism is transmitted through a gear mechanism giving thirty changes of speed, arranged in geometrical progression with a maximum ratio of 80 to 1. This insures ample driving power at the proper speeds for all work. The power is taken directly from the line shaft, through a constant-speed pulley with a friction control and reversing motion. All the changes of speed which may be obtained without stopping the countershaft are controlled by interlocking levers conveniently



Full Swing Side-carriage Turret Lathe.

supported at the upper vee, and has a bearing on a planed surface at the lower edge of the bed near the floor, thus giving as wide a bearing to resist the cutting strain as possessed by the ordinary form. The tool-post of this cross-slide is arranged on a turret base with facilities for holding four regular tool-posts, like the ones shown in the cut, or straps for flat cutters, if it is desired to use them.

Another novelty in construction will be noted in the shape of the main turret. The turret is hexagonal in form, four sides being finished with bored center holes and clamping surface for holding boring bars, etc., while the remaining two sides are open to receive universal facing heads for holding any form of facing and turning cutter. The turret is equipped with a rotating stock bar with a dead stop for each face.

Both turret and cross-slide carriages are provided with both turning and screw-cutting feeds. These feeds are entirely independent both as to rate and direction, and simultaneous cuts can be taken with each in the rate and direction desired. Owing to the weight of the slides necessitated by the heavy work for which the machine is designed, the plan has been followed of giving a power control for each of them, operated by handles within easy reach of the operater. This makes it unnecessary for him to tire himself by the rapid handling of these parts.

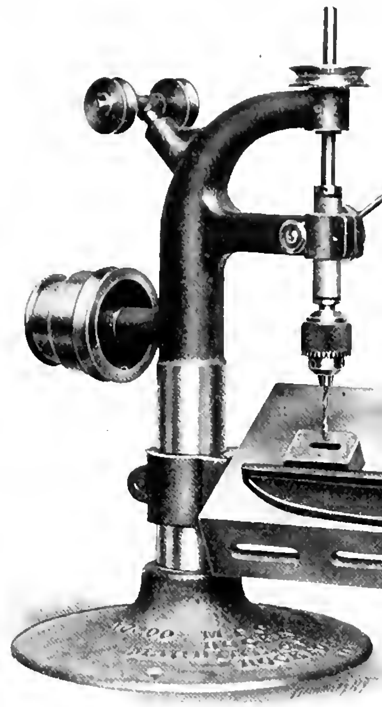
It will be noted that the head-stock and bed are made in one piece. This is an unusual construction for a machine as large as this, but it has several important advantages. It gives a strength and rigidity to the frame work which meets the exacting requirements of high-speed cutters, allowing them to obtain their maximum efficiency at the proper feeds and located, thereby preventing disastrous results through carelessness on the part of the operator. When desired, the lathe is equipped with motor drive. Any constant-speed motor may be used.

The lathe has a swing of 22 inches over the vees and 18 inches over the carriage. The spindle is bored to 3½ inches in diameter, and has a front bearing of 6⅝ inches in diameter. The turret, which has a width of 20 inches across the flats, has 3-inch holes for tools, and a maximum traverse of 52 inches from the face of the chuck. The lathe is fitted with an extra heavy three-jawed universal chuck. It weighs, complete, 8,000 pounds. It is built by the Steinle Turret Machine Company, Madison, Wis.

ROCKFORD SENSITIVE BENCH DRILL.

A sensitive bench drill, having a capacity of ¼-inch holes as a maximum, is manufactured by the Rockford Machine & Shuttle Co., Rockford, Ill. As will be noticed from the accompanying cut, one of the prominent features of this tool is the arrangement of the table, which can be swiveled around a horizontal axis, and can be set to any position and locked in any angle, thus greatly facilitating the drilling of holes at an angle to the locating or bottom surface of the piece in which the holes are drilled. The table has, of course, also a vertical adjustment for a considerable distance, as is plainly shown in the cut. The spindle, which is made of tool steel, is driven by means of a round belt running from a grooved pulley cast in one piece with the 2-step cone pulley constituting the main drive. The belt runs over idlers to the grooved pulley on the

spindle. The lower end of the spindle is fitted with a taper, and takes any 5/16-inch drill chuck. The counter-shaft has a 2-step cone pulley for a 1⅛-inch wide flat belt, and, of course, tight and loose pulleys, as usual. One feature worth mentioning is the adjustable angle plate shown in place on the table. This angle plate is intended for use when the table



Rockford Sensitive Bench Drill.

is tilted, to support the work on one side, when being drilled on an angle. This angle plate can be moved as desired, and locked at any place to the side of the table by means of the binding screw shown. The side of the table is provided with slots making it adaptable for work which can conveniently be clamped in this position. The size of the table is 8 x 8 inches, and its vertical adjustment is 5 inches. The greatest distance between the spindle and the table is 7¼ inches, and between the spindle and the frame 4½ inches. The lever feed of the spindle is 2¾ inches. The weight of the machine, including counter-shaft, is 83 pounds.

DEGEN'S ELLIPSOGRAPH.

The accompanying cuts show an interesting instrument for the drawing of ellipses and hyperbolas, recently patented by Mr. Julius Degen, of Trenton, N. J. The most interesting feature about this tool is its adaptability for drawing an

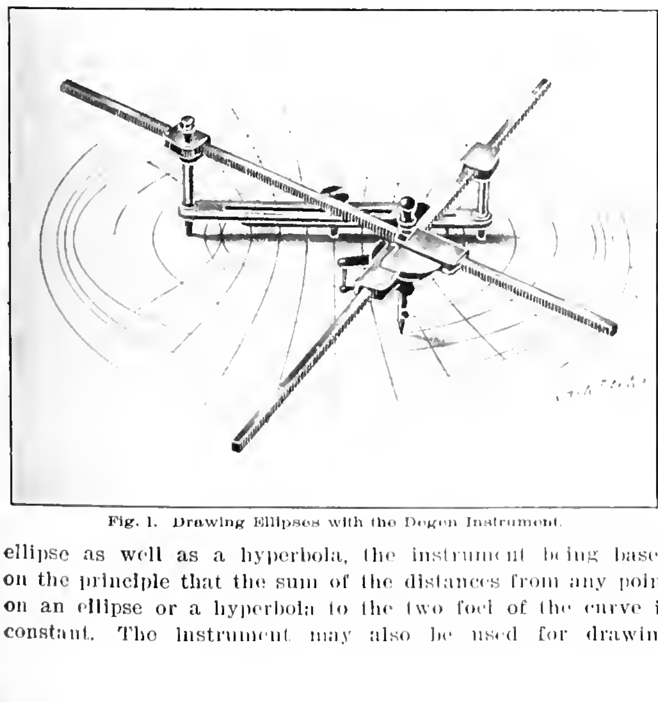


Fig. 1. Drawing Ellipses with the Degen Instrument.

ellipse as well as a hyperbola, the instrument being based on the principle that the sum of the distances from any point on an ellipse or a hyperbola to the two foci of the curve is constant. The instrument may also be used for drawing parabolas. In such a case an attachment not shown in any of the cuts takes the place of one of the posts shown at the foci. This attachment is permitted to slide along a T-square, and the pen or pencil then describes a parabola, so that, in fact, all the curves for conical sections may be drawn mathematically correct by this instrument.

The mechanical construction of the instrument is as follows: Two posts, provided with points, are connected by two slotted beams clamped together by a thumb screw. These slotted beams permit an adjustment of the distance between the two posts, the points of which, when the instrument is in use, are placed in the foci of the curve to be drawn. On the top of each of the posts is a stationary pinion, about the axis of which a head or casing swivels. Through this casing each of the two racks shown are passed, an easy sliding fit being permitted. The teeth of these racks are engaged with the tooth of the stationary pinion. These two racks cross each other, and engage at the crossing point with a traveling pinion, the vertical shaft of which is extended, and at the bottom of which a pencil or pen holder is attached. Around the traveling pinion there is a casing made as a guide for the racks. When the instrument is used, and the pen is moved by holding the knob at the upper end of the vertical shaft, the traveling pinion will revolve, moving inward on one rack exactly the same distance as it moves outward on the other, thereby causing the pen to move along a curve, every point on which is so located that the sum of the distances from any point of the curve to the foci is constant. When it is wanted to describe a hyperbola, the pen is

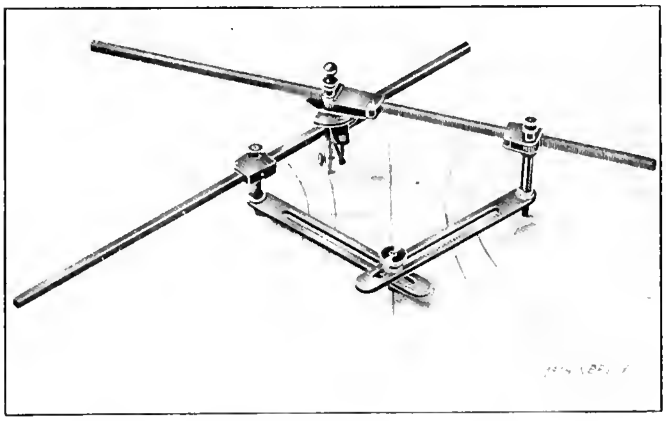

Fig. 2. Using the Ellipsograph for drawing Hyperbolas.

passed in the direction toward the center of the mechanism, and, as the same condition will obtain, the pen evidently will describe the desired curve. When the curves are drawn with ink, it is necessary that the pen always travels tangent to the curve being drawn, and the pen has to be guided around the vertical shaft continuously. A special mechanism is contained in this instrument for accomplishing this purpose. This mechanism is based on the fact that the tangent in each point to an ellipse or hyperbola bisects the angle between the two lines connecting the point in question with the foci of the curve. Each of the traveling heads or casings is provided with a flange in which is cut a spiral groove. Between the two flanges a steel plate swivels around the axis of the traveling pinion, having a slot running in a radial direction. A pin engaging both of the grooves previously referred to and also the slot in the plate between the two flanges, causes this plate to revolve around the vertical shaft whenever the instrument is put in motion. The steel plate has an extension at a point opposite the radial slot, to the end of which is riveted a small vertical pin engaging a hole at the end of a small horizontal arm, which is threaded into the head carrying the pen. By this arrangement a revolving motion is conferred upon the pen which keeps it constantly in the proper direction.

G. E. CENTRIFUGAL AIR COMPRESSORS.

After an extensive series of experiments, covering a number of years, the General Electric Co. is now producing a line of direct connected centrifugal compressors for supplying air in large quantities at moderate pressures. They are built

for a number of capacities, and, for each capacity, in three sizes for the nominal pressure service of 0.88, 1.7, and 2.7 pounds per square inch, respectively, though they may be used at pressures greater or less than these by varying the speed at which they are run. They may also be arranged to act as "exhausters" for pressuress within 3.25 pounds per square inch or 6.5 inches of mercury below atmospheric pressure. They are not adapted to low pressures, which field is satisfactorily filled by the ordinary fan blower. Their range of work covers more nearly that of the pressure blower, and therefore they are especially adapted for air blast for burning fuel, as in oil, gas or other furnaces.

Design.

This centrifugal compressor is a modified fan blower designed for high efficiency at pressures that are high for this

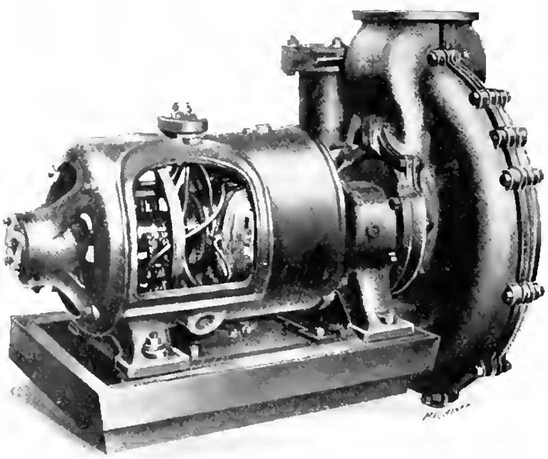

Fig. 1. Centrifugal Air Compressor driven by Direct-current Motor.

form of apparatus. It consists simply of an impeller of improved design rotating in a case. The impeller receives the air on both sides so as to avoid the end thrust. The general internal arrangement of the machine bears a close resemblance to that of the so-called turbine pump, so that the term "turbine compressor" or "turbine blower" has been aptly applied to this apparatus.

An important feature of the design is the fact that the compressor and its motive power are designed for each other,

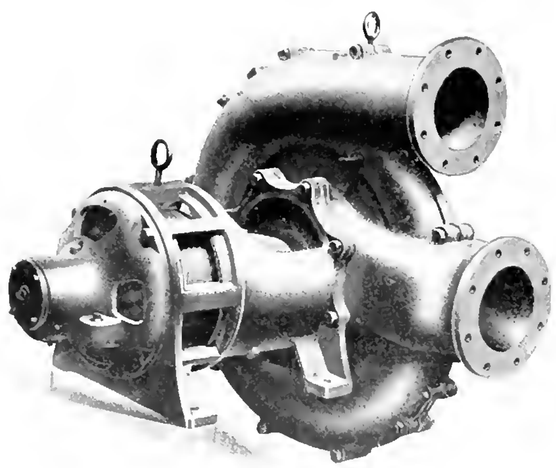

Fig. 2. Centrifugal Air Compressor driven by Alternating-current Motor.

and sold as a single unit. The compressor may be driven by a direct-current motor, an induction motor, or a non-condensing steam turbine. Under these conditions there is no belting, gearing or other transmitting device requiring attention and repair, the driving and driven members being mounted on a single shaft. On sizes below 50 horse-power, the frames of the two members are bolted together and stand on feet cast integrally with them. The larger sizes have a base or bed plate on which the frames, casings, and bearings are mounted.

Comparison with High-Pressure Fan and Positive Blowers.

This turbine compressor fills the field at present occupied by the high-pressure fan blower and the positive pressure blower. As compared with the ordinary fan blower design for the same service, it need only to be said that the efficiency is about one-third greater, while the new machine at the same time retains all the advantages of the older machine, such as its simplicity and the low cost of maintenance. There are also many points in which this rotary compressor shows superiority in comparing with the positive pressure blower. One of these is in the matter of pressure regulation

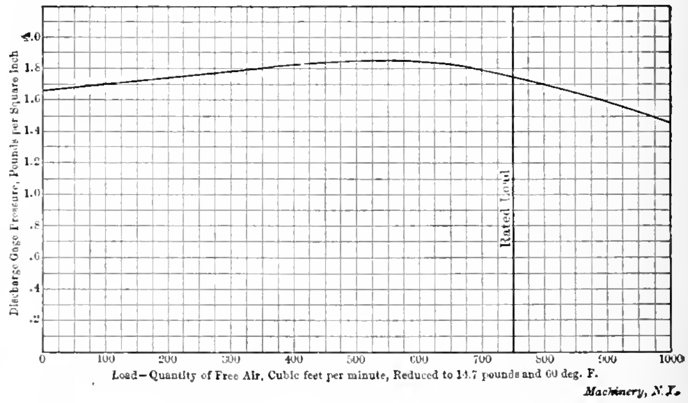

Fig. 3. Pressure Curve for Centrifugal Compressor, with Varying Load.

and consequent economy. With the positive pressure blower the machine normally receives a certain number of cubic feet of free air per minute which is forced into the main at the desired pressure. Ordinarily the means taken to regulate this pressure is the installation of a safety valve set at the reqnired number of pounds per square inch. When the demand for air falls off, so that the blower is furnishing more than is needed, the pressure rises, and the excess escapes through the valve. All of this lost air involves waste of power. On the other hand, if the demand for air is somewhat in excess of the capacity of the machine the pressure drops below that desired for the use to which it is applied. As compared with this, the rotary compressor resembles the high-pressure fan blower in furnishing the air at a nearly constant pressure, practically independent of the amount furnished, within the capacity of the machine.

The characteristics of the apparatus in this respect would be appreciated by referring to Fig. 3, which shows the variation in pressure of one of these machines running at high speed, and with the outlet pipe throttled to various degrees. It will be seen that the variation in pressure is about 10 per cent within the full range from zero to the rated load, while

TABLE OF STANDARD SIZES, SINGLE STAGE CENTRIFUGAL COMPRESSORS FOR INDUSTRIAL AIR BLAST.

Drivers may be 220 volt, 60 cycle, 3 phase induction motors, either Form M or K, 125 or 250 volt D.C. motors or non-condensing steam turbines.

SERVICE.	Rated Pressure, pounds per sq. in.	Nominal Capacity, cubic feet Free Air per min	Diameter of Discharge Pipe, inches.	Nominal H P.	Max. Press. D C. or Turbine Drive, pounds per sq. in.
Foundry cupola or low press. air blast.	0.88	2600	12	20	1.5
	0.88	3600	16	30	1.5
	0.88	7000	20	50	1.25
	0.88	10000	28	75	1.25
Moderate pressure air blast.	1.7	750	8	11	3.7
	1.7	1400	10	20	3.7
	1.7	2000	12	30	3.7

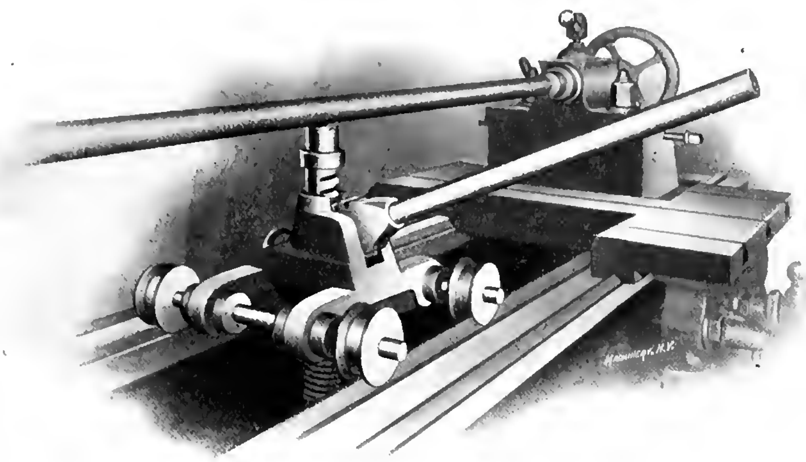
High pressure air blast.	2.7	1200	8	30	4.2
	2.7	2400	12	50	4.2
	2.7	3400	14	75	3.0

the drop is not alarmingly great even with an overload of 33 per cent in cubic feet of free air furnished per minute. This constancy of pressure is, of course, obtained without regulating devices of any kind, being inherent in the design of the machine, the only requirement being that the speed of the impeller be kept constant.

The turbine compressor also invites comparison with the positive blower on the score of rating and capacity. A positive machine is often rated from its mechanical displacement, no allowance being made for the heating of the air and the drop in pressure while entering the machine, not to mention the leakage around the moving parts. Actual tests have shown a loss of 50 per cent or more in capacity as measured by theoretical displacement in the case of a positive pressure blower. The builders of this device state that their centrifugal compressor will deliver as much air as a positive blower having a rating 33 per cent greater.



Johnson & Bassett Shaft Straightener.

A further point in which this apparatus invites comparison is in its remarkable simplicity, there being only two moving parts, the rotor of the driver and the impeller of the compressor. There are no parts other than the two supporting bearings where wear can possibly occur. The bearings being self-oiling, the only attention which the machine requires is the renewal of oil in the reservoir at intervals. A number of machines have been in service for long periods without renewal or adjustment of any kind, and without attention, except the monthly renewal of oil.

Rating and Capacity.

As shown in the accompanying table, these compressors are built in standard sizes comprising a number of capacities for each of three pressures. They are made of such capacity as to permit the use of a single machine in a central location in a factory rather than installing a number of small blowers scattered in various places. Even the smallest machines listed are too large for small gas furnace installations, only comparatively large installations being provided for. For gas furnaces, an air blast capacity of about ten times the quantity of gas supplied is ordinarily required. For this work a machine rated at 1.7 pound per square inch should be used. For furnaces requiring a concentrated and positively directed jet, a machine rated at 2.7 pounds pressure should be used. The first four sizes on the list are especially adapted for supplying air blast and foundry cupolas.

The rated pressures given are at the beginning of the pipe line, and with the inlet full. Provision must be made for any pressure drop through the inlet supply pipe or in the main. All sizes are provided with inlet pipe flange connection, and the supply of air should be taken from a cool place out-of-doors to get the most efficient operation. The pressures given are for an air supply at a temperature of about 60 degrees. If the supply is hotter than this, or if the barometer is abnormally low, there will be a slight decrease of pressure. For an average case where the inlet air is heated somewhat, and where there is sufficient length of inlet and discharge pipe to give an appreciable drop, the three groups listed may be usually depended upon to give actual pressures in the mains at a distance from the machine of about 0.625, 1.25 and 2 pounds per square inch respectively. Extremely small pipes will give lower pressures. With direct-current motor drive, the rated pressure is merely nominal, and may be set by hand adjustment of the field rheostat up to the maximum value given.

JOHNSON & BASSETT SHAFT STRAIGHTENER.

The straightening of shafts in the machine shop is often accompanied by more or less difficulty, because of the lack of proper appliances for doing this kind of work. Realizing that there is a demand for a good, and at the same time inexpensive, tool in this field, Johnson & Bassett, of Worcester, Mass., have placed upon the market the shaft straightener shown in the accompanying cut. This illustration shows what the makers call a No. 1 shaft straightener for use in lathes having from 14 to 24 inches swing. The cut shows the device applied to a 14-inch swing lathe, but its adjustable feature permits it to be used for the larger sizes as well. The capacity of the device is 1½-inch; that is, it will straighten shafts of any diameter up to this dimension. The wheels with which the device is provided can be run either on the vees or on the flat part of the bed, and are easily adapted to different sizes and makes of lathes. The device is not heavy, and can be transferred from one lathe to another with comparative ease. The advantages of this device are the simplicity and ease of application and adjustment, and the enormous leverage obtainable, due to the design. The device will undoubtedly be found a convenient and handy tool in many machine shops.

GAS OR OIL HEATED SODA KETTLE.

The Gray & Prior Machine Co., of Hartford, Conn., developed the soda kettle shown in the cut, for its own use. The peculiarity of this construction lies in the fact that it is heated by a Bunson gas, or a blue flame kerosene burner, instead of by the usual steam heated jacket, making the apparatus available for places where steam cannot be used, such as garages, and machine shops driven by motor or oil engines, where the steam heating plant is shut down during the summer. This provision makes the apparatus portable as well, so

Gray & Prior Soda Kettle.

that it may be moved from place to place in the shop as necessity may require. The use of permanent steam pipe connections and steam trap for taking care of the drainage is also obviated. The burner used has an inner and an

outer ring flame, either or both of which may be used. The double flame needs to be used only when warming up the cold bath in the morning.

THE SCHMIDT DRIVING CHAIN.

The transmission chain herewith illustrated is manufactured by the Schmidt Drive Chain Co., 265 Broadway, N. Y. These chains are adapted for high speeds, silent action, and automatic compensation for lengthening of the links due to wear.

As may be seen from Fig. 1, this chain differs from others of this class in having the contact lugs formed midway of the links between the pivots. This gives a straight path for the links to follow, so that they are practically in simple tension and are not liable to bend and change their pitch under excessive or suddenly applied loads. For this reason the makers claim that for a given load the chain is lighter, giving less dead weight and a higher efficiency.

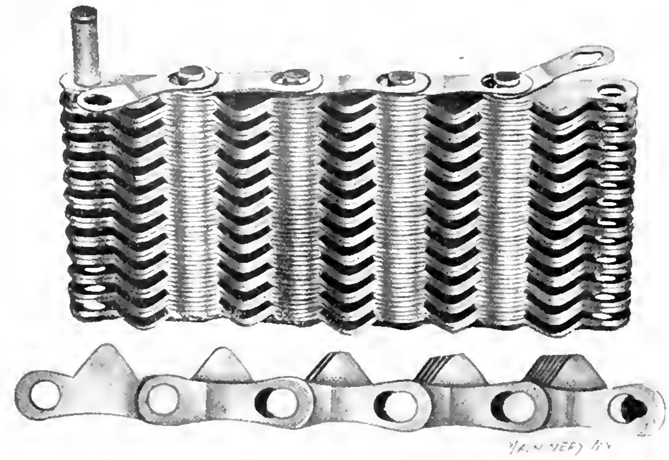


Fig. 1. The Schmidt Driving Chain.

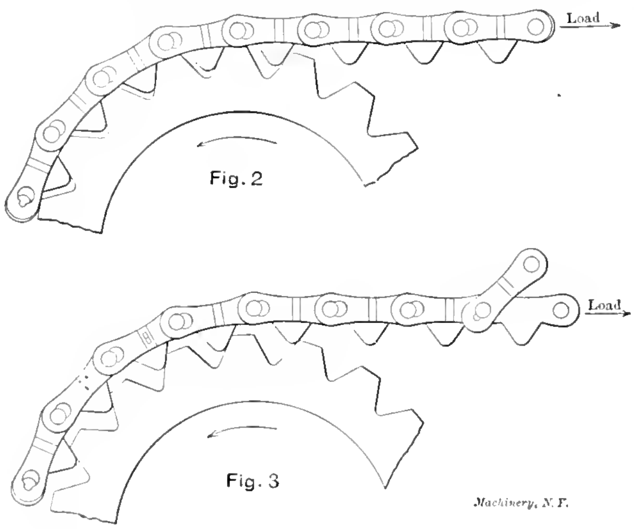
Its action when new, and after elongation, may be compared by the diagrams shown in Figs. 2 and 3. As the pitch is elongated by wear, the beveled driving lugs on the links climb up the inclined faces of the teeth until they have found the proper pitch. For this reason the chain may be used until the pitch has elongated ½ inch per foot, or more, without the action losing its smoothness and accuracy. The teeth of the wheels have a considerable angle, and the lugs on the driving chains are so rounded as to prevent interference on sprockets having a small number of teeth. Very large gears may also be used, the number of teeth being limited only by the capacity of the cutting machine. Speed ratios as high as 20 to 1 are well within the capacity of this drive.

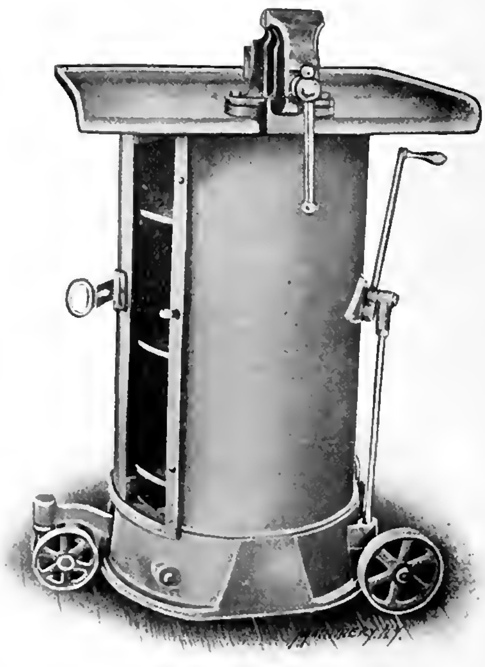


Condition of Chain when New, and when the Links have elongated One-half Inch per Foot due to Wear.

The construction of the chain is new. The outer end of each pin orifice in the links has the same radius as the pins. The links, therefore, always have full bearings on the pins, giving a large bearing surface, and doing away with the excessive wear in a new chain resulting from the use sometimes met with of a circular hole of larger diameter than the pin, which gives only a line bearing until the metal wears and forms a seat for it. The method of retaining the pins is novel and interesting. They are not riveted, but are held in place by means of special edge or retaining links, having a key-shape hole which passes over the end of the pin and enters a circular groove. These retaining links are offset and over-lap, and lock each other, as well as the pins, in place. One of them on each side of the chain, however, is made so that the chain may be disassembled for general overhauling, or for changing its length, without the use of tools.

PORTABLE VISE STAND.

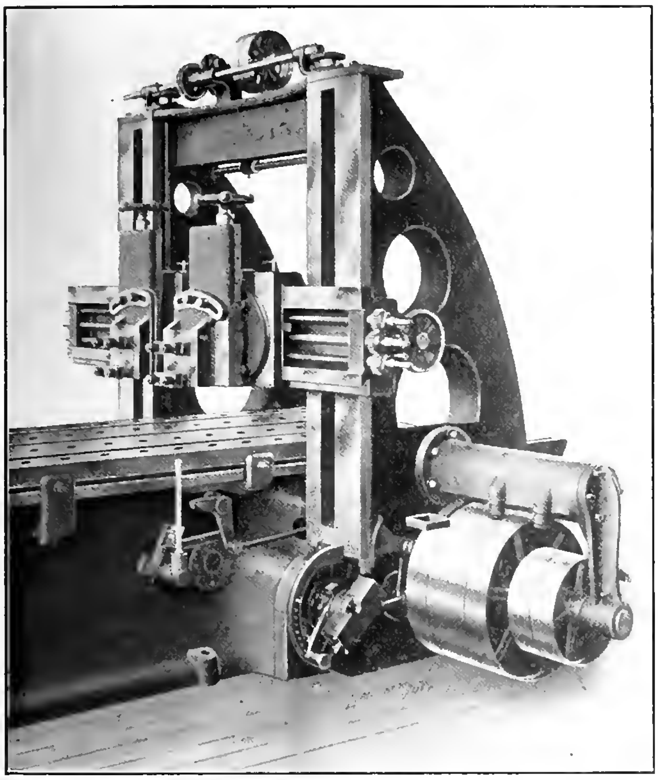
The portable vise stand, while it has not as yet become very much used, would undoubtedly fill a need, because in every shop there are a number of occasions arising almost daily where a portable work bench or vise stand, which can be easily moved from one place to another, is required. This need, having been recognized by the New Britain Machine Co., New Britain, Conn., has caused the design of the portable vise stand shown in the accompanying cut. This stand consists of a circular column of rolled boiler plate to which is fitted a cast-iron top so shaped that tools or work may be conveniently placed upon it without danger of falling off when moving the device from place to place. The bottom of the column rests on a cast iron base plate, being large enough to give ample floor support, and on the vise side far enough back from the working line so that, when standing by the vise, nothing is in the way of the workman's feet. The interior of the column is provided with three shelves, two of which are adjustable, intended for the storing of tools, the column having a sliding door. The door is so placed that the workman can easily open it and see the contents without moving from his working position. No truck is required for transporting this vise holder from one place to another. All that is necessary is to raise the self-locking handle to the position shown in the cut. This raises the stand from the floor and makes it bear on three wheels, one of which is mounted on a swivel. The stand can then be easily pushed across the floor, and when the desired point is reached, the lowering of the lever drops it upon its base, ready for use. These stands are equipped with a standard make of vise, but may be equipped with any vise desired, or even without the vise, if requested. The stand is built in two sizes: one in which the top tray is 20 x 26 inches, carrying a 3½-inch vise, and one with the top tray 24 x 32 inches, provided with a 5-inch vise. The height of the vise in both cases is 41 inches.



Portable Vise Stand.

IMPROVEMENTS IN THE CHANDLER PLANER.

The readers of MACHINERY are familiar with the Chandler planer, built by the Chandler Planer Co., Ayer, Mass., which was first described in our issue of July, 1904. As will be remembered, the most striking feature of this tool is the fact that it is driven by three belts from the counter-shaft—of which three, one is the regular forward motion belt, while the other two control the return, one of them giving a much higher speed than the other, and a much higher return than has been accomplished by any ordinary means. In operation, when the table is to be returned for the next stroke, the moderate speed backing belt is first thrown on, momentarily, thus quietly reversing the planer platen and the gears and pulleys which drive it; then the continued movement of the belt shifter throws off this moderate speed, and shifts on the high-speed reverse, which rapidly returns the table to position for commencing a new cut. In shifting back to the cutting stroke again, the sequence is reversed. First the moderate speed belt is engaged, slowing down the platen until it is under control; then the forward motion belt is shifted onto the tight pulley. It will be seen that the moderate speed reverse belt stands midway in operation between the forward and fast reverse belts, and serves to make the transition between the two extremes quiet and controllable.



Improved Features of the Chandler Planer.

Other features of the tool are: the use of case-hardened and ground journals for the bearings of all high-speed shafts; a device by which the high-speed return can be disengaged and only the moderate speed used; a back-gear incorporated in the machine which can be used when a slow-cutting speed and high-belt ratio are required; and a feed mechanism which can be varied while the machine is in operation without requiring the clumsy and dangerous adjustment of moving parts. Besides these features there have been a number of recent improvements which will be understood by reading the following paragraphs, and referring to the accompanying cut.

The arrangement for throwing in or out of action the third or high-speed reversing belt has been much simplified. As now made, this is effected by simply manipulating a little tappet, pivoted to the lever operated by the platen dog on the left. When this is thrown up, the lever is carried clear over, and the third belt is brought into use. When this is turned down the platen dog can only shift the lever far enough to engage the moderate speed return.

The orthodox slotted plate cam for operating the belt shifter has been replaced by a set of circular cams, contained within the tubular arm by which the outboard bearing of the driving shaft is supported. The circular cams are much easier to machine than the plate variety, the mechanism is less exposed, and the mechanical connections with the reversing lever are much simpler, consisting merely of a gear on the cam shaft, meshing with a rack which is joined to the reversing lever by a connecting-rod.

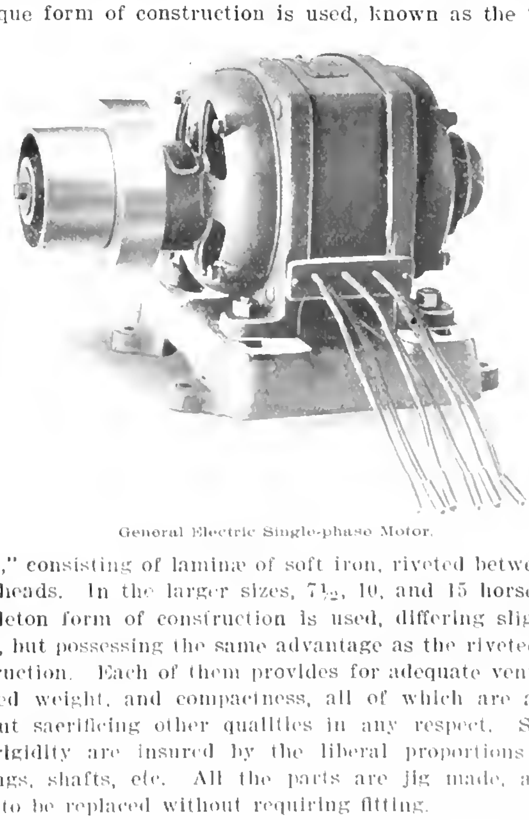
A friction feed-box has been designed which is not radically new in principle, but which is so well proportioned that it is able to work under severe conditions where a positive arrangement is ordinarily deemed necessary. This device is of the type in which the arresting of the friction member against the positive stop which limits its motion, serves to relieve the friction almost entirely. This design has been successfully applied to the severe service of operating heavy feeds on a 48 x 48-inch four-head planer, one feed-box driving all the heads, at the greatly increased cutting and return speeds of which the machine is capable.

Perhaps the neatest and yet the simplest of the new features is the means provided for altering the feeding from the commencement to the end of the stroke, or *vice versa*. As every planer hand knows, this is ordinarily done by shifting the crank-pin to the other end of the slot in the face of the feed-box. This is a ticklish job, especially if the planer is a large one with heavy feed mechanism, and more especially if the planer is in action. The method used on the Chandler planer is clearly shown in the cut. As usual, a slip pinion is used to connect the feed gear on the end of the cross-rail with the cross and vertical feed screws and shaft. The improvement consists simply in providing an extra stud above and below the central stud on which the pinion is ordinarily located. When it is placed on either of the other two studs, the train of pinions on the feed screws is rotated in the opposite direction, and the time of feeding is changed.

It might be mentioned that the planer shown is a special one, in which the back gear mechanism is omitted. For this reason the lever controlling it does not appear.

GENERAL ELECTRIC SINGLE-PHASE MOTOR FOR MACHINE DRIVING.

The General Electric Co. has placed on the market a single-phase motor for direct-connected machine driving, to fill the demand for a machine that would be rugged, compact, easy to operate and ample in capacity. As may be seen in the cut, these motors are similar in general appearance to the polyphase motors produced by the same makers. In the small sizes, such as that shown, up to and including 5 horse-power, a unique form of construction is used, known as the "riveted frame," consisting of laminæ of soft iron, riveted between cast steel heads. In the larger sizes, $7\frac{1}{2}$, 10, and 15 horse-power, a skeleton form of construction is used, differing slightly in detail, but possessing the same advantage as the riveted frame construction. Each of them provides for adequate ventilation, reduced weight, and compactness, all of which are attained without sacrificing other qualities in any respect. Strength and rigidity are insured by the liberal proportions of the bearings, shafts, etc. All the parts are jig made, allowing them to be replaced without requiring fitting.



General Electric Single-phase Motor.

The machine possesses all the simplicity of the polyphase

type, including the absence of rubbing contact and complicated internal mechanism. The rotor is of the well known high resistance "squirrel cage" type, while the stator windings are similar to those of the three-phase motor. By shifting the bearing head brackets, the motors are adapted to either floor, wall, or ceiling use.

Starting devices are provided which require a comparatively small starting current, varying from 2 to 3½ times the full load current throughout the whole line. The maximum starting current is required only on small motors in which a slightly different starting apparatus is provided, hence it does not assume abnormal proportions. When connected with lighting circuits, they can be thrown on without appreciably affecting the line, provided proper transforming capacity is installed, as usually provided for normal conditions. Clutch pulleys are provided with motors of 1½ horsepower size, or larger. These are so arranged that when the rotor has attained the given speed the friction band of the clutch, actuated by centrifugal force, engages the outer shell and the load is assumed. All the motors of the line can be directly connected to all kinds of machinery where moderate starting torque is required, as is the case with fans, blowers, generators, etc. With machinery required to be started under full load, as in the case of pumps, etc., clutch couplings are employed which are thrown in when full speed has been reached. Devices to start and stop the motor, automatically can be supplied when regular attendance is not required, as when used in isolated pumping stations, refrigerating plants, etc.

The fact that these motors can be run from an ordinary alternating-current light circuit makes them easily adaptable to the needs of the small power user. Their compactness and small weight per horse-power, due to the riveted frame form of construction, makes them applicable to special cases where heavy or bulky machines could not be used.

NEWTON GEAR HOBBING MACHINE.

The Newton Machine Tool Works, Inc., Philadelphia, Pa., has had in operation in its own works for the past five years a machine for hobbing worm, spiral, and spur gears. This

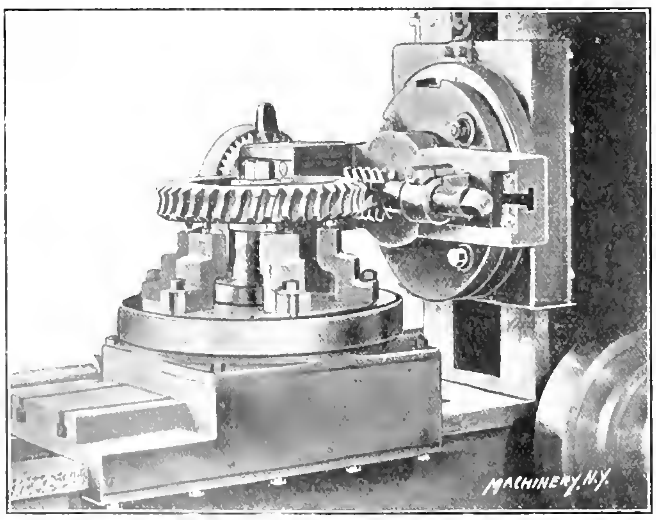


Fig. 1. The Machine arranged for Hobbing Worm-wheels.

has been so successful that another has recently been built for its own use, and the firm is prepared to build them for the trade as well.

The machine as arranged for cutting spur gears is shown in Fig. 2. The principle is well known to our readers and needs not to be minutely described. A hob, having teeth of the same shape as a rack, is used, set at an angle to the gear equal to the angle of the spiral on which its teeth are cut, so it can be fed straight down through the blank without interference. The hob and work are connected with each other by change gearing to rotate at the same ratio as that between the number of teeth in the gear and the number of threads on the hob. The machine being started up with the members

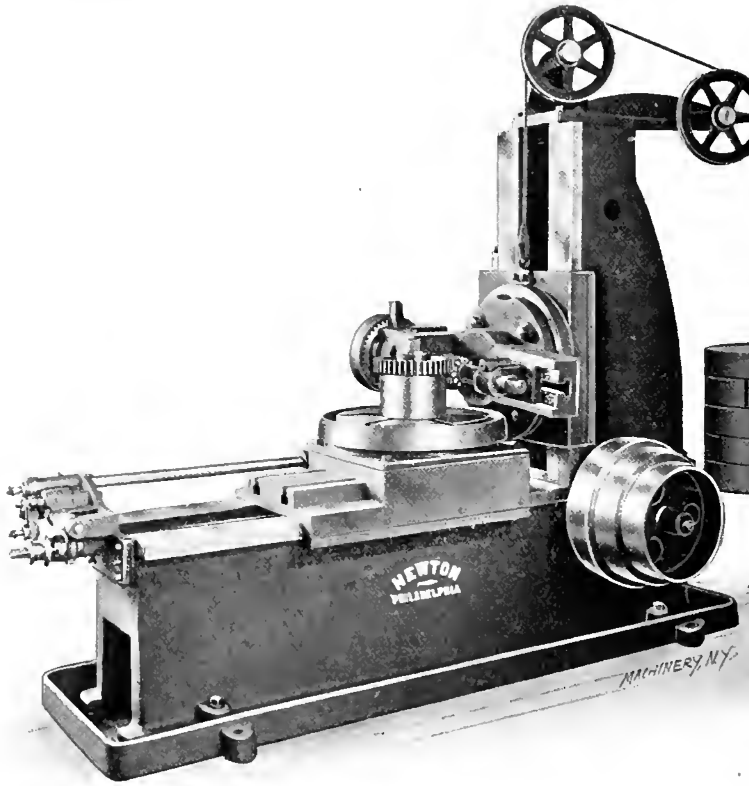

Fig. 2. Newton Gear Hobbing Machine at Work on a Spur Gear.

rotating at this ratio, and the hob being set to cut the proper depth, it is fed steadily down through the work, completing all the teeth at one feeding of the slide.

In Fig. 1 the machine is shown set up for hobbing worm gears; in this case the head is set, of course, to have the spindle horizontal. The blank and hob are geared together at the proper ratio as when cutting spur gears, but the work table with the blank is fed in toward the cutter until the proper depth has been reached, instead of having the cutter head fed down the face of the slide as in Fig. 2.

All the feed movements are by power, and are obtained by change gearing. The change gearing, for the feed of the table on the bed in hobbing worm-wheels, is located at the outer end of the bed, in the position indicated in Fig. 2, the feed movement for the screw being obtained from the splined shaft which drives the dividing worm. The dividing wheel of this machine is 20 inches in diameter, and the machine is of such dimensions as to take in blanks up to 40 inches in diameter. As will be noted, the head is counterbalanced. The machine has every appearance of strength and rigidity.

R. W. SPEED VARIATOR.

This device, made by the R. W. Speed Variator Co., Singer Building, New York City, is capable of transmitting power positively with a variable velocity with small gradations, a change being made without stopping the movement and without shock or jar. The way in which this is accomplished will be understood from a study of the accompanying cuts and description.

Fig. 3 shows a general view of the apparatus, while the line cuts Figs. 1 and 2 explain the mechanism. The driving member of the device is normally pinion A, Fig. 1, while cone B is the driven member. Obviously their functions may be reversed as occasion requires. The cone is formed with a

series of recesses, or "pits," as the builders call them, of suitable form to mesh accurately with the conoidal pin shape tooth on pinion *A*. These several rows of pits are arranged around the circumference of the cone at equal distances apart, and their number for each row varies in geometrical progression from one end to the other. One of the holes in each row is arranged in a straight line on the vertical plane of the axis of the cone, as shown in Fig. 1. This row of holes is formed in a tongue *C* adapted to have a limited sliding movement in a corresponding T-slot cut in the periphery of the cone, as shown in Fig. 2. This tongue furnishes means by which the pinion may be shifted from one row of pits to another without requiring it to be disconnected from the cone. If it is desired to move it to a larger diameter, for instance, as soon as the tooth in the pinion has engaged with the hole in the tongue, the latter is shifted to the left, carrying the pinion with it just far enough, and in time, for the next tooth to engage with the next larger row of holes on the cone. If it is desired to move it still further, the shifting is repeated as many times as may be required to bring the pinion to the desired point on the cone. The process may be reversed by shifting in the other direction, the tongue being moved a step to the right at each revolution, carrying the pinion with it from one row of pits to the next succeeding.

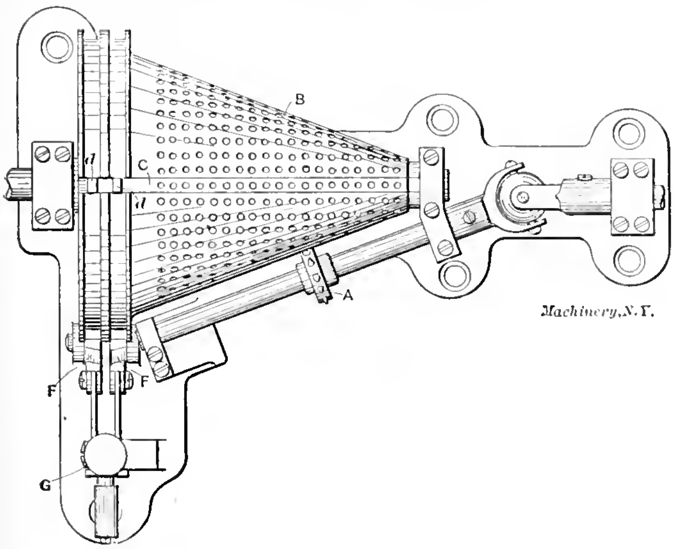

Fig. 1. Plan View of Variable Speed Mechanism of Ingenious Design.

Tongue *C* is moved automatically, the mechanism at the large end of the cone being provided for this purpose. Two lugs *d* are formed on the left-hand end of the tongue. At

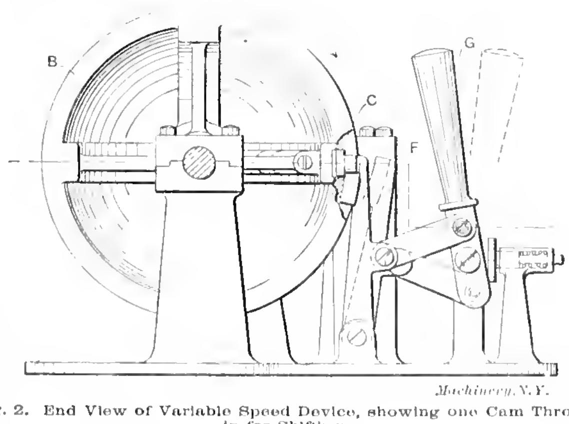

Fig. 2. End View of Variable Speed Device, showing one Cam Thrown in for Shifting.

the larger periphery of the cone, two grooves are turned and lugs *d* normally stand midway on these grooves. This normal position is maintained by spring connections, which return the tongue to this position whenever it has been displaced longitudinally. Two cams *F* are pivoted at the base of the device, and are connected with handle *G* in such a way that either of them may be thrown into the corresponding groove, it being impossible for both to be thrown at the same time. When one of these cams is thrown in, its point enters the space between the lug *d* and the flange, forcing it outward against the pressure of the constraining spring, and carrying

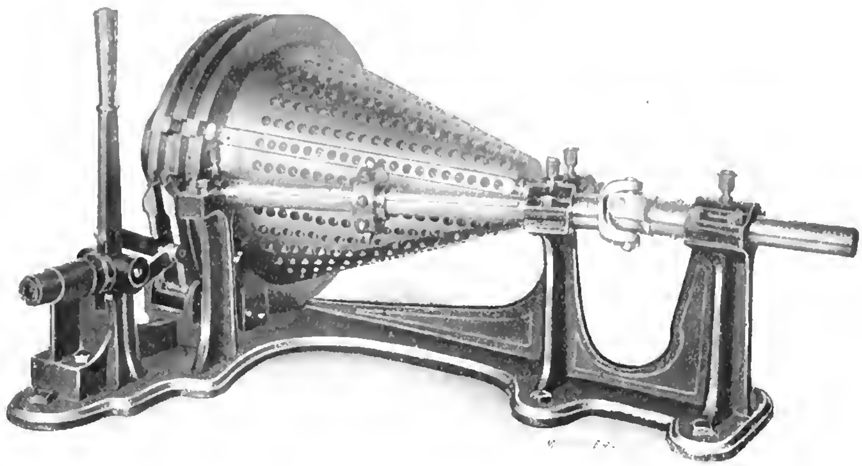

Fig. 3. General Appearance of Variable Speed Mechanism.

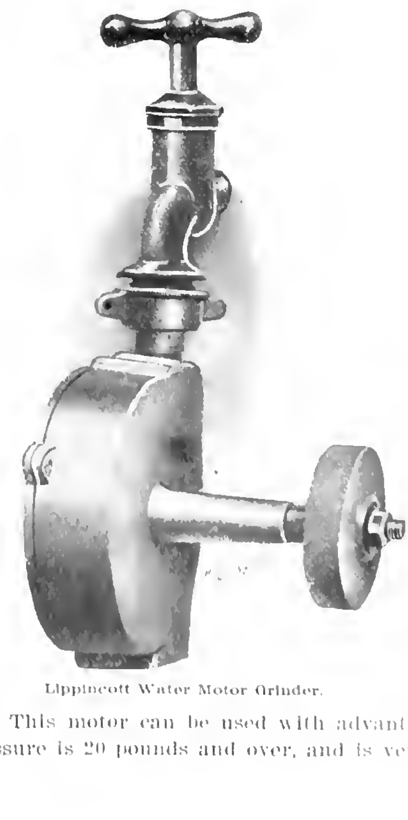
the pinion with it to a new row of holes. After the cone has turned a short distance, the lug passes the cam and drops back into the neutral position. If lever *G* is still held in the same position, the cam will act as before, on the next revolution of the cone, shifting the pinion another step to a new row of pits. This action will continue as long as the lever is operated, or until the last step on the cone has been reached, in which case an automatic mechanism throws the cam out against the force applied to it by the operator. When the handle is moved in the opposite direction, the reverse motion takes place, and the pinion is moved down step by step toward the opposite end.

This device finds its application as a counter-shaft mechanism in driving machinery of various kinds; in textile machinery where slight variations of speed are required, as in driving rolls on which cloth is wound; and in feed change mechanisms and other devices of a similar nature.

LIPPINCOTT WATER MOTOR GRINDER.

In the accompanying illustration is shown a water motor mounted directly on a faucet, and provided with a small



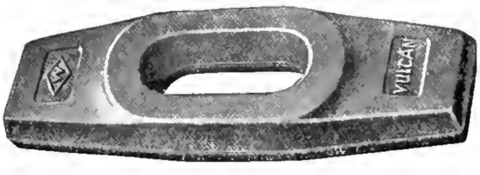
Lippincott Water Motor Grinder.

emery wheel. This motor can be used with advantage where the water pressure is 20 pounds and over, and is very service-

able for grinding all kinds of small tools. At 20 pounds pressure a motor makes 4,000 revolutions per minute, and at 50 pounds pressure, which is, perhaps, about the average water supply pressure, the speed averages 5,000 revolutions. These motors are very handy both in machine shops and elsewhere, an advantage being that belting aud counter-shafts are done away with, and that the speed and power may be instantly regulated by the admission of water through the faucet. The stream of water issuing from the motor is made useful in cooling the tools. The motor may be attached to any faucet in less than a minute, and emery wheels may be interchanged in a very short time. A suitable rest may be provided to give the proper angle for the grinding of twist drills. This water motor is manufactured by the Lippincott Motor Griuder Co., Newark, N. J.

WILLIAMS DROP-FORGED PLANER CLAMP.

The half-tone herewith shows a stiff, substantial, drop-forged clamp intended to be used on the planer or milling machiue, or, in general, on any machine tool where clamps of this description may be required. The advantage of clamps manufactured in this manner is the possibility of having an assorted and uniform supply of clamping devices, and as such these clamps are likely to prove valuable additions to the machine shop equipment. These clamps are made from a



Williams Drop-forged Plauer Clamp.

strong, tough grade of steel, and are submitted to a case-hardening process after forging, so as to enable them to stand hard usage. This clamping device is made by J. H. Williams & Co., Brooklyn, N. Y., and may be had in three sizes ranging from 4 to 8 inches in length, and 1⅝ to 2⅛ inches width at the ceuter, the thickuess varying from ¾ to 1⅛ inch. The oval hole in the clamp permits of considerable adjustment, the length of the slot varying from 1⅜ to 2 13/16 inches, according to size. The width of the slot is from 11/16 to 13/16 inch.

BEVEL GEAR CUTTING ATTACHMENT FOR AUTOMATIC SPUR GEAR CUTTER.

E. J. Flather Mfg. Co., of Nashua, N. H., has recently designed an attachment which may be applied to its automatic spur gear cutting machines, and used for cutting bevel gears. As may be seen in the cuts, the attachment is bolted to the front face of the work spindle head. The attachment comprises a body on which is mounted a head carrying a supplementary spindle. This supplementary spindle may be adjusted at any augle from the vertical to the horizontal. It is connected with the work spindle for indexing the blank by meaus of a bevel gear on its inner end meshing with a second bevel gear mounted on the axis by which the supplementary head is adjusted for the required angle. This latter bevel gear, in turn, meshes with a third attached to the work spindle. It will be seen that with this provisiou the index wheel of the machine controls the supplementary spindle on which the bevel gear is mounted at whatever angle the supplementary head may be set. The bevel gears of this connection are carefully cut, and are provided with adjustmeut for reducing the back lash to zero.

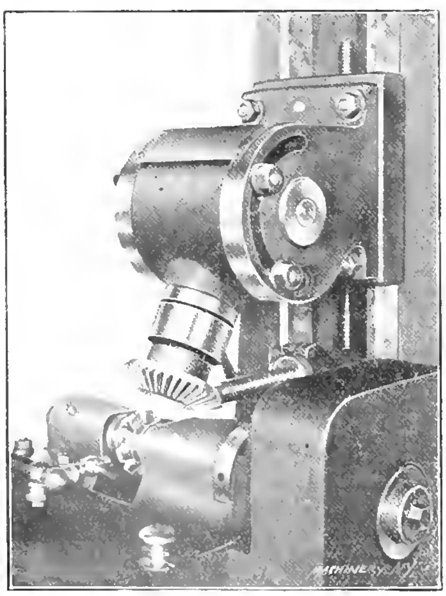


Fig. 1. Detail View of the Attachment.

In cutting bevel gears with this attachment, the head is set to the cutting angle, and the cutter set central as usual, if it is thought best to take a central cut through the teeth previous to the finishing cuts. For the finishing or side cuts, the blank is rotated the proper amount by the provision made for this in the mounting of the index worm, while the cutter is shifted sideways to correspond with the rolling movement

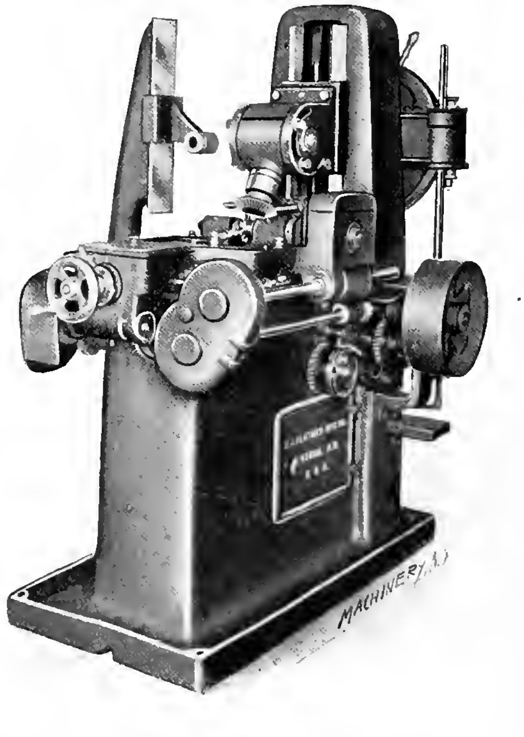

Fig. 2. Bevel Gear Cutting Attachment applied to an Automatic Spur Gear Cutter.

by the regular sidewise adjustment provided with the machine. This latter adjustment is effected by a spanner wrench acting on the nut encircling the spindle sleeve, seated in a recess on the inboard cutter spindle bearing as shown in the half-tones. This attachment has proved to be perfectly satisfactory with the small and medium size gears which constitute the great portion of the work done on a machine of this size.

DIAL GAGES FOR ACCURATE MEASUREMENTS.

The accompanying half-tones illustrate a number of interesting dial gages made by B. C. Ames & Co., of Waltham, Mass., who make a specialty of fine watch and clock making machinery. The gage shown in Fig. 1 is termed a jaw gage, and it is intended for the measuring of diameters of small

Fig. 1. Jaw Gage for Accurate Measurements.

work, particularly those occurring in watch or clock manufacturing, or for any small and fine measurements like wire, paper, sheet metal, etc., where extreme accuracy is required. The device works on the rack and pinion principle, and the reading is made to 0.001 inch, although, of course, much

finer sub-divisions can be estimated between the comparatively large graduations of the dial. The capacity of this gage is 0.2 inch. The dial is provided with two hands, the long hand indicating the number of thousandths, while the small hand shows the number of revolutions that have been made by the large indicating hand. The case enclosing this gage is made particularly strong so as to be able to withstand the hard usage of a machine shop without injuring the mechanism contained, and is provided with feet to stand on the bench.

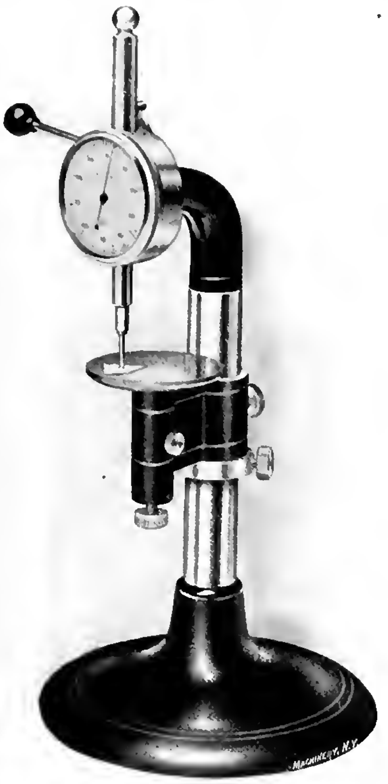

Fig. 2. Upright Dial Gage of the Rack and Pinion Type.

In Fig. 2 is shown what is called an upright fine gage, which is also graduated to 0.001 inch and made on the rack and pinion principle. The platen or table of this gage is made to turn around its center, and is provided with a fine adjusting screw used for bringing the platen up to such a height that the hand of the gage will indicate at zero when the end of the measuring rod rests against the platen itself, or against the surface of any standard gage with which it may be desired to compare when testing work. The bracket carrying the platen is fitted to the upright portion of the stand

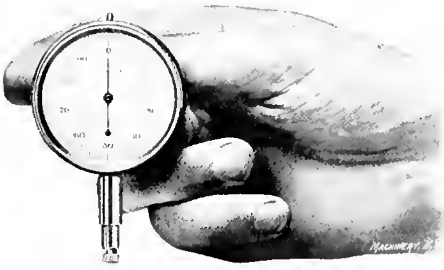

Fig. 3. Dial Gage Head.

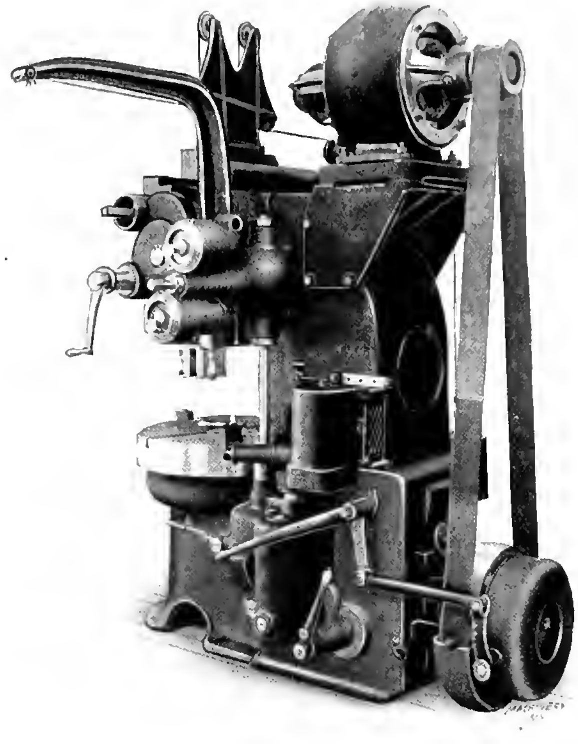
as shown, which gives a long range to the gage. In Fig. 3 is shown a gage head which is of the same construction as that used in the upright gages. This head is provided with a back suitable for attaching to it any kind of mounting. The many varied uses to which this gage may be applied will readily suggest themselves to the toolmaker who is required to make accurate measurements. The gage can also be used as a center indicator, snap gage or limit gage. It is well adapted for being applied to fine measuring devices for the lead of screw threads, and for gage testing.

THE GISHOLT BORING AND TURNING MILL.

The boring and turning mill illustrated in the accompanying cut is one of the latest products of the Gisholt Machine Co., 1316 Washington Ave., Madison, Wis. The machine is motor driven, a 5-horsepower variable speed motor being provided, the speeds ranging from 400 to 1,600 revolutions per minute. A single friction pulley is substituted for the three-step cone pulley ordinarily used on belt driven machines, and the machine is gear driven. The friction pulley is controlled by a lever, as shown, and the table is under absolute control of the operator, and can be conveniently moved any fractional part of a revolution. The machine is provided with eight feeds, and, on account of its friction device, the danger of stripping the gears through careless handling is reduced to a minimum. An automatic feed tripping device permits any of the feeds to be positively stopped at any predetermined point. The dials for the feed trip may be plainly seen in the cut at the end of the cross rail. The tripping arrangement will also throw out the feed at either end of the traverse movement



Gisholt Boring and Turning Mill.

whether the dials are set or not. All feed screws are provided with index dials graduated to 0.001 inch. The machine is furnished with either a plain table or chuck, and the extreme swing of the machine is 36½ inches. The motor of the machine, being mounted as shown, does not require any additional floor space, and the machine is fully self-contained.

ONE-BELT REVERSIBLE COUNTER-SHAFT.

A new counter-shaft has been brought out by the Smith Counter-shaft Co. of Boston, Mass. This counter-shaft gives two forward and one reverse speed, using but one belt from the line-shaft to the counter-shaft. The half-tone, Fig. 1, and the line cut, Fig. 2, show the general appearance and

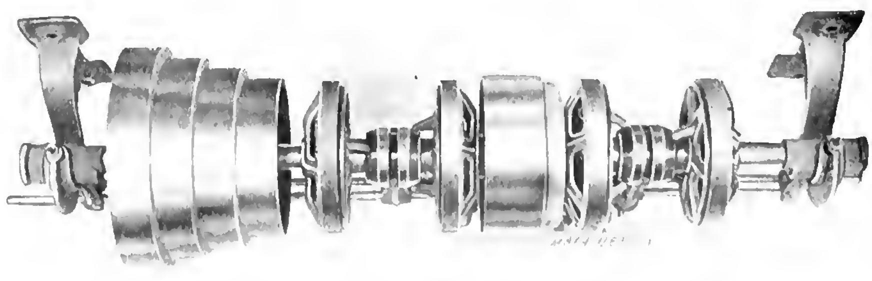


Fig. 1. Smith One-belt Reversible Counter-shaft.

construction of this counter-shaft. From Fig. 2 it will be seen that the device consists of a pulley with a spur gear attached to the hub, an internal gear connected with frictions *A* and *B*, and a three-arm spider carrying intermediate pinions meshing with the spur gear and the internal gear. The three-arm spider is connected with the frictions *C* and *D*. The

operation of the device is as follows: Friction *C*, when engaged, keys the spider to the shaft, while friction *D*, when engaged, holds the spider stationary, preventing it from rotating; friction *B* keys the internal gear to the shaft, and *A* holds it stationary. The female members of frictions *C* and *B* are keyed to the shaft, and those of *A* and *D* are fastened to the over-head beams, preventing rotation. The clutch operating arrangement acts as follows. When the shifting rod is moved to the left frictions *C* and *A* are engaged. This gives a slow forward speed. When the shifting rod is thrown to the right, frictions *B* and *D* become engaged, which gives

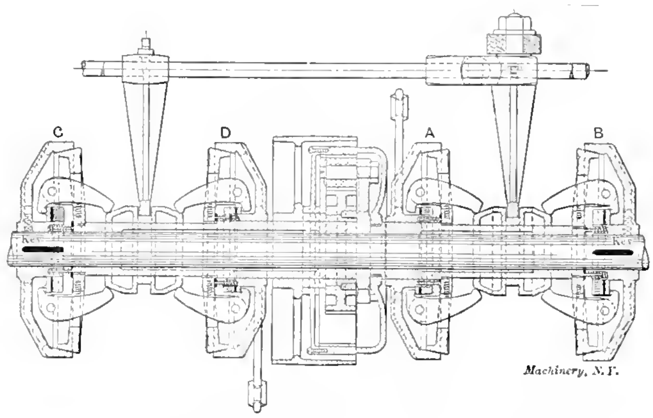

Fig. 2. Section through Smith One-belt Reversible Counter-shaft.

the reverse drive, the three-arm spider being held stationary and the internal gear being keyed to the shaft. A high forward speed is obtained when the shifting rod is first thrown to the left, and then, at the same time gripping a latch lever operating a disengaging mechanism, is again thrown to the right. This causes a connection between the pulley itself and the shaft, thereby driving the shaft with the same speed as the pulley. In this case frictions *B* and *C* are both engaged, the mechanism permitting the engaging of friction *B* without disengaging friction *C*. A neutral position of the shifting rod will stop the counter-shaft regardless of which frictions have been engaged.

COMBINATION FOOT AND POWER PRESS.

The machine shown herewith, made by the Automatic Specialty Company, Cincinnati, Ohio, is constructed with a view of supplying the demand for a small, quick-acting punch press for the manufacture of light sheet metal and brass goods. It has the advantage of being useful in cases where power is not available, as well as in shops where it is. This makes it adapted to the use of tinners, stove and cornice workers, and other manufactories, where foot power is the only motive power in use. As a belt driven fly wheel press, the makers believe that it will compare favorably with any other machine in the market of 50 per cent greater weight, since especial care has been taken to distribute the metal so as to give the greatest strength and power obtainable. The wearing surface and bearings are simply constructed and accurately

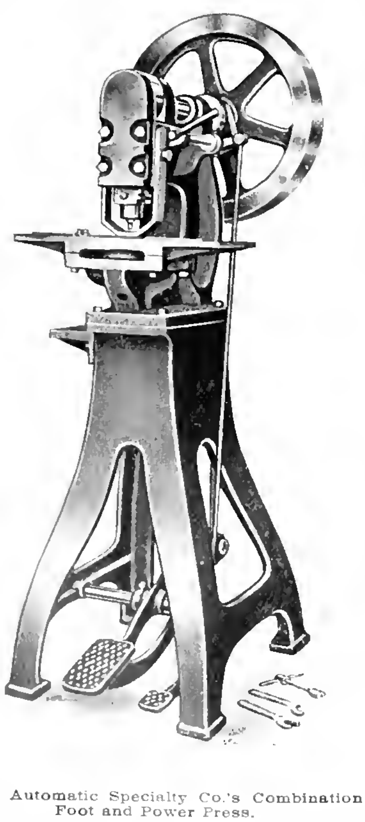

Fig. 1. Automatic Specialty Co.'s Combination Foot and Power Press.

fitted, and are made of suitable materials, and of such proportions as to give durability under the severest service to which a press of this size and character should be subjected. The ram is fitted with an adjustable gib to take up the wear, though this would be reduced to a minimum owing to the large area of bearing surface provided. The automatic clutch may be operated either by the hand lever shown at the right of the spindle, or by the right-hand foot lever. The fly-wheel is bronze bushed, and can readily be replaced at small cost.

When being used as a foot press, the treadle beneath the machine is connected with a crank-pin on the fly-wheel which is revolved by the foot of the operator in this way. For light work, a working stroke can be made at every revolution of the fly-wheel by this method. For heavy work, beyond the range of the usual foot press, the fly-wheel may be speeded up for several revolutions and the automatic clutch thrown in, as when working with power, when the stored momentum will punch a hole well up to the full capacity of the machine.

The machine, as shown, is regularly provided with a front and side gage on the bolster plate for guiding the stock to the punch when duplicate pieces are wanted. A stripper, as shown, is fastened to the sides of the column. The equipment includes a set of three wrenches and a choice of three punches of standard sizes ranging from 1/8 to 3/4 inch. The full capacity of the machine is for holes up to 7/8 inch in diameter through 1/8 inch brass or soft iron. The distance from the center of the slide to the back of the throat is 5 3/4 inches; from the bed to the bottom of the slide when up, 4 1/2 inches. The fly-wheel, which is 19 inches in diameter, weighs 105 pounds and should run from 175 to 200 revolutions per minute. The weight of the machine is 500 pounds.

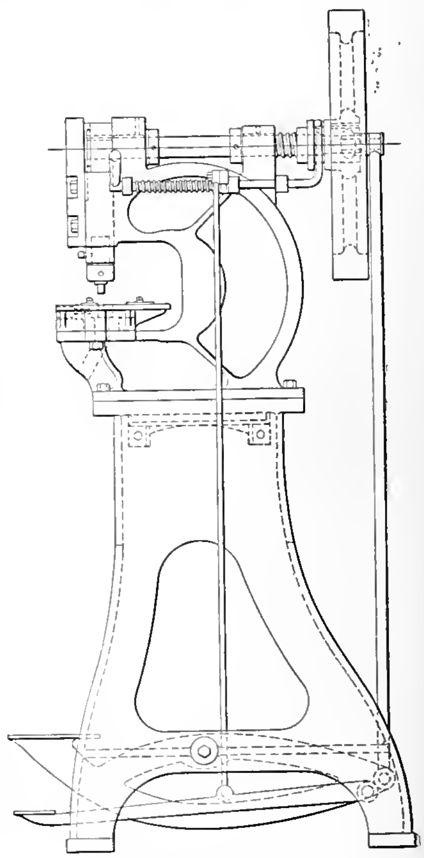

Fig. 2 Design of Combination Foot and Power Press.

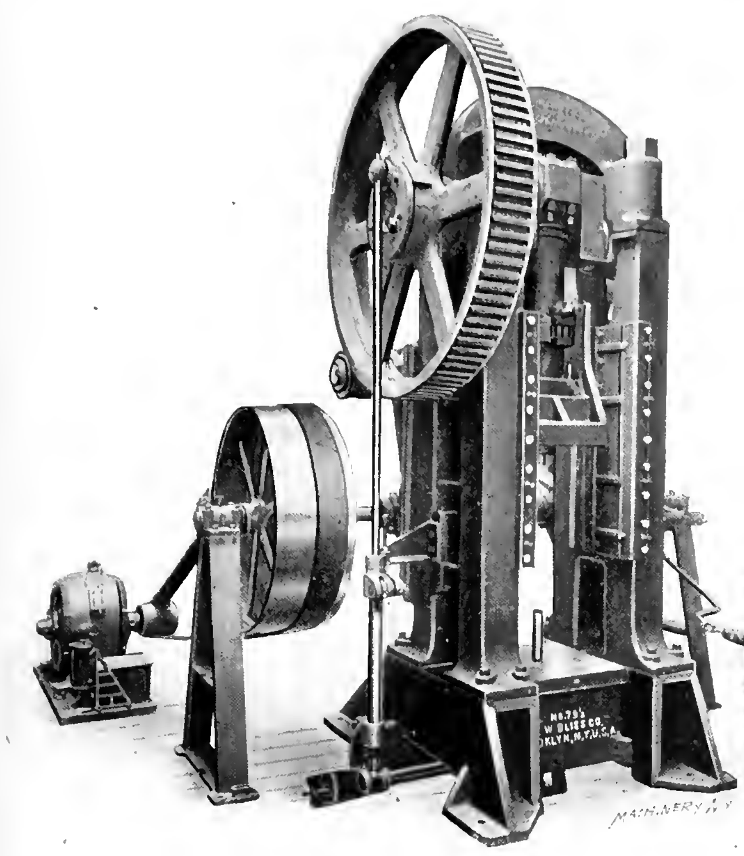
BLISS SINGLE CRANK PRESS OF UNUSUAL SIZE.

This press, built by the E. W. Bliss Co., 5 Adams Street, Brooklyn, N. Y., is stated by its builders to be the largest machine of this type the company has ever built, if not the largest ever built by any one. It can be used for a variety of purposes, such as heavy blanking, trimming and shearing, and it is in addition provided with a long enough stroke (24 inches) to make it especially suitable for the work of drawing cold from heavy sheet steel, such articles as automobile pumps, cream separator bowls and deep drawn seamless shells. It can be applied to such of this work as does not require the blank holder that is essential in the manufacture of parts drawn from thin sheet metal. With the thicker metals for which the press is intended, no blank holder with attendant toggle or cam action is required or provided.

The machine is provided with a base of suitable foundation area for a machine of its size. Double frame columns on each side connect this bed with the arched crown piece on the top, which binds them together and furnishes the bearing

for the crank-shaft. The crown piece is solid with the bearing box, and the caps are so formed that the crank-shaft can be removed or replaced in its working position without disturbing the crown piece.

Four vertical tie rods, each six inches in diameter, pass through the frame columns connecting the bed and the crown piece, and receive all the tensile stress due to the pressure exerted by the machine, thus relieving the frame columns of all working tension. The frame columns themselves are of cored section, of ample dimensions to impart rigidity to the entire structure, and to support the bearings of the back gearing and driving shafts. The bed is provided with a cored opening 12 inches in diameter, and a bored recess 16 inches in diameter, into which a heavy plate may be inserted when the work is such that it is preferable to dispense with the opening in the bed.



Bliss Large Size Single Crank Press.

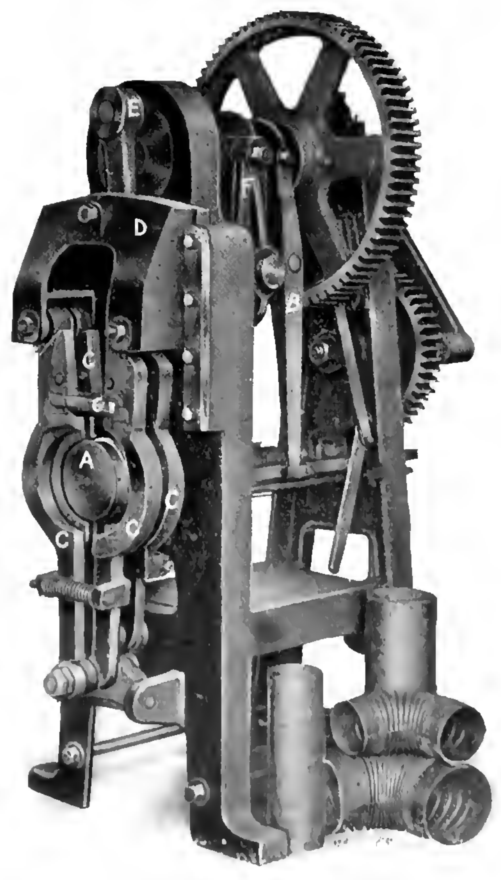
The driving and intermediate gears and pinions are made of steel, the main gear and pinions having specially designed short teeth shrouded, thus attaining unusual strength without any undesirable enlargement of the pitch. The press is started and stopped by a single hand lever, operating an unusually powerful friction clutch and brake. The press can be readily stopped at any position of its stroke up or down. The main shaft is of high carbon open-hearth steel. The Pitman is of cast steel, provided with a 6-inch forged steel adjusting screw, whose adjustment is effected by means of a ratchet, as may be seen in the cut. A powerful knock-out is provided, operated by a crank-pin in the hub of the main driving gear as shown. This may be easily adjusted for various strokes, or may be rendered inoperative when its use is not required. The parts of the knock-out beneath the bed may be readily removed to make way for work which it may be desired to pass through the bed instead of being extracted from above.

The following dimensions will serve to give an idea of the size and capacity of this machine. Stroke of slide, 24 inches; adjustment of slide, 8 inches; depth below floor line, 30 inches; total height above floor line, 16 feet 7 inches. The fly-wheel is 62 inches in diameter, 10½ inches face, and weighs 2,500 pounds. The gearing ratio is 58 to 1. The total weight of the machine is 75,000 pounds.

MACHINE FOR FORMING RIBBED ELBOWS IN STOVE PIPING, ETC.

This tool, built by the Toledo Machine & Tool Co., Toledo, Ohio, is an example of the ingenious special machinery, designed from time to time to perform seemingly complicated operations that occur in large-scale manufacturing. The operation to which this machine has been applied is the manufacturing of ribbed elbows in sheet metal piping. The ribbed elbow was invented to do away with the cost of the operation of cutting out and assembling segments of which the ordinary curved pipe angle was constructed. This further improvement in the method of making it should result in a further cheapening of the cost of this article. As has been stated, and as may be seen from the cut, the machine is highly specialized. The work is done over a "horn," as it is technically called in press work. This is seen at *A*. It is supported from the rear of the machine by a backwardly-extending shank. On this shank slides a work-holding chuck by which the tube to be pressed is grasped by the turning of a small hand-wheel. The tube need only be rolled to the proper diameter. When the machine is started up, a cam on the counter-shaft operates lever *B*, which by a ratchet movement advances the chuck and the work step by step for each rib formed. At the conclusion of the required number of ribs, an automatic stop arrests the movement of the machine.

In forming ribs, the first movement after the work has been fed to a new position on the horn is the closing down over it of the 4-hinged clamping arms *C*. These are closed by an engagement with the cam surface at their upper ends on rollers carried in hood *D*, which locate the material downward by the motion of the crank *E*. The work being thus firmly held to the horn, an expander, seated in a recess in the upper surface of that member is pressed outward,



Toledo Press for forming Ribbed Elbows

and a ridge formed in the upper side of the work. When this has been done, lever *F*, actuated by a cam on the main crank-

shaft, through its connection with strap *G*, draws in toward the frame of the machine the two outer of the four clamping arms *C*, these being hinged at the bottom for this purpose. By this means the rib previously formed is pressed tightly together between the faces of the four arms, the expander having meanwhile withdrawn into its seat again. The continued movement of the crank-shaft opens out the clamping arms, feeds forward the stock another step, continues the previous operations, and forms a new rib. These ribs being formed to full depth on one side of the piping only, a curve is formed in the work. The line of this curvature is regulated by the number of ribs pressed.

It will be seen that the operation of the machine is practically automatic. The work is ejected from the holder at the completion of the required number of ribs, and the parts returned to position for commencing the new operation, the only attention on the part of the operator being the clamping in of new cylinders. The work is formed at the rate of 60 or 75 ribs per minute, making it possible to form approximately 200 elbows per hour. The labor cost of making the elbows is still further reduced from the fact that it is not necessary to rivet or close the seams prior to this operation.

ZEH & HAHNEMANN ARMATURE NOTCHING MACHINE.

Zeh & Hahnemann of Newark, N. J., have recently completed the design of a line of armature disk and segment making machinery, of which we show one example here. This machine, known as the No. 3, is intended primarily for notching disks of moderate size, from 3½ to 30 inches in diameter. As may be seen, it is built along the general lines of the ordinary punch press, but with the bed and work-holding mechanisms specialized for the work it has to do. The bed is in the form of a bracket clamped to the face of the column, and adjustable for height to suit the tools to be used. The thrust of the cut is taken by a screw jack directly in line with the compressive strain. This jack serves also as a means of adjusting the bracket vertically. On two arms projecting forward from the bracket is supported the work-holding and indexing mechanism. The work is clamped between disks by the operation of the cam lever shown at the top of the clamping arm. The lower disk is connected with the vertical spindle whose lower end carries the notched indexing wheel. A slotted disk on the end of the crank-shaft operates through the bell crank and connecting-rods shown, an arm swinging about the axis of the work spindle and carrying a dog by means of which the disk is indexed. A cam on the crank-shaft just alongside the slotted disk, by similar connecting mechanism, operates the lever by which the index wheel is locked and released for each operation. The work is securely locked before the punch enters the material. The automatic stop on the index ring is adjusted to throw out the clutch at the completion of the work. All the reciprocating parts of the feed mechanism are light and are given a motion which starts and stops them gradually, thus insuring smooth action at all speeds. The adjustments for different diameters and different numbers of notches are easily made. If it is desired to hold the work in some other way, the clamping arm may be readily removed. This machine weighs complete about 1,600 pounds.

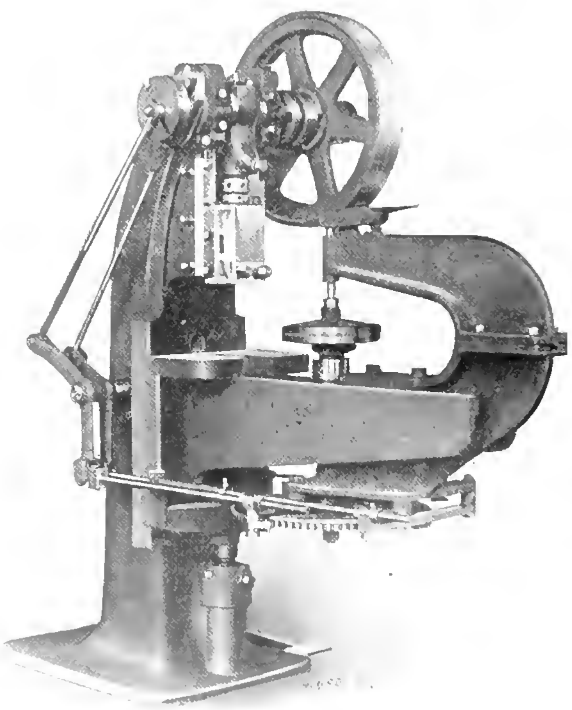


Fig. 1. Zeh & Hahnemann Armature Notching Machine.

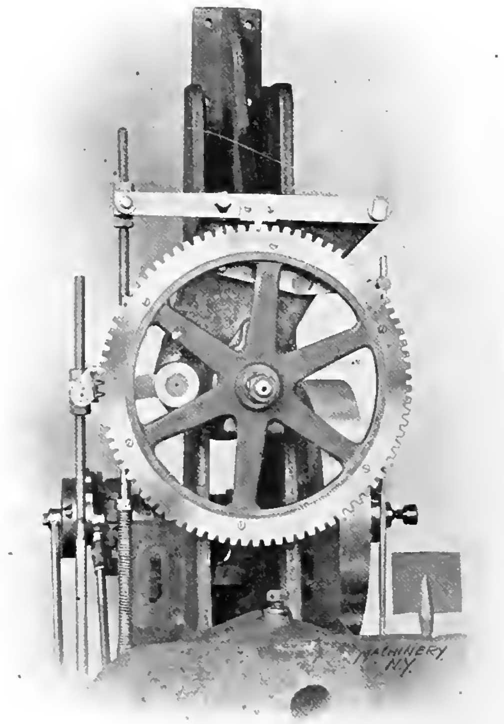

Fig. 2. View of Indexing Mechanism, Zeh & Hahnemann Armature Notching Machine.

FISCHER INSTALLATION OF WOOD TURNING LATHES.

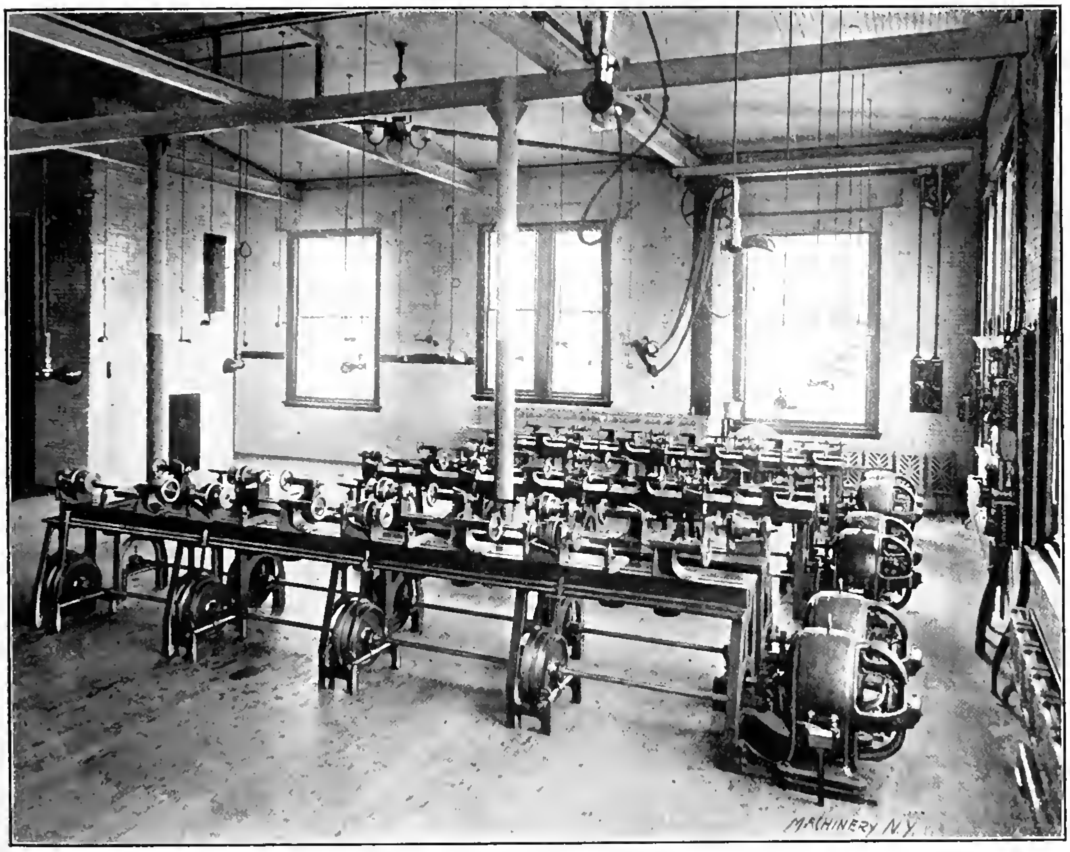
The accompanying half-tone illustrates a rather novel installation of machine tools containing many interesting features. The tools shown are wood turning lathes, but of course the principle involved could be applied in every case of light turning. As seen from the cut, there are four individual head-stocks and tail-stocks mounted on one long bed, the four units all being driven by one motor at the end of the bed. The motor drives the shaft shown under the lathe beds, which may properly be termed the line-shaft. At the left of the operator on each machine there is a lever connected to a clutch which engages a friction drive by means of which the power from the motor is transferred to the three-step cone pulleys shown. This arrangement permits each operator to throw in or out his power independently, and makes his machine a complete unit. Installations of this kind are especially intended for use in trade schools and manual training schools, the arrangement involving a great saving, as it does away with all overhead belting and ordinary counter-shafts. It is evident, however, that the principle involved, as well as the identical arrangement here shown, would be of value even for other installations than trade schools. The half-tone shows an installation made by the Fischer Machine Co., of Philadelphia, Pa., in the new Southern Manual Training School of Philadelphia. The view given in the photograph shows 24 lathes in six batteries of four lathes each. At the same school 24 more lathes working on the same principle have been installed in the floor above. The length of each lathe bed is 17 feet for 12-inch lathes, and 14 feet for 10-inch lathes.

NEWTON COMBINATION COLD SAW CUTTING-OFF MACHINE.

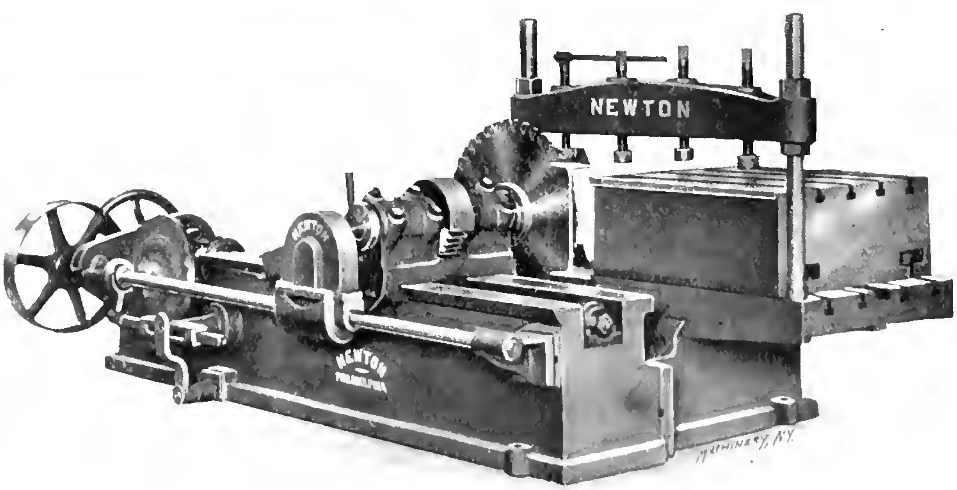
In the cut herewith is shown a cutting-off machine built by the Newton Machine Tool Works, Inc., Philadelphia, Pa., known as its No. 2 Combination Cold Saw Cutting-off machine. This machine is fitted with an inserted tooth saw, and is specially adapted for cutting I-beams on a square or miter cut.

The table of this machine is adjustable for convenience of setting the work, and it is so designed that the top of the table can be easily removed, as indicated in the cut, and the machine can be fitted with a cutter head and used as a rotary planer, this provision being in particular desirable in small bridge building and structural shops. The carriage has a continuous automatic feed with quick return by power. The inserted teeth of the saw are of different widths, and one wide and one narrow tooth is inserted alternately. They are set very close together and are held in place by means of an inverted wedge and a set-screw. The drive of the machine is through spur gearing, driving a hardened steel worm working with a phosphor bronze worm-wheel. In the cut the saw is shown cutting through a 15-inch I-beam, the lineal feed in this case being 1¼ inch per minute. This feed was obtained without any strain on either the work or the blade, and without any "jump" when the saw passed from the heavy to the light cut. This steadiness is due to the rugged construction of the spindle drive and feed mechanism with which the machine is provided.

This cutting-off machine has a capacity for round stock up to 7 inches in diameter and for I-beams placed in a vertical position up to 15 inches high. Any section 7 inches high by 24 inches long may be cut by being placed on the side, so that 24 inch I-beams may be cut by laying them flat on the table. The weight of the machine is about 8,000 pounds.



Fischer Machine Co. Manual Training Lathes.



Newton Combination Cold Saw Cutting-off Machine.

ANNUAL MEETING OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

The fifty-fourth annual meeting of the American Society of Mechanical Engineers will be held in the Engineering Societies Building at 29 West 39th Street, New York, December 3-6, 1907.

Symposiums on foundry practice, giving the experiences of prominent men in that work, have been arranged. The specific heat of superheated steam will be taken up, an important and exhaustive work which will be presented by a professor of engineering at Cornell. The utilization of low grade fuels in gas producers, combustion control in gas engines, tests of producer gas engines, etc., will be given a session. Other live topics, such as industrial education, power transmission by friction driving, cylinder port velocities, etc., will be discussed. Following are papers to be presented: The Rational Utilization of Low Grade Fuels, by F. E. Junge; A Foundry for Bench Work, by W. J. Keep and Emmett Dwyer; Patterns for Repetition Work, by E. H. Berry; Foundry Blower Practice, by W. B. Snow; Molding Sand, by A. E. Outerbridge; Cylinder Port Velocities, by Jacob H. Wallace; Industrial Education, by W. B. Russell; Power Service in the Fonndry, by A. D. Williams; Foundry Cupola and Iron Mixtures, by W. J. Keep; Specifications for Iron and Coke, and Method of Testing Foundry Output, by R. Moldenke; Control of Internal Combustion in Gas Engines, by C. E. Lucke; A Volumetric Study of Cast Iron, by H. M. Lane; Duty Test on Gas Power Plant, by J. R. Bibbins; Some Limitations of Molding Machiues, by E. H. Mumford.

The usual entertainments will be provided, and the excursions to various points will include certain notable engineering works now open for the first time to semi-public view. Among them will be the great twin tunnels under the Hudson and East Rivers. The three libraries of the Founders Societies are now open evenings until 9 o'clock.

INDUSTRIAL NOTES FROM EUROPE.

BRITISH TRADE TOPICS.

Though the returns of the principal British imports and exports still show increases as compared with previous years, the ratio of the increases are diminishing, and things generally are coming to a more everyday level. Coincidentally with the general prosperity, conditions are not very encouraging with some of the less prominent branches of the metal working trades, particularly in those sections where these are conducted on what may be called semi-domestic lines. In certain Midland districts a good deal of brass work is produced in small workshops contiguous to the dwellings of the owners, a melting furnace and a few lathes often forming the whole plant. Wonderfully cheap work is turned out of some of these shops in the way of plumbers' and brewers' brass work, such as cocks, valves, unions, etc. Some will confine themselves to goods intended for water service only, others, in a larger business, will give attention to steam work also. Locks and hinges are other goods manufactured on this system, as also a great deal of art metal work. In fact, in the latter class, shops classed as "brass finishers" may prove to be without machinery with the exception of a polishing head or two. Methods employed in the brass trade generally are in a transitional stage, the low fixed costs involved in the home system of production preventing a more general adoption of modern methods. For some time there will probably be a field of machine tools occupying an intermediate position, which will assist both the smaller employers and their workmen to adapt themselves to the changing conditions with as little loss as possible. A method of finishing the conical bore of brass and iron cocks, very generally employed, involves the use of square tapered reamers which are held in a chuck in the lathe, the casting being held in a handle while the cored hole is rough reamed out. A taper fluted reamer is then used for finishing, the teeth being finely pitched to minimize chattering. In some shops square reamers are used both for roughing and finishing, the finishing reamers being "packed" by wood segments, fastened to the reamer by string or wire. These reamers are produced at a very low price by Birmingham makers, who also supply screw threading tools at low rates. When dull, the reamers are usually softened, and filed up by the users, a cutter grinding machine being an almost unheard of luxury; and in fact, it will be rather a problem to supply modern tools for this work, at an attractive price. The taper plugs of the cocks are turned to suit the barrels, and the final process consists of grinding the two together with emery, etc., no attempts being made to secure interchangeability, as more metal may be taken out of one casting than another when turning up, so that the workman keeps each set comprising body plug, washer, and nut, together as he goes on. Of course, there are also large works where work is produced on modern tools, but the small shops have still a fair chance of existence.

Other work produced in quite small shops includes the stamping and piercing of metal work. Women and girls are employed to a considerable extent in several departments of these trades, a remark also applying to bolt and nut making. In the latter branch the work is often subdivided amongst small shops, some making the smaller sizes on hand-bellows-blown forges, and sending them to other small shops to be threaded. The weird-looking tools to be seen in some of these shops, and the quite passable work produced on them, would be a surprise to those accustomed only to modern refinements. One is inclined to wonder if the existence of such establishments is to be commended or deprecated. At any rate they indicate an amount of self-reliance on the part of their owners or founders, which the factory system tends to eliminate, and a certain proportion of these works develops into large factories with more or less well equipped tool-rooms.

Wrought iron and steel fittings, for steam and gas pipes, is a line, the production of which is distributed between large and small works. Tees, elbows, crosses, etc., are cut out from the strip, scarfed, welded, and swedged at a wonderfully quick rate by a smith and a helper. A "shop" will often employ twelve or fourteen men on fittings ranging from 1/8 inch to 2 inches, larger sizes being dealt with at other similar works. In fact, men are known as 1/4-inch, 1/2-inch, or 1-inch "hands," as they confine themselves to one or two sizes only, becoming so expert on these that, when on piece work—the usual system—it does not pay them to change. The forging is often carried out at one shop and the threading at another, the large tube works often subletting contracts for the smaller fittings to the small shops.

Considerable trouble has recently been taken to formulate standard lists and limits for bolt and pipe threads, but the limits have a rather humorous aspect when considered in relation to the threading tackle sometimes used in the "Black Country." We have heard of concerns turning out hundreds of tons of bolts without a lathe even being on the premises. Yet no taps are bought outside the shops. The taps are forged to size in a forging machine, fluted and then threaded with a screw-plate. Similarly, solid dies are used, and when worn are heated, and closed by swedging and then retapped. Machines for the purpose are made very strong and simple, and fool-proof.

Labor Union Topics.

At the time of writing, the shipbuilding and boiler-making workmen have, by accepting the employers' conditions respecting procedure in case of disputes, averted a threatened lockout, but the railway trouble on the question of recognition, by railway directors, of trades union officials as representing the men in matters concerning conditions of labor, is now entering on an acute stage. The directors have flatly refused to acquiesce in the proposition, and a strike on the question appears probable, but in the meantime Mr. Lloyd George, the president of the Board of Trade, is understood to have an eye to the interests of the general public, and will exert all the influence at his command towards the prevention of a rupture. Otherwise an unprecedented disturbance of commercial, industrial, and domestic economy is threatened.

Fraudulent Use of Trade Marks.

Sheffield is taking active steps to prevent fraudulent use of trade marks, etc., long associated with its products. Government assistance is being given as far as possible, and a public prosecution will be instituted in any definite case brought forward. Much injury has been done to Sheffield's trade in edge tools by its trade mark being used on inferior foreign cutlery, such practices not only diverting local trade, but also lowering a well-earned reputation.

Textile Industry.

Considerable discussion has taken place during the last few years, as to the adaptability of the American Northrop type of automatic shuttle feeding loom to British conditions of working, and the classes of goods dealt with. Mr. A. M. Fletcher, of Hyde, recently read a paper before the Association of Textile managers at Manchester, in which he stated that 790 of these looms were now working at the weaving sheds of Ashton Bros., of Hyde. In spite of much opposition, he considered the firm had brought about a revolution in the weaving trade. An advance of 25 per cent in the wages of the weavers had enabled the married men to earn enough money to keep their wives at home in comfort. He claimed that the Northrop loom did not necessitate the use of better cotton than was used before, and that it placed British firms in a position to compete with the American manufacturers for the Chinese trade.

Machinery Trade Topics.

The *Engineering Magazine* is pointing out that American methods of securing South American trade need revision, and this seems to be borne out by the fact that Mirrlees, Watson & Co., Ltd., Glasgow, have secured the order for machinery for a new sugar factory at Porto Rico in competition with the leading continental and American firms. The value of the contract is about $280,000.

In the machine tool trade, the principal current developments appear in the direction of spur gear hobbing machinery, and special tools for the motor car building trade. In the latter case the requirements of the repair shops are being catered for quite as fully as those of the manufacturers.

Not many years ago cut gearing was over here looked on as a luxury, but such is now far from being the case, and the number of concerns specializing in the gear-cutting line is

now so large that the eclat formerly associated with the business tends to diminish, and there is some danger of competition for orders leading to work very little, if any, superior to the best class of cast gears. JAMES VOSE.

Manchester, England, November 1, 1907.

MISCELLANEOUS FOREIGN NOTES.

MESSRS. G. F. SMITH, LTD., Halifax, England, has brought out a new small-sized radial drilling machine. The arm will swing through a complete circle 6 feet in diameter, and the machine is particularly intended for small work, such as met with in automobile manufacturing. The bed is placed on legs and has T-slots on the front and on the sides. The weight of the machine is about 2,200 pounds and occupies a floor space of 6 feet by 2 feet 6 inches.

MESSRS. J. BUTLER & CO., Halifax, England, have placed on the market a boring and turning mill of very small dimensions, primarily intended for motor car works. The machine is designated as a 30-inch boring and turning machine, but will handle work up to 3 feet 6 inches in diameter. The tool carrying slide can also be fitted with a turret head, an improved device being employed for revolving and securely holding the turret. The machine will swing pieces 33 inches deep under the turret, and 29 inches deep when employing boring bars. The vertical feed of the tool bar is 14 inches and that of the turret 24 inches.

RUSSIAN TRADE CONDITIONS.—The German consul at Moscow reports to his government that the imports of machinery to Russia in 1906 were smaller than had been expected, due partly to the unstable political conditions of the country, about which, it seems from his reports, foreign manufacturers have entertained exaggerated opinions, and partly to increased import duties. The refusal of credit to many Russian dealers of responsible standing has caused an uncalled for decrease in the machinery trade. Germany undoubtedly gets the lion's share of the Russian machinery market at the present time, but conditions are favorable for establishing extended trade relations between the United States and Russia, more so since there now are several direct steamship lines between New York and Russian ports on the Baltic.

THE NORTHERN MACHINE TOOL WORKS, Felling-on-Tyne, England, has placed on the market a new horizontal drilling, boring and milling machine, which is one of the largest of this type of machine that has ever been built. The main spindle is 7 inches in diameter, and has both automatic and hand traverse in and out of 5 feet 6 inches. The column will move horizontally along the bed a distance of 12 feet, and the head will traverse up and down the face of the column a distance of 7 feet, so that the machine will operate over an area of 12 feet by 7 feet at one setting. Power motion is provided for moving the spindle in every direction quickly, and a slow feed is also provided for milling in the vertical or horizontal directions. The approximate weight of the machine is 90,000 pounds.

ELECTRICAL INDUSTRIES IN GERMANY.—The electrical industries in Germany are in a satisfactory state, and the great economy of expense and labor obtained by the electric transmission of power has, it is claimed, opened up ever-increasing fields of operation in the mining and iron industry. Last year, an electrically-driven reversible rolling mill was constructed, which enabled the production of energy in the mill where it was installed to be completely centralized, and increased the output of the rolling mills by fully 10 per cent. This success is noteworthy, as reversible rolling mills were heretofore driven exclusively by steam engines. A further interesting accomplishment of the German electrical industry is the construction of a continuous current electromotor for driving a converter blast. This electromotor has a capacity of 2,000 horse-power, and is one of the largest of its kind.

INDUSTRIAL PROGRESS IN INDIA.—There is at the present time an unparalleled industrial activity even in the remotest part of the world. It is reported from Calcutta that iron works and a steel mill will be established in India, and it is intimated that this departure marks the beginning of an industrial era in that country, and that the markets of India will in a near future offer opportunities to machinery builders. Of course, the English manufacturers will have some advantages in this trade over American machinery builders on account of the political tie between India and Great Britain, but it will not be out of the way for our manufacturers and dealers to keep close watch of the industrial development of a country, so rich in natural resources as India. When industrial progress gets a good footing there, the development will be rapid and progressive. The imports for July this year exceeded those of the same month last year by $10,000,000, and the exports by $16,500,000.

BRÖDRENE SUNDT, Christiania, Norway, have placed on the market a new 6-foot vertical boring and turning mill which appears to be an excellent example of modern European machine design. The various details are constructed with a view to surplus of strength so that heavier cuts than those usual can be taken by the machine without fear of failure. The gear box for driving the machine is of friction type with back gears in the ratio of 1 to 7. The vertical and horizontal movements of the heads are independent of each other, and the heads can be swiveled 45 degrees to either side for conical work. The machine can be driven either by countershaft and cone pulley, single pulley or by electric motor, as required. The maximum height of the tool head over the table is 36 inches, the horizontal and vertical movements of the tools being 32 inches. The maximum swing is 73 inches, the table being 57 inches in diameter. A 10 H. P. motor is used for driving, when the boring mill is motor driven.

THE SPREAD OF GERMAN INDUSTRIES.—On account of the increased tariff protection applied by several European nations, a great many large German enterprises have found their foreign trade seriously hampered, and in several instances they have promptly and effectively met the situation by establishing branch factories in the countries where they were most anxious to retain large circles of customers, whose confidence and trade had been slowly gained during years of persistent effort. The tendency to migrate has been most prominently marked by the organization of branch establishments in Austria, and for self-evident reasons it has been most marked among the varied industries of Saxony. Large and successful manufacturing plants, located in the valleys on the north side of the mountain range separating the two empires, have found it a comparatively easy matter to build branch factories on the southern slopes, where climatic conditions are practically the same, and the scale of wages is distinctly lower. Reports from other sections of Germany indicate, however, that the movement is general and widespread, although not so strongly marked as in Saxony.

THE MACHINE TOOL TRADE IN GERMANY.—Recent reports from Germany indicate that there are many persons who believe that the era of prosperity in that country, which has continued uninterruptedly for several years past, is at an end and that business is on the verge of a decline. The more true state of affairs, however, is most probably that the abnormal activity of a few years past is calming down to more normal industrial conditions. The machine shops complain that they do not receive new orders to as great an extent as they have for some time past, but in view of the fact that they could neither cope with the demands on their establishments, nor secure skilled workers, at the time the prosperous conditions were at their height, it was rather to be expected that the amount of new orders would fall off. In general, the iron, steel, and machinery industries are in a satisfactory condition. The export trade is still increasing with considerable acceleration. For the first seven months of the current calendar year there was an increase in exports of machinery amounting to 17 per cent, as compared with the exports of 1906. At the same time the imports of machinery have increased by 11 per cent, plainly indicating that there is no serious reaction as yet. The increase in exports and imports referred to is made on the basis of weight. If value were considered the percentages would be still higher, owing to present increased prices of machinery. In spite of these high prices, however, machine tool builders in Germany complain that the profits earned are not what they ought to be, owing to the cost of raw material and to the increased wages. Though deliveries had to be contracted for

six months ahead and more, the machine tool industry showed no inclination to utilize the state of the market for the extension of the works. In the beginning of 1906 the home orders were shelved in preference to orders from abroad. The industry subsequently continued to work for the home market, which demanded continuous supplies, though the profits in the home market were not what had been expected; but it was argued that the profits abroad, where increased customs rates had rendered exporting more difficult, were just as problematical. Hence, the present apprehensions, which most likely, however, will prove to be of less significance than expected in some quarters.

* * *

THE MAURETANIA.

Rarely are New Yorkers or the New Jersey crowd of commuters, who nightly cross the Hudson to their suburban homes, treated to so striking a sight as that presented by the turbine liner *Mauretania* as she steamed to her pier on the evening of November 22. The *Mauretania* reached Sandy Hook early in the forenoon after having made her first crossing from Daunt's Rock off Queenstown, Ireland, in about 5 days and 5 hours, but a combination of fog and low tide prevented docking until in the evening. As she slowly moved up the river her gigantic hull was silhouetted against the Jersey shore, the four immense smoke-stacks showing faintly above. Seven decks above the load water line were illuminated—some of them brilliantly—by electric lights. The combination of brilliant illumination, dark background and great size made a most impressive spectacle.

Though a sister ship to the *Lusitania* the *Mauretania* is of even greater size and carrying capacity. (See MACHINERY, August, 1906, and October, 1907). She is 5 feet longer, and because of the use of higher grade steel by her builders, Swan, Hunter & Co., Wallesend-on-Tyne, a considerable saving in gross weight was made for the same strength of hull. This saving increases the cargo capacity about 500 tons without increasing the gross tonnage displacement. In most essentials, however, the *Mauretania* and the *Lusitania* are alike. Although she is conceded to be a slightly faster ship than her mate, the *Mauretania* failed to lower the transatlantic record because of severe weather conditions. However, an indication of future possibilities is found in the fact that 624 knots were run in one day of fair weather. This breaks all previous records. Following are some of the principal data: Length, 790 feet; breadth, 88 feet; depth, 60½ feet; boilers, 25; heating surface, 159,000 square feet; grate surface, 4,060 square feet; Parsons turbines, 4; power, 68,000 to 70,000 H.P.; speed, 25 knots.

* * *

LAYING OUT A PROPELLER.

An article on laying out a screw propeller by Mr. J. S. Watts was published in the September issue of MACHINERY, which gave plain, practical instructions for draftsman. Mr. W. J. Goudie, the author of an English work, "The Geometry of the Screw Propeller," attacked the article in a letter published in the October issue of the *Practical Engineer*, London. Mr. Goudie's attack was based on a misconception of meaning of one paragraph of Mr. Watt's article. He quoted as follows "First, on the development of the blade fill in the dimensions at every 12 inches, by scaling the drawing," and then said: "A reference to the end elevation shows that these dimensions refer to the horizontal intercepts between the vertical axis and the leading and following edges of the expanded blade." In reply Mr. Watts says: "There is nothing in my article to lead any one to suppose that. In any case, the horizontal intercepts could not be determined at that stage of the work. If my critic had read my article carefully he would have found I first drew the development of the blade, that is, a view of the blade laid out flat on the paper, and then added these dimensions by scaling the development, afterward finding out what my critic calls the horizontal intercepts from these dimensions. To make it clear to him I will further say that the dimensions of the development of a blade are the lengths from the various points on the leading edge to those on the following edge, measuring *along the blade*. These were the lengths set off on the inclined sections and are not the horizontal intercepts as he wrongly supposes."

It is unnecessary to quote further from Mr. Goudie's letter, inasmuch as the succeeding criticisms were based on the original misconception. Mr. Watts states that the method has yielded satisfactory results on dozens of propellers. The one used as an example in the September issue has been at sea some months, working in an aperture too small to allow for any serious mistake.

* * *

DISCONTINUANCE OF THE TECHNOLEXICON.

We learn with much regret that the Verein deutscher Ingenieure (Society of German Engineers) has discontinued work on the universal technical dictionary for translation purposes, known as the "Technolexicon." This great work was to have been published in English, German and French, and was begun in 1901. In June, 1906, the work had progressed so far that 3,000,000 word cards had been collected, these being the contributions of 2,000 firms and individuals. The work has turned out to be so costly, however, having exceeded all expectations, that if it was completed within the allotted time the cost would exceed the pecuniary resources of the society. All communications for the "Technolexicon" should be addressed, henceforth, to Th. Peters, Verein deutscher Ingenieure, Charlottenstrasse, Berlin (N. W. 7), Germany.

DUTY ON ADVERTISING MATTER ENTERING AUSTRALIA.

The following information relative to the rate of customs duty applicable in the Commonwealth of Australia to advertising matter received in mails from other countries has been received by the Post Office Department at Washington from the Postal Administration of Australia. All advertising matter is dutiable at 12 cents a pound. Duty at this rate is levied on trade catalogues, price lists, trade circulars, and all similar advertising matter, introduced through the mails, even when forwarded in single copies addressed to individuals, provided that the total weight of such single copies forwarded by any consignor by any one mail to any one State of the Commonwealth is not less than two pounds in weight. It may also be mentioned that duty at 12 cents per pound is levied on the total weight of magazines, etc., containing advertisements to an extent of more than one-fifth of the printed matter contained within the outside covers.

FREE ENGINEERING LIBRARY TO OPEN EVENINGS.

On and after Wednesday, November 6, 1907, the reference libraries of the American Institute of Electrical Engineers, the American Society of Mechanical Engineers, and the American Institute of Mining Engineers, 29 West 39th Street, New York, will be open evenings until nine o'clock on all week days except public holidays. These libraries, constituting practically one library of engineering, situated near the New York Library, in the new headquarters of the Engineering Societies, are available to members of the above societies, engineers, and the public generally, subject to proper regulations. Strangers are requested to bring letters of introduction from members or to secure cards from the secretaries of the respective societies.

* * *

CASSIER'S GAS POWER NUMBER.

The November issue of *Cassier's Magazine* is a special gas power number containing 212 pages of reading matter on the general subject of gas power. Among the articles is a historical review of the internal combustion engine by H. H. Suplee (the editor) and discussions upon large gas engines by E. T. Adams, W. H. Booth, and F. E. Junge, representing the practice of America, England and Germany respectively. An important article on the utilization of waste furnace gases is contributed by Mr. B. H. Thwaite, the original chief promoter of the use of waste furnace gases for power. The number as a whole is a notable effort to place on record the developed engineering practice of what promises to be the chief motive power. There seems little doubt but that the gas engine will eventually displace the steam engine, because of its superior economy.

AMERICAN MACHINIST CELEBRATES THIRTIETH ANNIVERSARY.

The *American Machinist* celebrated the thirtieth anniversary of its birthday with a special issue, November 7, which eclipsed all its previous birthday issues in point of size, general typographical appearance and editorial work. There are 532 pages, including the cover, of which 433 are advertising. In this we include the description of the publishing plant. On the front cover is a beautiful and striking allegorical group representing Time, Power and Speed with the legend underneath: "With Time came Power and Speed," the whole typifying, of course, general progress and improvement. The special editorial articles include a review of machine tool progress for the past five years which have intervened since the previous birthday issue, advances in factory construction, cutting steels, constructive materials for machinery, pyrometry, electricity in shops, industrial education, industrial betterment, heat treatment of metals, etc. The issue is in itself good evidence of very material mechanical progress in the matters of machine composition, presswork, papermaking and engraving. And it is also fitting to say that there is abundant evidence of progress editorially in selection, arrangement and all that is included in the manifold activities of the editor of a progressive trade journal. The whole trade press should be proud that the advertising patronage and support of its readers make such issues possible, particularly those which are closely concerned in the machine tool business. It is gratifying evidence of the solidity and importance of the art—a basic art, but one which, perhaps, has not been so recognized until comparatively recent years.

CARROLL D. WRIGHT RECEIVES CROSS OF THE LEGION OF HONOR.

The Cross of the Legion of Honor has been conferred upon Hon. Carroll D. Wright, former United States Commissioner of Labor, in recognition of his distinguished services as a labor statistician, social engineer and improver in general working conditions. The presentation was made by M. Bonzom, acting French Consul-General, at a dinner given in Col. Wright's honor by Mr. Charles Kirchhoff, editor of the *Iron Age*. The event took place on the evening of November 9, at the Engineers' Club, New York, and was attended by the advisory council of the Museum of Safety Devices, and others. The Museum of Safety Devices is a branch of the American Institute of Social Service, Dr. Josiah Strong, president, of which society Col. Wright is a member. It was considered fitting and appropriate that the presentation should be made under the auspices of the society which is laboring to improve the condition of labor and to reduce the terrible roll of accidents resulting from our present industrial system.

* * *

PERSONAL.

Herbert T. Kehew, formerly auditor of the Crucible Steel Co. of America, is now secretary and treasurer of the Pittsburg Automatic Vise & Tool Co. He succeeds to the position temporarily held by Mr. F. D. Blackburn, resigned.

George A. Gallinger has been made manager of the Pittsburg office of the Independent Pneumatic Tool Co. of Chicago, having been promoted from his former position of general salesman.

Albert J. Ott has been appointed general agent in Illinois, Indiana and Wisconsin for the "Lo-swing" lathe manufactured by the Fitchburg Machine Works, Fitchburg, Mass. Mr. Ott was with the Vonnegut Hardware Co., of Indianapolis, Ind., for thirteen years.

* * *

OBITUARY.

Richard D. Hurley, manager of the Pittsburg office of the Independent Pneumatic Tool Co., died in Chicago November 5 and was buried November 7 at his old home in Galesburg, Ill. Mr. Hurley was only thirty-nine years old, and his untimely death will be a shock to a large circle of friends and acquaintances. He was a brother of Mr. John D. Hurley, vice-president and general manager of the Independent Pneumatic Tool Co., Chicago, and Mr. Edward N. Hurley, organizer and former president of the Standard Pneumatic Tool Co.

NEW BOOKS AND PAMPHLETS.

GEOLOGICAL SURVEY OF NEW JERSEY: Annual report of the State Geologist for the year 1906. 192 pages, 6 x 9 inches. It contains an account of the fire-resisting qualities of some New Jersey building stones; the glass sand industry of New Jersey; properties of trap rocks for road construction; notes on the mining industry, etc. Copies may be obtained from Mr. Henry B. Kümmel, State Geologist, Trenton, N. J.

MACHINE SHOP WORK. By Frederick W. Turner. 190 pages, 6¼ x 9¼ inches. Illustrated. Published by the American School of Correspondence, Chicago, Ill. Price, $1.50.

This book on machine shop work treats of tools operated by hand and power driven tools, including the heavy drill press, planing machines, and milling and grinding machines. The matter is prepared in the characteristic manner followed in all the instruction papers of the American Correspondence School, being copiously illustrated and written in simple language. The book will be found of particular interest and value to young mechanics and others who would instruct themselves on the elements of machine shop work.

HOW TO USE WATER POWER. By Herbert Chatley. 87 pages, 4¾ x 7 inches. 23 diagrams and illustrations. Published by the Technical Publishing Co., Ltd., London, and D. Van Nostrand Co., New York. Price, $1.00.

This little book treats of source of power, transmission of power, the hydraulic press, applications of the hydraulic press, water wheels, turbines, pumps, hydraulic engines, tidal power, water supply, sewage disposal and dams. It contains folding plates showing a hydraulic power system, "loss of energy" diagram, guide and vane angles for turbines and section of a reservoir dam.

MODERN STEAM TRAPS. By Gordon Stewart. 104 pages, 4½ x 7 inches. 71 illustrations. Published by the Technical Publishing Co., Ltd., London, and D. Van Nostrand Co., New York. Price, $1.25.

The contents of this book first appeared as a serial in the *Practical Engineer* of London, and it has been reprinted in book form in response to requests. It contains chapters on expansion steam traps, float-operated steam traps, bucket-type steam traps, thermostatic steam traps, differential water pressure steam traps, Bundy steam traps, etc. The book is one that should be of interest to engineers and others connected with steam power plants, and to contracting engineers having to do with the installation of steam power and heating.

MECHANICAL DRAWING. By Irvin Kennison. 142 pages, 6½ x 9¼ inches. Illustrated with numerous examples of drawings, lettering, diagrams, etc. Published by the American School of Correspondence, Chicago, Ill. Price, $1.00.

This work is typical of a large number of published works on mechanical drawing. It is gotten up in the characteristic style of the text-books published by the American Correspondence Schools, and should be a clear, concise and valuable aid to the student who would instruct himself in the elements of mechanical delineation. It describes instruments and materials, gives geometrical definitions, geometrical problems and examples of projections, examples of lettering, instructions for tracing, blueprinting, arrangement of assembled drawings, etc.

PATTERN MAKING. By James Richie. 141 pages, 6 x 9 inches. Illustrated. Published by the American School of Correspondence, Chicago, Ill. Price, $1.00.

Pattern-making is an important part of all mechanical construction, and this work endeavors to give a good elementary knowledge of the tools, methods and general construction of machine patterns. It treats of materials and tools, methods of molding, simple and built-up patterns, and gives numerous illustrations throughout. The style of description is simple and well within the grasp of the average man. The book is one that can be recommended to young machinists and others who desire to acquaint themselves with the general requirements of pattern-making, but have no intention of following the art. By this we mean that they wish to understand the needs of the pattern-maker without actually being one.

HYDRAULICS. By S. Dunkerly. Vol. I. 343 pages, 5¼ x 8½ inches. 269 cuts. Published by Longmans, Green & Co., London and New York. Price, $3.00.

Vol. I of this work treats of hydraulic machinery. The second volume will take up the resistance and propulsion of ships. The notes for the first volume were written at the Royal Naval College at Greenwich. The order of the book, by chapters, is: Flow of a Perfect Liquid; Fluid Friction; Pressure Machines; Reciprocating Pumps; Turbines; Centrifugal Pumps. Details are given of a British hydraulic gun brake. Prof. Osborne Reynolds' four-stage turbine is discussed, and the results of trials given; also full details of Prof. Reynolds' hydraulic brake and four-stage centrifugal pump. A valuable feature of the work is a large number of numerical examples with answers in the appendix.

BALANCING OF ENGINES. By Archibald Sharp. 212 pages, 5¼ x 8¼ inches. Illustrated. Published by Longmans, Green & Co. Price, $1.75.

This work discusses the balancing of steam, gas, and gasoline engines, and is a most acceptable addition to the literature on the subject which is quite meager. The contents, by chapters, are as follows: Primary Phenomena of Motion and Force; Preliminary Theorems in Mechanics; Inertia Forces of Revolving Masses; Masses Reciprocating in the Same Axial Plane—Long Connecting-rods; Revolving and Reciprocating Masses; Inertia Forces of Second and Higher Orders; Transverse Couples Due to Connecting-rods; Engines with Cylinders in Different Longitudinal Planes; Kinetic Energy of Pistons and Connecting-rods; Torque and Crank Shafts; Primary and Secondary Balance; Displacement of Engine Frame Due to Unbalanced Forces and Couples; Engines for Various Purposes; Large Gas Engines

CONSTRUCTION AND WORKING OF PUMPS. By Edward C. R. Marks. 259 pages, 4¾ x 7 inches. 159 illustrations. Published by the Technical Publishing Co., Ltd., London, and D. Van Nostrand Co., New York. Price, $1.50.

This book, which is of the second edition, was first published in 1902. It discusses the elementary principles of pumps, explains their action and shows simple diagrams to illustrate. Various types of pumps are described, including boiler feed, fly-wheel, duplex, Worthington, Mumford & Anthony, Mumford Cameron type, pulsometer compound feed, and a great variety of other types, thus making the work very comprehensive of pumping practice in general, and especially of British practice. Centrifugal and rotary pumps are included, and high-duty pumping engines giving present practice in England and America. The work is one that can be recommended for a concise description of various types and principles involved.

POCKETBOOK OF ELECTRIC LIGHTING AND HEATING. By S. F. Walker. 438 pages, 4 x 6¼ inches. 272 illustrations. Published by Norman W. Henley & Son, 132 Nassau St., New York. Price, $3.00.

This book was prepared with a view of presenting in handy form the information required by central station engineers and others in charge of electric power plants. The first chapter is on electrical units, defining the various units used by the electrical engineer and giving tables of resistance of insulating materials, hysteresis tests on iron; laws of electric circuits, etc. The following chapters take up

electric generators, motor generators, alternating current generators, transformers, accessories for generators, etc., accumulators, switchboards, forms of switches, circuit-breakers, fuses, field-regulators, systems of distribution, cables, method of laying cables underground, measuring instruments, lamps, etc. The book contains a great deal of strictly high grade matter in condensed form; its small size makes it convenient to carry in the pocket.

Chemistry of Gas Manufacturing. By Harold M. Royle. 328 pages, 5½ x 8½ inches. Illustrated. Published by Norman W. Henley & Son, 132 Nassau St., New York, and Crosby Rockwood & Son, London. Price, $4.50.

The work is a practical treatise for gas engineers, students, and others interested in gas manufacture. The author has confined himself strictly to certain aspects of the chemistry of gas manufacture, leaving the manufacture of gas aside. The contents by chapters are: Proportion of Standard Solutions; Coal; Furnaces—Testing and Regulation; Products of Carbonization; Analysis of Crude Coal Gas; Analysis of Lime; Ammonia; Analysis of Oxide of Iron; Naphthalene; Analyses of Fire-Bricks and Fire-Clay; Weldon and Spent Oxide; Photometry and Gas Testing; Carbureted Water Gas, etc. A number of valuable appendices are included. The work is one that should have some interest to chemists and engineers outside of gas manufacture, especially those who have to do with the analysis of coal, combustion, economy of boiler furnaces, etc.

Pocketbook of Mechanical Engineering. By Charles M. Sames. 195 pages, 4 x 6½ inches. Illustrated with numerous diagrams. Bound in flexible leather. Published by the author, 542 Bramhall Ave., Jersey City, N. J.

This valuable little pocketbook has passed through two editions, the book in hand being of the third edition. New matter has been added on high-speed steel, superheated steam, reinforced concrete and machine design. The recommendations made for speeds, feeds and cuts in Mr. F. W. Taylor's notable presidential paper presented before the American Society of Mechanical Engineers are given in condensed form; Knoblauch & Jakob's values for specific heat of superheated steam at constant pressure are given; also a table based on other researches giving values for the mean specific heat through the whole range of temperature from saturation up to various pressure temperature conditions ranging from 50 pounds gage to 250 pounds gage. An addition of doubtful value is eight pages of section paper bound in at the back. It is our opinion that most purchasers of the work would prefer to have this space utilized for more engineering matter and to buy their section paper of the stationer. The work as a whole is one that can be heartily recommended to those who desire a condensed handbook of mechanical data.

CATALOGUES AND CIRCULARS.

C. P. Mingst, Evansville, Ind. Circular describing the one- and two-cylinder Mingst marine gasoline engine.

Skinner Chuck Co., New Britain, Conn. 1907 price list of Skinner chucks, containing tables of specifications of lathe chucks, planer chucks, drill chucks, etc.

D. Saunders' Sons, Yonkers, N. Y. Catalogue containing illustrations and descriptions of hand tools and machines for cutting and threading steam and gas pipe.

Brown Hoisting Machinery Co., Cleveland, Ohio. Circular of locomotive cranes for handling ore, coal, limestone, slag, etc. These cranes may be used on any standard gage railway track.

Gould & Eberhardt, Newark, N. J. Catalogues on automatic gear cutting machinery, and Eberhardt's shapers, illustrating and describing the various types of gear and rack cutting machines and attachments, and the "High Duty" shaper with its attachments.

Diamond Saw and Stamping Works, Buffalo, N. Y. Catalogue No. 13, giving specifications for the Sterling hack saw blades, frames, and power hack saw machine. The special features of the power hack saw machine are: driven by milled gears, tight and loose pulleys, automatic shut-off, gravity feed and swivel vise.

Ingersoll Milling Machine Co., Rockford, Ill. Catalogue No. 16 of heavy milling machines, showing milling machines of various types, with one, two, three or four spindles, in sizes from 20 inches wide up to 10 feet wide. These machines are suitable for all kinds of work from very light to very heavy milling.

S. Obermayer Co., Cincinnati, Ohio. Descriptive matter of the "National" iron filler cement for foundry use. This cement filler is a powder that is mixed with water just prior to using. It hardens and expands at the same time, filling blowholes solidly with a metalized compound that can be readily machined.

General Electric Co., Schenectady, N. Y. Bulletin No. 4532, descriptive of direct-current motor-starting rheostats, types SA and SO. Type SA is made for one minute duty with no-voltage release; type SO is similar to type SA, but in addition to the no-voltage release attachment it has an overload coil in series with the motor armature.

Manning, Maxwell & Moore, Inc., 85-87-89 Liberty St., New York. Circular descriptive of the Ashcroft prismatic water gage for locomotives, marine and stationary steam engines. The glass and its casing are so designed that the water shows black and the steam space has a silvery appearance, thus making the water level unmistakable in any light.

Potter & Johnston Machine Co., Pawtucket, R. I. Catalogue of manufacturing automatic chucking and turning machines, and universal shapers. The automatic lathes are made in 5½ x 10-inch and 8½ x 16-inch sizes, and the shapers in 15- and 24-inch sizes. The catalogue gives tooling diagrams and forms for records of tool positions, and other instructions for the operation of the automatic machines.

Westinghouse Machine Co., East Pittsburg, Pa. Catalogue of Westinghouse storage batteries for portable use. The company has been in the storage battery business for several years, but no literature on the portable batteries has been issued until the present publication. Batteries for trucks, car lighting, electric locomotives, railway signaling, etc., are listed.

Electric Controller & Supply Co., Cleveland, Ohio. Booklet entitled "You Can Reduce Operating Costs," which is descriptive of magnetic switch controllers for the operation of electric motors. The booklet illustrates various types of electric controllers, and points out their advantages as compared to manually-operated controllers. Their use undoubtedly has made the electric motor practicable in many services which otherwise would be impossible because of the tremendous electrical overloads temporarily imposed in starting and reversing.

Beaman & Smith Co., Providence, R. I. Catalogue of milling and boring machines built in a great variety of styles to fit individual needs. These include combined vertical and horizontal milling machines, duplex milling machines, four-spindle milling machines, horizontal spindle machines, locomotive port milling machines, boring and tapping machines, cylinder boring machines, engine frame finishing machines, horizontal spindle drilling, boring, tapping and milling machines, pump boring machines, tapping attachments, valve machines, etc.

Fitchburg Machine Works, Fitchburg, Mass. Catalogue of the "Lo-swing" lathe. This lathe is "a single purpose machine for increased output and maximum efficiency." It is built for the one purpose of turning shafts and similar machine parts that require to be trued on centers and reduced to one or several diameters, as the case may require. The catalogue illustrates the construction of the machine and the work that it is adapted to, and is a very interesting example of trade literature. Mechanics unacquainted with the principle of this comparatively new machine will find a study of it well worth while.

Seneca Falls Mfg. Co., Seneca Falls, N. Y. Catalogue illustrating and describing "Star" 9- and 11-inch screw cutting lathes, power and foot driven; "Seneca Falls" screw cutting lathes, built in 12-, 14- and 16-inch sizes; speed lathes; wood-turning lathes; and lathe tools, attachments and accessories. The attachments include an ingenious milling and gear cutting attachment which converts the 9- and 11-inch lathes into fairly efficient gear cutters and milling machines, thus enabling the possessor of a lathe to greatly extend its usefulness.

Sawyer Belting Co., Cleveland, Ohio. "Auto-Calculator" for belts and pulleys, and pocket lumber scale. This handy device is a slide rule made of celluloid and heavy paper board, one side being the slide rule for calculating the revolutions per minute of a driven pulley, having given the diameter of the driver and the revolutions per minute; or for finding the required pulley diameter, having given the revolutions per minute of the driver and driven pulleys, and so on. The opposite side carries the lumber scale, this being a table of sizes of lumber and contents, in board feet. The calculator also gives the belt speed and the horse-power for 4-ply, 6-ply, 8-ply and 10-ply belts for pulley faces 1 to 20 inches.

MANUFACTURERS' NOTES.

Cincinnati Shaper Co., Cincinnati, Ohio, has erected an addition to its factory, 90 x 100 feet.

Arguto Oilless Bearing Co., Wayne Junction, Philadelphia, Pa., has been awarded a gold medal for its exhibit of "Arguto" oilless bearings at the Jamestown Exposition.

Jantz & Leist, Cincinnati, Ohio, manufacturers of motors and dynamos, are now located in their new shop at the corner of York St. and Western Ave.

The Philadelphia Gear Works, Inc., 1120-22 Vine St., Philadelphia, Pa., held a housewarming, reception and dance at its new building, 1120 Vine St., November 22.

Kern Machine Tool Co., Cincinnati, Ohio, has completed a large addition to its shop which doubles the floor space. The product of the company is upright drills.

Niles-Bement-Pond Co., Trinity Building, 111 Broadway, New York, has appointed Mr. A. J. Strong representative of the Pratt & Whitney Co. in Eastern Michigan with headquarters in Detroit.

W. F. & John Barnes Co., 231 Ruby St., Rockford, Ill., has completed a large three-story warehouse which was greatly needed to relieve the congestion in the shops.

Pittsburg Automatic Vise & Tool Co., Pittsburg, Pa., was awarded a gold medal at the Jamestown Exposition for its exhibit of vises.

General Electric Co., Schenectady, N. Y., made public, following a recent annual meeting of its sales managers, an order booked by the manager of the Pacific Coast territory for a Curtis steam turbine unit of 20,000 horse-power.

Ferracute Machine Co., Bridgeton, N. J., manufacturer of presses and dies for sheet metals, lately shipped presses to England, India, Austria-Hungary and France, besides several car-loads to points in the United States.

Independent Pneumatic Tool Co., First National Bank Building, Chicago, Ill., has appointed Mr. George A. Gallinger manager of its Pittsburg office, 1210 Farmers' Bank Building. Mr. Gallinger was the company's traveling man from its Chicago office.

S. Obermayer Co., Cincinnati, Ohio, has published a special edition of the *Obermayer Bulletin* devoted exclusively to the core room of the foundry. It contains a number of valuable articles on core work, and shows certain appliances for producing core work at low labor cost.

Technical Publicity Association, New York, devoted the meeting of October 31 to "The Mailing List," in securing foreign business. A number were elected to membership. Associations modeled on the lines of this body have been started in Chicago and London.

American Locomotive Co., 111 Broadway, New York, had a meeting of its directors November 6, for organization, and re-elected the retiring officers to serve for the ensuing year. Mr. S. T. Gallaway was elected secretary to succeed in that capacity Mr. Leigh Best, who has been secretary of the company since its organization. Mr. Best continues to hold the office of vice-president.

Hisey-Wolf Machine Co., Cincinnati, Ohio, manufacturer of portable electric tools, has moved into new shops on Township St., Cormany Ave. and Canal. The plant consists of three buildings on a lot 145 feet front by 165 feet deep. The main shop is two stories in height, with light on four sides. The offices and power-plant are in separate buildings.

Notice has been received that the International Jury in the section of Social Economy at the International Book Paper and Publicity Exhibition, which closed in Paris last month, made an award of the Grand Prix to the American Museum of Safety Devices and Industrial Hygiene. A diploma of honor, the second highest award, was made to Messrs. Charles Kirchoff and T. C. Martin, respectively, chairman and vice-chairman of the museum's advisory council; also to Dr. L. L. Seaman and Mr. Rudolph Lenz for their active interest in promoting the work of the museum. The museum is now occupying the entire fifth floor at 231-241 West 39th St., New York City, and all inquiries for space, exhibits and other information should be sent to Dr. W. H. Tolman, director of the museum.

Fulton Machine & Vise Co., Lowville, N. Y., which was burned out early last summer, has rebuilt its plant and is now in full working order. The concern is a stock company incorporated with a capital of $50,000. The officers are: A. S. Stoddard, president; C. T. Boshart, vice-president; E. W. Fulton, secretary and treasurer; T. S. Dibble, superintendent. The machine shop is 35 x 110 feet and is built of concrete blocks. The foundry is 35 x 95 feet. The product at the present time is "Star" solid jaw vise and a patent high-pressure valve.

Indianapolis Machine Tool Co., Indianapolis, Ind., builder of the new Libbey turret lathe, expects to be in its new factory and in full operation January 1, 1908. The new shop is located at West 21st St. and the Belt Ry. on a 4½-acre plot. The building is constructed on the unit plan and may be extended at any time in harmony with the existing plan. The main building is 100 x 150 feet. It has galleries on each side 25 feet wide and 10 feet wide across the ends. The main and gallery floors are of concrete. A 48-foot span electric traveling crane, capacity 5 tons, built by the General Pneumatic Tool Co., Montour Falls, N. Y., is provided for handling the work. The turret lathes will be built in large lots.

Niles-Bement-Pond Co., Trinity Building, 111 Broadway, New York. Catalogue of high-duty cold sawing machines built by the High-Duty Saw & Tool Co. These machines are equipped with the "Tindel" inserted tooth saw, which is of the simplest construction. It consists of a saw blade or body and the cutters only, there being no auxiliary parts required to hold the cutters whatever. The cutters are inserted in dovetail radial slots milled alternately on opposite

I.–FORMULAS FOR HORSEPOWER TRANSMITTED BY CAST IRON AND RAWHIDE PINIONS.

The tables of horsepowers transmitted by cast iron cut pinions are calculated by formulas derived from Reuleaux's "Constructor," using the following notation:

- A = coefficient of wear
- b = face or breadth of tooth
- C = circular pitch
- D = diameter of gear wheel, in inches
- H = horsepower transmitted
- N = revolutions per minute
- P = pressure on tooth at pitch circle in pounds
- R = pitch circle radius, in inches
- S = permissible working stress of material of tooth, in pounds per square inch of section
- V = velocity at pitch circle, in feet per minute,

then

$$H = \frac{bCRNS}{1058820} \qquad (1)$$

which is derived as follows:

A relation between the twisting moment PR and the corresponding horsepower is given by,

$$PR = 63025\frac{H}{N} \qquad (2)$$

The formula for strength is,

$$bC = 16.8\frac{P}{S} \qquad (3)$$

Combining (2) with (3) by substituting $\frac{63025H}{RN}$ for P in (3) gives $bC = \frac{1058820H}{RNS}$ which by transposition becomes (1)

The fiber stress S must be made less the higher the speed, and Reuleaux recommends for cast iron:

$$S = \frac{9600000}{V+2164} \qquad (4)$$

which value was substituted in (1) for calculating the tables.

Allowance for wear is not provided in the tables, being left to the discretion of the designer. According to Reuleaux $A = \frac{PN}{b}$ should not exceed 28000

$$A = \frac{126050H}{Db}, \text{ or}$$

b should be greater than, or at least equal to, $4\frac{1}{2}\frac{H}{D}$.

In a pair of cast iron gears the greatest wear comes on the smallest gear. The coefficient A should not be greater than 28000 for the largest gear and may be taken as low as 12000 without obtaining inconvenient dimensions. To avoid excessive wear on the smaller gear, steel or bronze may be substituted.

The table of horsepowers transmitted by shrouded rawhide spur pinions of one inch face is calculated by the same formulas as were used for cast iron pinions, viz:

$$H = \frac{bCRNS}{1058820}$$

in which the notation is the same as before.

The permissible working stress per square inch of material is taken at 2520 pounds up to 2 diametral pitch, and for greater pitches it may be taken at the following values:

D.P.	$1\frac{3}{4}$	$1\frac{1}{2}$	$1\frac{1}{4}$	1
S.	2340	2010	1670	1340

Owing to the elasticity of rawhide pinions, which enables them to sustain shocks without increase of stress, the working stress is made constant for the different pitches at all speeds. Hence the horsepower values in the tables are simple multiples of the first column, throughout.

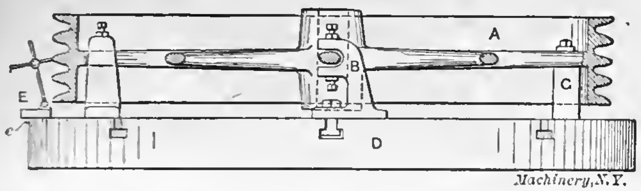
SHOP OPERATION SHEET NO. 49.

W. L. McLaren. MACHINERY, January, 1908.



To Set Up a Sheave Pulley Casting for Boring and Turning on a Vertical Boring Mill.

1. Select as many clamp blocks *B* as there are arms to the pulley casting. These clamp blocks should be high enough to raise the casting *A* above the table *D* far enough to allow facing the under side of the rim. Measure the distance from the center of the casting *A* to the inside of the rim, and then fasten the clamp blocks *B* to the mill table, making the distance from the outside of each block to the center of the table about 1/2 inch less than this measurement.

2. Place the pulley casting *A* on the boring mill table *D*, and insert the arms of the pulley into the slots in the clamp blocks *B*. Set the pulley approximately central with the table by shifting the pulley until the distances between the inside of its rim and the clamp blocks are about equal.

3. Set the rim of the pulley parallel with the mill table. This can be done by measuring from the table to various points around the rim, using a surface gage. Adjust the pulley with the lower set-screws in the clamp blocks *B*.

4. Now place the surface gage *E* upon the table in the position shown. Lower the rear pins *c* of the gage, and hold them firmly against the mill table. Set the pointer of the gage about 1/4 inch from the pulley casting, and then move the gage to various points around the table, until the place where the casting is closest to the pointer is found. Set the pointer against the casting at this place, then move the gage to the opposite side of the table and measure the distance between the pointer and the casting. Move the casting toward the pointer a distance equal to one-half this measurement. Again test the casting for height, and if necessary, change lower set-screws in blocks *B* until the rim is again parallel with the table. Tighten the upper set-screws lightly.

5. Start the machine and hold a piece of chalk against the outside of the rim. If the casting is not central with the table a mark will be made on that part of the rim which is farthest from the center. Adjust the casting if necessary, by hitting it lightly with a soft hammer, until it runs perfectly true.

NOTE.—If clamp blocks *B* cannot be obtained, support the arms by blocks *C*, and adjust the height of the casting by placing thin pieces of iron or brass between the blocks and the arms. Clamp the arms to the table by using bolts and straps. If the blocks *C* are used, it will be necessary to have a block or angle-piece bolted to the boring mill table, and against an arm, to act as a driver.

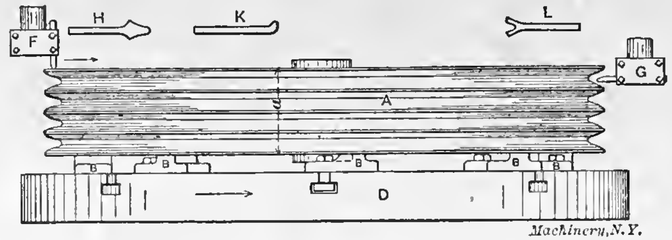
SHOP OPERATION SHEET NO. 50.

W. L. McLaren. MACHINERY, January, 1908.



To Turn and Face a Sheave Pulley Casting on a Vertical Boring Mill.

1. Set the cross-rail of the machine about six inches above the top of the pulley casting *A*.

2. In tool-clamp *F*, place a roughing tool, and take a rough facing cut over the rim, feeding the tool toward the center.

3. In tool-clamp *G*, place a long, round-nosed, right-hand side tool. With hand feed, rough out one side and half the bottom of each channel. Replace this tool with a similar left-hand tool, and rough out the other side and half the bottom of each channel.

4. Reset the roughing tool in clamp *F*, placing it in a horizontal position. Take a down-feed cut over the outside of the casting, the cut being deep enough to clean up the crests on the grooved rim.

5. Replace the tool in clamp *G* with a rough forming tool, similar to *H*. Fasten this tool in a horizontal position, and feed it into one of the grooves until every part of the groove has been trued up. Before withdrawing the tool from the groove, make a depth mark on the face of the tool. This mark should coincide with the trued surfaces of the grooved rim. Machine each groove in the periphery of the rim, feeding the tool into each until the depth mark coincides with the trued surfaces. If a groove does not clean up when the tool has been fed to the depth indicated by the mark, it will be necessary to make the groove deeper, re-mark the tool, and machine all the other grooves to the same depth.

6. Replace the tool in clamp *F* with a bent roughing tool *K*, set horizontal, and face the bottom of the rim, working between the casting *A* and the table.

7. Replace the rough forming tool in clamp *G*, with a finishing tool *H*, which is ground to a gage. Repeat the operation described in step 5, and make all the channels conform to a gage.

8. Replace the tool in clamp *G* with a forming tool *L*. Set the tool in a horizontal position, and, feeding by hand, round off all the crests between the channels.

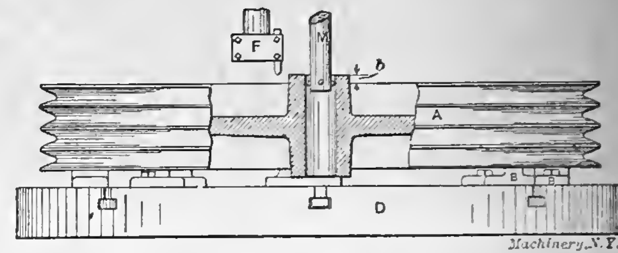
9. Place a broad-nosed finishing tool in clamp *F*, and a bent finishing tool, similar to *K*, in clamp *G*, and finish the top and bottom of the rim to dimension *a*. When taking these cuts a coarse feed should be used, and both the top and bottom of the rim faced simultaneously.

NOTE.—It will not be necessary to stop the machine at every change of tools.

PUNCH PUNCH

SHOP OPERATION SHEET NO. 51.

W. L. McLaren. MACHINERY, January, 1908.



To Bore and Face Hub of a Sheave Pulley Casting on a Vertical Boring Mill.

1. In the tool-clamp *F* place a round-nosed roughing tool, and face the top of the hub within 1/32 inch of the finish dimension *b*. If the hub is to be central with the rim, as is usually the case, the dimension *b* will equal one-half the difference between the distance through the hub and the width of the rim. When facing the hub, the dimension *b* is obtained by placing a straight-edge across the hub and measuring from the straight-edge to the rim.

2. Replace the roughing tool in clamp *F* with a flat finishing tool, and finish the top of the hub to dimension *b*, using a coarse feed.

3. Replace the tool-clamp in opposite head by a boring-bar *M*, provided with a single point cutter, set to fully clean the cored hole. Start the cut, feeding down. Test the hole with inside calipers for diameter at top and bottom. If these diameters are not equal, move the head slightly and take another light cut.

4. Replace the single point cutter with a double end cutter of proper size to bore the exact finish diameter, and take the cut, feeding down.

NOTE.—Boring bars, especially for large boring mills, are often made with an extension which passes down through a bushing in the table. This extension of the bar is a close sliding fit into the bushing, and prevents the bar from springing.

5. Release the casting *A* from the clamp blocks *B*, and turn it over; rest the rim on four to eight parallels, according to the diameter of the casting. Center it roughly by measuring from the edge of table *D*. Clamp to table with three to eight clamps and bolts, according to diameter of casting.

6. Face the hub as described in steps 1 and 2, and to conform to dimension, as at *b*.

NOTE.—If hole in hub is large enough, and the casting is set a sufficient height from the table *D* to permit it, an upwardly bent facing tool may be placed in the boring-bar, which is lowered through the hole for that purpose. The lower side of the hub can then be faced, provided there is room enough in the hole to allow the bar to move far enough in a horizontal direction. The length through the hub may be measured with a "hook scale." When the hub can be faced in this way, considerable time will be saved, as it will not be necessary to turn the casting over and reset it.

MACHINERY.

January, 1908.

DESIGN OF ROTATING DRUMS.

ULRICH PETERS.*

THERE are many materials, such as marls, sand, clay, ore, phosphate rock, gypsum, cement, etc., used for different manufacturing purposes, which require to be either dried, roasted, or calcined, or freed from the water chemically bound. Usually such materials are freed from their moisture at the mine or factory, in order to save the unnecessary expenses of shipping water. Technically, this drying, evaporating, burning up, or roasting is most quickly performed in the so-called rotary dryers or kilns. This dryer, or kiln, consists of a slowly-rotating cylindrical tube or drum, which not seldom has a length of over 100 feet and a diameter up to 8 feet. The axis of rotation of these dryers is not always horizontal, often being more or less inclined. The shell usually rests on rollers, and the inside shell, according to requirements, either is provided with cascade bars (see Fig. 1), which lift and distribute the material over the entire space, or may be brick lined, or left bare.

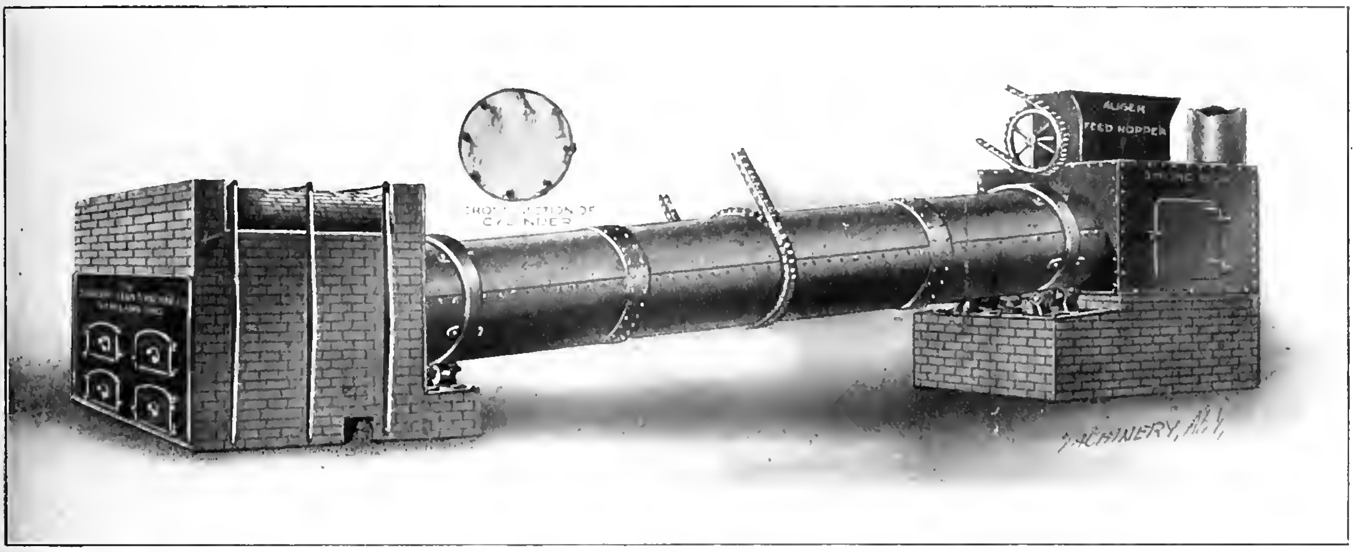


Fig. I. General Appearance of Drying Drum.

Large foundry tumblers are used for the purpose of smoothing and polishing the surfaces of various products, such as castings, tubes, etc., and similar tumbling barrels are also used in laundries. These drums or barrels, when not charging and discharging through the ends, are provided with suitable openings, located on the side of the drum, for the purpose of charging and removing the material. Finally, there are a great many revolving mining screens which have a close technical relation to the above drums, so far as construction is concerned. The object of this article is to discuss the principal points considered in calculating the strength and proportion of rotating cylinders.

In the following:

W = total weight of drum in pounds,

U = total weight of the uniformly distributed material,

L = length of the cylindrical drum, in feet,

C = cantilever arms, in feet,

M = moment; M_b = bending moment; M_t = twisting moment.

R = moment of resistance, usually called section modulus,

I = moment of inertia,

D = outside diameter, d = inside diameter of drum,

S = unit stress in material.

In general, a beam supported at two points, A and B, located at equal distances C from the end, Fig. 2, will have anywhere at the distance x the bending moment,

$$M_x = \frac{W + U}{2}\left(\frac{x^2}{L} - x + C\right) \qquad (1)$$

By moving the supports toward the ends, making $C = 0$, Fig. 3, the equation reduces itself to

$$M_x = \frac{W + U}{2}\left(\frac{x^2}{L} - x\right) \qquad (2)$$

A maximum bending moment is produced when $x = \frac{L}{2}$, therefore

$$M_b = -\frac{W + U}{8} L \qquad (2a)$$

Similarly by concentrating both supports A and B in the middle, $C = \frac{L}{2}$, (Fig. 4):

$$M_x = \frac{W + U}{2}\left(\frac{x^2}{L} - x + \frac{L}{2}\right) \qquad (3)$$

The maximum moment will again occur in the middle, *i. e.*, when $x = \frac{L}{2}$.

$$M_b = \frac{W + U}{8} L \qquad (3a)$$

Both maximum moments, Figs. 3 and 4, are equal, except that the moments are oppositely directed in rotation bout A or B. It is obvious now that there is a certain value for C in which the negative moment in the middle of the beam equals the positive moments at the supports A and B. As the bending moments between A and B change from a negative to a positive value, there will be two points O and O, Fig. 2, where the moments $M_x = 0$. In order to find this value for C, we simply make (Fig. 2) the moment in the middle equal the bending moments at the supports A or B; so that we have the condition:

$$-M_m = M_c \qquad (4)$$

or

$$-\frac{W + U}{2}\left(\frac{L}{4} - \frac{L}{2} + C\right) = \frac{W + U}{2}\left(\frac{C^2}{L} - C + C\right) \qquad (4a)$$

which equation, reduced, gives us the value for

$$C = (\sqrt{\tfrac{1}{2}} - \tfrac{1}{2})\, L = 0.207\, L \qquad (5)$$

The value substituted in equation (4a) gives for the maximum moment

$$-M_m = M_c = \frac{W + U}{47} L \qquad (6)$$

This formula indicates that a continuous beam of the length L, if supported symmetrically at the distance $C =$

* Address: Kenwood St. and Beechwood Boulevard, Pittsburg, Pa.

0.207 L from the ends, will possess the greatest carrying capacity. As regards the methods of supporting in the cases in Fig. 3 and Fig. 4, the continuous beam will carry about 6 times more weight. This, naturally, applies also to cylindrical drums supported on rollers.

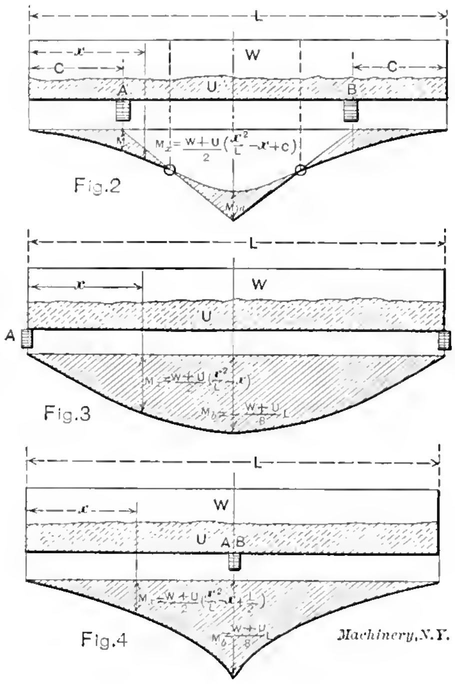
The moment of inertia of a circular ring section is

$$I = \frac{\pi}{64}(D^4 - d^4) \tag{7}$$

and the section modulus

$$R = \frac{\pi}{32}\,\frac{D^4 - d^4}{D} \tag{7a}$$

From formula (7a) by combining with the general equation



Figs. 2, 3 and 4. Bending Moments for Drum supported at Different Places.

(1) for the bending moment, we get for the maximum fiber stresses in bending:

$$S = \frac{16\,D\,(W + U)}{\pi\,(D^4 - d^4)}\left(\frac{x^2}{L} - x + C\right) \tag{8}$$

As these drums are built up of several single shells, it will be a good plan to distribute the joints in such a manner so that no joints come at the places of maximum bending, that is in the middle and at the supporting points. Then, at the joints where bolt and rivet holes weaken the material, the above fiber stress will have to be divided by the efficiency of the joint, which, according to best practice, seldom exceeds 85 per cent. Care should also be taken to provide a sufficient number of rivets, to take care of all occurring shearing stresses, such as we have in common built-up girders. Finally, stiffeners will have to be provided at intervals around the drum to keep it in shape. In barrels, which have to be provided with openings, the decrease in strength may, to a certain extent, be compensated for by reinforcements, such as bars, angles and beams (Fig. 5).

As the drum is rotating, the maximum fiber stress will alternately assume postive and negative values, similar to those we have in connecting-rods. On that account, the maximum fiber stress should be lower than the allowable stress for bridges or girders. Then, too, the drum is not only subjected to stresses by flexure alone; besides the shearing stresses already mentioned, there is also a torsional shearing stress due to the rotating power, which produces a twisting moment M_t in the drum. We may combine the bending and twisting moments to an ideal moment, by means of the Reuleaux formula—

$$M_o = \tfrac{3}{8} M_b + \tfrac{5}{8}\sqrt{M_b^2 + M_t^2} \tag{9}$$

From this the actual maximum fiber stress may be calculated by dividing formula (9) by the ideal section modulus R_o.

$$S_o = \frac{M_o}{R_o} \tag{10}$$

$R_o = R \times$ coefficient of strength of joint.

The torsional moment is easily figured from the frictional resistance of the supporting rollers and the turning moment of the material inside the drum.

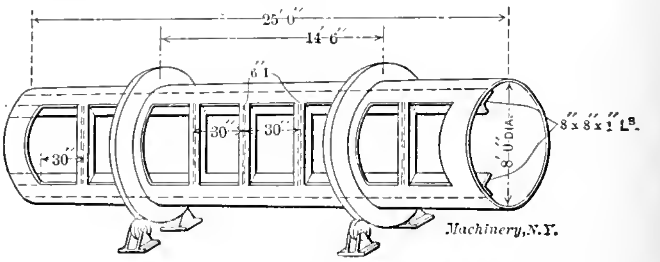


Fig. 5. Schematic View of Drum, showing Openings.

In order to illustrate this more clearly, we may proceed now with a specific example. Fig. 5 shows a drum used in a certain manufacturing operation, which is required, when it is filled, to carry a load $U = 200,000$ pounds of a material resembling sand, weighing, say, about 160 pounds per cubic foot. The natural slope of the materials is $\sim$ 45 degrees when calcined, and the weight is then 90 pounds. On account of the bolt or rivet holes for the supporting rings, we make M_c 10 per cent less than M_m, and derive then C, according to formula (4a) as follows:

$$-\,0.9\left(\frac{L}{4} - \frac{L}{2} + C\right) = \frac{C^2}{L};$$

$$C = \tfrac{1}{2}\,(\sqrt{1.71} - 0.9)\,L = 0.204\,L.$$

As the length $L = 25$ feet, we have $C = 5.1$ feet.

Therefore the most advantageous distance between the supporting rollers is $L - 2C = 25 - 10.2 = 14.8$ feet $\cong$ **14 feet 6 inches.**

This distance would produce the least bending moment if the load is distributed over the entire length of drum. While

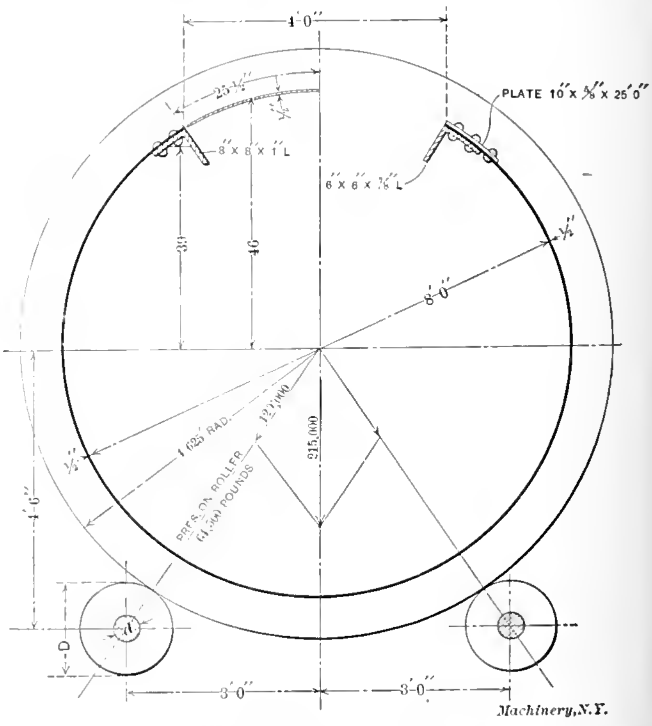

Fig. 6. Section through Drum.

in operation, however, such circumstances may probably occur that the load is mainly distributed between the supporting rollers, in which case it will throw a greater bending stress on the drum. Consequently, in the preliminary and final calculations for the required shell thickness, we will consider as the bending moment:

$$M_m = \frac{U\,(L - 2\,C)}{8} = \frac{200,000 \times 14.5}{8} = 362,500 \text{ foot pounds.}$$

To allow for sufficient stiffness, on account of the large diameter of the drum, the extreme fiber stress should be taken very low, say $S = 2{,}000$ pounds per square inch, giving the value for the moment of resistance

$$R = \frac{M_m}{S} = \frac{362{,}500}{2000} = 181.$$

[The moment of resistance is arrived at in the manner in common use with structural designers, lengths being expressed in feet, but stresses in pounds per square inch. In fact, the value for R then becomes merely a constant.—EDITOR.]

According to this value, we find in the accompanying table the nearest thickness of shell to be 5/16 inch. From the preliminary estimate we can now "guesstimate" that a thickness of ½ inch will be about right, when considering the additional torque, the efficiency of the rivet joints, and the abrasion inside the drum by the material, as well as the

For moments expressed in inch-pounds, multiply the corresponding value in table by 12.

considerable dead weight of the drum itself. This latter, according to the table amounts to $\frac{1036}{2} = 518$ pounds per running foot, not including the weight of joints and rivets, also necessary stiffening angles around the drum, etc. Assuming these to be 15 per cent of the weight, the total weight of drum amounts to about $W = 518 \times 1.15 \times 25 = 14892 =$ 15,000 pounds approximately.

If it is desired to find the amount of reinforcement which will exactly compensate for the cutting away of the plate for the openings of 4 feet width, it will be sufficiently accurate to make the momentum of plate section equal the momentum of reinforcing angle, so that (Fig. 6)

$$25\tfrac{1}{2} \times \tfrac{1}{2} \times 46 = A \times 39$$

From this follows the required area of reinforcement

$$A = \frac{586.5}{39} = 15 \text{ square inches.}$$

Selecting the commercial size $8 \times 8 \times 1$ inch angle, of 15.25 square inches area, this allows also for the rivet holes. Taking, for instance, a $6 \times 6 \times \frac{3}{4}$-inch angle of 9.71 square inch area, an additional strap $10 \times \frac{5}{8}$ inch thick will be required, as shown to the right in Fig. 6.

We are now ready to figure the maximum torque required to rotate the drum. Referring to Fig. 6, if the sum of the weight of contained material and of the drum equals 215,000 pounds, then the pressure on each of four rollers will be 64,500 pounds. If the coefficient of friction is assumed to be 0.08 (which would be about right for a proportion of d to D as one to four), we have $0.08 \times 64{,}500 = 5{,}160$, and if the radius of the drum at its contact line with the rollers is 4,625 feet, we have for the torque:

$$4 \times 5{,}160 \times 4.625 = 95{,}460 \text{ foot-pounds.}$$

The weight of the shell produces the bending moment

$$-M'_m = \frac{W}{2}\left(C - \frac{L}{4}\right) = \frac{15{,}000}{2}(5.1 - 6.25),$$

$$M'_m = 8625 \text{ foot-pounds.}$$

Obviously, the total maximum bending moment in the drum

$$M_b = M_m + M'_m = 362{,}500 + 8625 = 370{,}825 \text{ foot-pounds.}$$

Then the ideal bending moment, formula (9)

$$M_o = \tfrac{3}{8} \times 370{,}825 + \tfrac{5}{8}\sqrt{370{,}825^2 + 95{,}460^2} = 378{,}500 \text{ foot-pounds.}$$

Taking the strength of the rivet joint about 50 per cent of that of the full plate, it follows, from the table, the actual moment of resistance for a shell thickness of ½ inch:

$$R_o = \frac{303 \times 50}{100} = 151.5,$$

which finally gives us the corrected value for the maximum fiber stress, from bending and twisting,

$$S_o \frac{378{,}500}{151.5} = 2500 \text{ pounds per sq. in.}$$

There are varied opinions regarding the allowable stress as well as regarding the friction coefficients, and it is extremely important that the practical engineer should use good judgment and reliable data. Frequently, the material undergoes considerable changes before and after the process. The loss of strength through the higher temperature will have some influence on the thickness of the shell; and it will be almost impossible to give any more definite general rules to the designer for proportioning the drum and its parts than the outline of the process of calculation presented above.

By the continuous calcining process, Fig. 1, the torque will always remain approximately constant, while, as a rule, the intermittent working dryers, as here presented, will require variable power for turning the drum during an operation period. Not seldom the maximum torque is at a certain stage of the operation, and not at the beginning or end of the process.

[It will be noticed that in the above calculations reference has not been made to the influence on the twisting moment by the distribution of the material in the drum, which influence, of course, increases with speed of rotation, and depends on the number and location of cascade bars and the natural slope assumed by the material. The latter condition, of course, produces an eccentric loading, but for a given slope of material it is a comparatively easy matter to determine the center of gravity of the material, and thus figure the torque with reference to the central axis.—EDITOR.]

An investigation of man-hole explosions at Aberdeen, Scotland, discloses the fact, says the *Engineering Record*, that coal gas, leaking from street mains, may become odorless by filtering through a moderately thick layer of earth without losing its explosive effect.

FOUR 4000 H. P. GAS ENGINES.*

JAMES COOKE MILLS †

In the rebuilding of San Francisco from the very bed-rock, one might say, advantage has been taken of new discoveries, mechanical devices and inventions to provide the wheels of industry with the best power-producing machinery yet known to man. This spirit of substantial progress is no more evident than in the construction and installation of the most modern power plant in this country, for the California Gas and Electric Corporation, furnishing current for all the railways controlled by the United Railways.

The new electric plant has been in constant service for several months, auxiliary to the system which is fed by hydro-electric plants and two steam plants; and the success of the gas engines is so marked that it is the intention of the public service corporation to install more of the gas engine units until, in all probability, the output will amount to 50,000 H. P.

The plant now comprises four units, each of twin-tandem, double-acting gas engines, operating on crude oil water gas and rating at 4,000 B. H. P., with one-third overload capacity momentarily, or 4,600 B. H. P., on the usual overload rating of 15 per cent, at which rating the engines have frequently run for several days without inconvenience or interruption in the service. They are by far the largest and most powerful gas engines ever constructed, and the illustrations, Figs. 1 and 2, give some idea of the massive steel frames, huge cylinders, and the complicated valve sets and gears. Between the twin engines, and driven by the main shaft, is the Crocker-Wheeler 25-cycle alternating-current generator. One gas engine unit of the same size drives a 60-cycle A. C. generator.

The cylinders are cast in two parts, the joints being circumferential and placed half way between the ends, and coupled up by broad flanges. They are supported on pedestals and rigidly bolted to the tie piece between them carrying the guides for the piston rod, on top and bottom. The front end of the forward cylinder bolts direct to the frame block, and this, in turn, is bolted to the foundation by long bolts extending clear through the frame to the top. This design gives the full height and strength of the frame to insure against vibration. The frame block carries the cross-head with guides on top and bottom, and also the main shaft block for the two main journals, which are 30 inches diameter and 56 inches long. The fly-wheel is 23 feet in diameter and weighs 97,000 pounds for the 25-cycle units, and 135,000 pounds for the 60-cycle units. The main blocks weigh 93 tons each, and the total weight of the engine is 600 tons. The main shaft alone weighs 52 tons, and the cranks, pins, piston-rods and all working parts are of unusual size and strength. With four double-acting cylinders, each 42 inches diameter and of

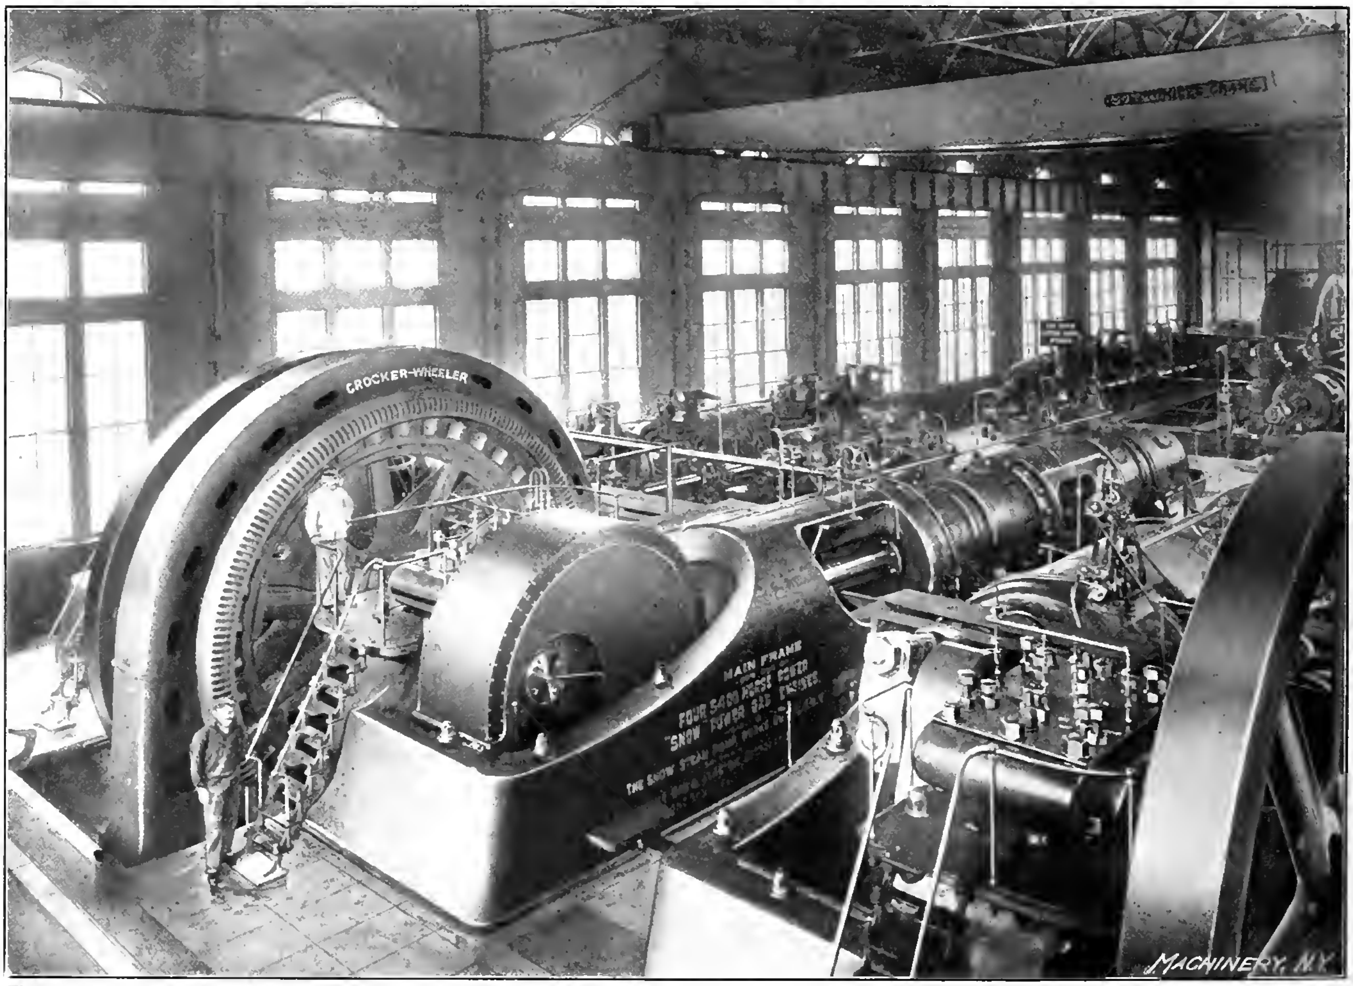

Fig. 1. Gas Engine Installation made by the Snow Steam Pump Works, Buffalo, N. Y., for the California Gas and Electric Corporation, San Francisco, Cal.

60-inch stroke, the engine is compactly built, and the space amounts to 74 by 35 feet—a space comparatively small for a gas engine of this type. The speeds of the engines are 88 and 90 revolutions a minute for the 25- and 60-cycle units respectively.

The tail-rod slides in guides, shown in the illustrations, and relieves the cylinder walls of wear. It adds a third support for the piston-rod, the cross-heads in front of the forward cylinder and between the cylinders in the tie piece providing the other two. The piston-rod is 15 inches diameter, the crank-pin is 19 inches diameter and of the same length. The wrist-pin is slightly smaller, being 17 inches diameter and 18 inches long. These figures give an idea of the massive construction employed throughout.

The valves are all located on the same side of the cylinders, the intake valves being above and the exhaust valves below. They are operated from a common lay-shaft geared to the main shaft. Their action is positive, being operated by vertical rods, rocker-arms, and cams. The inlet valve, mixing chamber, and cut-offs are designed so that gasoline can be injected to the surfaces which require cleaning, and any deposit is removed without touching the parts.

All cylinder working parts—cylinders, pistons, and piston

† Address: 1518 N. Michigan Ave., Saginaw, Mich.

rods are thoroughly water-jacketed, each part being supplied with a separate water pipe, so that the amount of water may be regulated. In this way the cylinder may carry a high temperature, the cylinder jackets a medium temperature, and the rods and metallic packing a low temperature.

Lubrication is effected by means of an individual oil-pump with four leads to each cylinder. The oil is taken in on the inhalation stroke, spread on the compression stroke, and made ready for the working stroke which follows next after in the order of the cycle. Positive feed lubrication for the journals is provided by pipes leading from a multiple feed oiler.

The crude oil water gas supplied to these engines is generated by the Lowe system. It is a notable fact that the engines can be started and synchronized to 88 revolutions a minute, with hydro-electric and steam plants, in from 55 seconds to two minutes from the moment of receiving the signal. This includes turning on the compressed air for the starting, the gas, oil, electric current for the igniters, and coming up to full service speed.

VANADIUM AND AUTO CYLINDERS.

One of the most serious features of deterioration in cars is the loss of compression through the wearing of the cylinders. Foreign engine castings always have been superior to any American products in this respect, but few have understood why. Light has been thrown on the subject recently by some experiments made by the American Locomotive Automobile Company. It was found that the inside of the cylinder castings obtained here will take a polish from the piston action quite readily, but that very soon after the inside polish has reached its best, it begins to check and crack away, leaving roughness. To this is due the loss of compression. Some imported Berliet cylinders, tried under the same conditions, took higher polish and held it, the compression showing no loss after long service. The fact that the Berliet castings have a considerable percentage of vanadium is believed to partly explain the difference. *Graphite.*

THE VARIATION OF THE STRENGTH OF GEAR TEETH WITH THE VELOCITY.*

RALPH E. FLANDERS †

The generally accepted formula for calculating the strength of gear teeth is that proposed by Mr. Wilfred Lewis, first published in the Proceedings of the Engineers' Club of Philadelphia, January, 1893.

The merit of this formula lies in the great number of variables taken into account as compared with other rules in more or less common use, and in the fact that these variables are rationally considered. The effect of each of them can be calculated with some assurance, with the single exception of the influence of the velocity on the safe stress. In the fourteen years since the formula was first proposed, the original values for the stress as affected by the velocity have been largely used. Many designers, however, have felt that these values are rather unsatisfactory, although most of them will agree that they err rather on the side of safety than otherwise. By referring to Mr. Lewis' original paper it will be seen that these values were not given as being definitely determined, but merely as agreeing well with successful cases met with in his own practice. It has recently been proposed, by some individuals interested in the matter, to undertake a series of tests for determining this as yet undetermined factor. This article is written with the purpose of calling attention to this matter, with the hope of bringing out suggestions as to the conduct of such tests; the writer also desires to indicate some considerations which he believes should be taken into account in making the experiments.

† Associate Editor of MACHINERY.

Variation in Strength is Due to Impact.

A variation in the strength of the teeth of a gear, due to a variation in the velocity, can be due, of course, to but one thing—impact. To illustrate this idea, and to show the cause of the impact, we will study the action of gearing under three different conditions. First, when made of an imaginary material which does not deflect under any strain below the breaking point. Second, with gears of commercial material, such as steel, with teeth of perfect form. Third, gears of commercial material with teeth of commercial accuracy.

1. *Gears of an imaginary undeflectable material.*—In Fig. 1 is a diagram in which the horizontal distances give velocity in feet per minute, and vertical distances give stresses in pounds per square inch, starting in this case at 4,000, which is assumed to be the maximum fiber stress in the gear we are considering, due to the load at the pitch line, which is supposed to be constant at all speeds. If the teeth of this gear are perfectly formed and well fitted together, so that there is no back lash, if the power is delivered to them

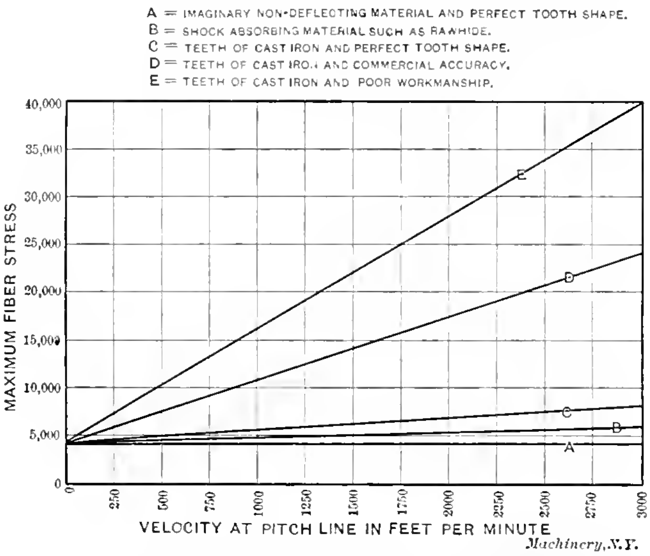

Fig. 1. Hypothetical Diagram showing the Relation of the Velocity to the Fiber Stress.

steadily and smoothly, and the mechanism they drive runs without shock, any disturbance of the even movement will be impossible, and impact will be entirely absent. In the diagram in Fig. 1, then, there will be no rise of maximum fiber stresses with the velocity, so that the horizontal line *A* will show the conditions for this imaginary case.

2. *With commercial material and theoretically accurate workmanship.* The conditions in this case are shown in Fig. 2, with all the phenomena greatly exaggerated. The full lines show the conditions under load, while the dotted outlines show the conditions when the load is removed from the driven gear. The teeth A_1, B_1 and A_2, B_2, carrying the load, are deflected by it, as shown. Tooth *B*, just about to come into contact with tooth *A*, is on that account shifted from its normal position; it should be located as shown by the dotted lines. If it were in this position, it would come in contact with tooth *A* under mathematically perfect conditions, and there would be no shock of engagement. As it is, the two come suddenly into action as shown at *E*, under different conditions than those contemplated by the design, thus the contact takes place in the form of a slight blow, after which the teeth are deflected more and more, until they have taken up their share of the load, as shown later at A_1 and B_1. If the gears are moving very slowly, the deflection takes place very slowly, and the problem is practically a static one. If the gears are running at a high velocity, the problem becomes essentially a dynamic one, and the stresses induced are greater than with the slow speed.

The increase in stress with the increase in speed for this second case could probably be represented by a line something like *C*, of Fig. 1. The location of this line is purely hypothetical. All we can say about it is that the increase in stress as the speed is increased would be comparatively small, and probably regular. The line has been drawn straight for convenience; we do not know what the real shape is.

3. *With commercial materials and commercial accuracy.* This is, of course, the practical case to consider. A line to show the relation of the velocity to the maximum fiber stress for a given gear, would very probably look something like *D* in Fig. 1. This is, in fact, approximately the line which embodies the conclusions of the Lewis tables for a static stress of 4,000 pounds. It is considerably higher than line *C*, because impact due to irregular tooth outlines is added to the impact due to the deflection. In all probability the latter is comparatively unimportant as compared to that due to irregularity of outline in gears of only ordinary workmanship.

Deflection Due to Impact is Slight, but Stresses are Great.

It may be objected that the deflections produced either by the gears coming into mesh out of step, as in case No. 2, or with the added aggravation of poor workmanship, as in case No. 3, are so minute that they could scarcely be considered as a serious factor in the problem. It is true that these deflections are minute—undetectable even, by ordinary means; but this admission does not destroy the argument for laying to this distortion the increase of the stress with the speed. If great loads produce slight deflections, slight deflections likewise produce great stresses, so that the slight bending brought about by the teeth coming into contact at *E* in Fig. 2, under slightly imperfect conditions, may produce great effects proportionately in the fiber stress, and the effects are magnified by the irregularities due to poor workmanship. When we stop to figure out what a load per inch of face is required to deflect a 2-inch circular pitch gear, say 0.003 inch, it is evident that an irregularity in outline of this amount would scarcely be negligible at high speeds, if our hypothesis is correct.

The phenomena of impact are complicated to a high degree. The maximum stresses produced depend on the rapidity of transmission of a wave of stress or deflection, produced in the material by the impact. If this wave is propagated slowly, the stresses are nigh; if rapidly, the stresses are low. The factors entering into the problem are the elasticity of the material, and the mass and shape of the part affected. In very simple cases the problem has been investigated mathematically, but our problem with the gear teeth is so complicated that we must of necessity at once apply to the engineer's court of last resort—experiment.

Practical Considerations Affecting the Conduct of the Proposed Tests.

It is now evident that other variables besides the strength of the material and the velocity at the pitch line enter into the fixing of the line on the diagram of Fig. 1. In addition, the following points will have to be considered.

1. *Accuracy of tooth outlines.* From what has just been said, it is evident that the variation of the stress with the velocity will be affected by the accuracy of the workmanship involved in forming the tooth of the gear. Investigating the conditions in the case of a second pair of gears, similar to those from which line *D* was determined, but of a considerably poorer grade of workmanship, we should expect to find results giving a line something like *E* on the same diagram, giving much higher values for the stresses resulting from the load. It is evident, then, in considering lines *C*, *D* and *E* that workmanship is a variable which should be considered in the experiments, and that a series of tests should be run with two sets of gears of varying workmanship, one of high and the other of only ordinary grade, to make sure that this consideration is really of importance.

2. *Design of wheel and mechanism.*—Another factor which may affect the increase of the stress with the speed is the design of the rim and spokes of the wheel. It is conceivable that a gear with a very heavy rim and rigid spokes will absorb the shocks due to high velocity less easily than a gear with a light rim and flexible spokes or arms. The whole structure of the machine in which the gearing is carried, so far as its rigidity and massiveness is concerned, should, in fact, affect this matter. The further away from the point of tooth contact the members of the structure are, however, the less effect will they have, so perhaps even the influence of the arms and rim can be neglected. The same consideration affects the design of the mechanism to be used in the tests. It is conceivable that a mechanism involving long shafts and other flexible members

might give, for a given set of gears, a line lower down on the diagram of Fig. 1 than would be the case if the construction were very heavy and rigid. The supporting mechanism must not in any case, of course, deflect in such a way as to prevent the teeth from having a full bearing on each other.

3. *The nature of the materials used.* Referring to what has previously been said as to the factors governing impact, it will be seen that the nature of the material used would affect the shape of the curve. It is probable, for instance, that two sets of gears, one made of cast iron and the other of a bronze alloy of the same tensile strength, would show lines of very different shape, owing to the difference in the modulus of elasticity and the specific weight of these two substances. From this it will be seen that we cannot be sure that the results found to be applicable to cast iron or steel could also be applicable to either a pair of bronze gears or to the case of a bronze gear meshing with a mate of steel or iron. That the nature of the material would have a vital effect on the shape of the curve is still more probable, when we consider the practice followed in the use of such substances as rawhide. This material is particularly fitted to sustain impact and absorb without undue stress the deflection caused by it. Owing to this characteristic, we might expect that the line for a gear of this substance would be practically horizontal, as shown at *B* in the diagram, approaching *A*, though governed by entirely different conditions from those producing *A*. So far as can be learned, this supposition agrees with the practice of the manufacturers of rawhide gears.

It may be found that the points mentioned have so much influence on the question at issue that it would be very difficult to lay down a law governing the variation of stress with velocity, and that the most that can be done is to determine the variation in cases of commercial workmanship and rigid design, using the relation thus established in an empirical formula, with the knowledge that poorer conditions may bring the fiber stresses much higher, while good workmanship and careful design may, on the other hand, bring them much lower. Qu· e possibly the factors now in use may be found to nearly fill commercial requirements, in which case we must conclude that the criticisms of their being too high have been founded on experience with cases combining the favorable conditions just mentioned.

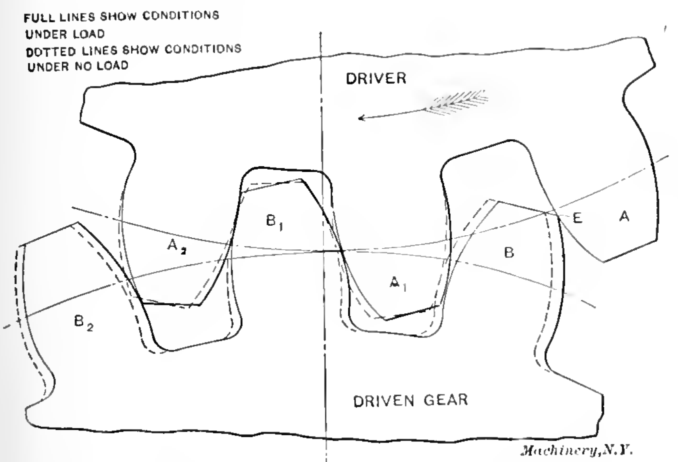

Fig. 2. The Action of Gear Teeth under Load, Greatly Exaggerated.

Practical Considerations Affecting Design.

The fact that the variation of the strength with the velocity is due to impact, suggests also a number of points relating to design. Most of these are already well known, and are standard practice, the conclusions being so obvious that simple common sense has suggested them without theoretical analysis being necessary.

1. *Value of accuracy.* It is evident that this theory of impact puts a premium on accuracy in workmanship for gears that are to run at high speed under a heavy load. It is probable that the strength of a given pair of gears may be cut in two if the tooth outlines are not carefully determined, and if the cutter is not set centrally. This suggests the desirability of a greater sub-division of the standard cutter series for work of this kind. Of course, the gears can always be made heavy enough for the required service, but the extra cost of accurate cutters and careful cutting will be repaid in cases where light weight and compact design are at a premium. In such cases the use of cutters specially designed for each gear is recommended.

2. *Resilience of design and materials.* In high-speed gearing it is evident that the shock due to the impact should be absorbed as quickly and as fully as possible. This suggests the use at abnormally high speeds of rawhide, wood, etc., for one of the members of the pair of gears. The introduction of spring couplings or similar devices may also be desirable, especially where the other parts of the mechanism are liable to transmit shock to the gearing.
